Abstract

Background: Impaired balance regulation after stroke puts patients and therapists at a heightened risk of injury during rehabilitation. Body weight support systems (BWSS) allow patients to safely conduct gait and balance training while minimizing risk and the fear of falling. Integrating perturbation-based balance training (PBT) modules with a BWSS may lead to further improvements.

Objective: This study aimed to evaluate the impact of a ceiling-track-mounted BWSS plus an integrated PBT (BWSS-P) module on the rehabilitation of stroke-related gait and balance impairments.

Methods: A multisite randomized active-comparator controlled trial was conducted. Inpatients with Berg Balance Scale (BBS) scores ≥21/56 were recruited from 4 sites. Participants completed 2-to-6 BWSS or BWSS-P study sessions. Both groups conducted the same balance and gait regimen, with the BWSS-P group also receiving 8 balance perturbations per session. BBS, Activities-Specific Balance Confidence, and 10 Meter Walk Test assessments were collected.

Results: A total of 126 patients were approached with 99 yielding sufficient data for analysis. With a corrected α level of .0054, both groups showed significant in-group changes over time for all outcomes evaluated ($P \leq .001$). However, the primary outcome measure, the BBS, did not show evidence of a difference between BWSS and BWSS-P groups over time ($F_{1,97}=1.57$; $P=0.21$) via linear mixed effects modeling with type III Wald F test with Kenward-Roger degrees of freedom. No significant between-group differences were noted for either secondary outcome measure, the Activities-Specific Balance Confidence scale ($F_{1,94.99}=0.36$; $P=.55$), or 10 Meter Walk Test ($F_{1,97}=4.15$; $P=.04$).

Conclusions: Although significant between-group differences were not observed, participants in both groups demonstrated similar improvements from before to after assessment. This novel PBT technology shows promise as an option for gait and balance recovery training, especially for individuals with impaired balance control or fear of falling. The BWSS-P intervention contributed positively to rehabilitation outcome overall and should be considered as a viable treatment modality when clinically appropriate.

Trial Registration: ClinicalTrials.gov NCT05110300; https://clinicaltrials.gov/study/NCT05110300.

Introduction

Each year, more than 795,000 people experience a stroke [1]. Strokes are devastating neurological events that can lead to cognitive and physical deficits, such as the inability to ambulate, impaired balance regulation, and loss of coordination [2]. Following a stroke, many patients are admitted to rehabilitation facilities to address these deficits and maximize their independence before returning to the home setting [3]. Gait and balance dysfunction are common secondary impairments to

XSL•FO
RenderX

stroke, usually requiring specific neurological rehabilitative interventions to regain functional independence [4,5].

As a result of these physical deficits, patients are at a higher risk of experiencing a fall following a stroke [6]. Moreover, fear of falling has also been shown to influence balance and gait control in older adults, with over 90% of survivors of stroke reporting that the fear of falling negatively impacts their performance of daily living activities [7]. These psychological factors are strong predictors of falling compared to some physical factors or the presence of pathology [8,9]. It is reasonable then to suspect that any fall that occurs during rehabilitation would either reinforce or create a psychological fear of falling that would impede patient recovery [9].

Unfortunately, falls during and outside of rehabilitation can prolong patients' inpatient length of stay, increasing the economic and financial strain on them and their families when the patient is unable to work [10]. Any falls, especially injurious falls, also increase the financial burden of an institution [11]. Focusing on balance and gait training early in patients' rehabilitation can improve their overall fall risk, reducing the need for other resources such as safety sitters and further improving the financial burden of the institution. One strategy for improving balance and gait training safely is to incorporate new and existing robotic technologies into neurological rehabilitation, including body-weight support systems (BWSS) [12].

BWSS are stationary or track-mounted suspended harnesses that support a predetermined portion of a patient's body weight. BWSS permits those with significant weakness and poor coordination to ambulate and perform more intensive therapy sessions sooner in their recovery with minimal risk of injurious falls [13]. Current evidence supports the safety and effectiveness of BWSS during rehabilitation training, showing greater improvements in patient outcomes in patients treated with BWSS versus without [14,15].

Perturbation-based balance training (PBT), the practice of purposefully unbalancing patients to rehabilitate their postural control, can also be used to improve patients' balance control following stroke or other age and disease-related balance impairments [16-21]. Where other training modalities can only provide nonreactive balance training, PBT can be used to improve both reactive and anticipatory control to unexpected and anticipated stimuli [22]. Conventionally, PBT is conducted using modified treadmills, unstable surfaces, or external force directly provided by a treating therapist [16-21]. These strategies present a risk to patients and therapists alike. Incorporating a stationary BWSS over a modified treadmill or unstable surface can decrease this risk; however, ambulation over a treadmill does not represent functional ambulation in the patients' home environment, and some patients struggle to use a treadmill. Unfortunately, there is little consensus about the optimal training regimen for PBT [23,24].

To reduce risk and replicate patients' functional ambulation, new devices have been developed that integrate PBT with an overhead track-mounted BWSS [12,25,26]. Using this "fall-free" environment, therapists can deliver PBT safely and consistently earlier in patients' plan of care. Previously, we conducted a pilot study of such a device [13].

In that study, we demonstrated that a standardized balance and gait training regimen using BWSS or BWSS plus an integrated PBT module (BWSS-P) was safe and did not negatively impact patient recovery [13]. The preliminary efficacy data from this pilot study demonstrated similar improvements in BWSS and BWSS-P groups from baseline to postintervention, but as a pilot study, it was underpowered to determine if there was a significant impact on patient outcomes between groups.

The goal of this study was to build upon this pilot study and conduct a definitively powered randomized controlled trial. We hypothesized that BWSS-P would demonstrate greater outcomes than BWSS-supported training alone.

Methods

Ethical Considerations

A multisite randomized active-comparator controlled clinical trial was conducted. The study was submitted, reviewed, and approved by each site's institutional review board for either local review or to complete a reliance agreement with the Gaylord Hospital institutional review board [27]. Enrollment began on December 15, 2021, and ended on November 6, 2023. Once approved, the study procedures followed were in accordance with the ethical standards of the responsible committee on human experimentation (institutional and national) and with the Declaration of Helsinki. This included maintaining the privacy and confidentiality of research participants' data and identity. Written informed consent was delivered and collected from each participant before study activities were conducted. Participants were not compensated for study participation. Before the study was initiated, the study was prospectively registered with ClinicalTrials.gov (NCT05110300) on October 26, 2021. For reporting, the CONSORT (Consolidated Standards of Reporting Trials) framework was used (Checklist 1).

Power Analysis and Interim Analysis

Referencing the early efficacy data collected in the pilot study [13], a Cohen *d* effect size of 0.39 was calculated for the observed Berg Balance Scale (BBS) change using a 2-sample, 2-tailed *t* test. Assuming a similar effect size, a 2-tailed power analysis (α=.05) and sample size estimation for 80% power were conducted. Using G*Power, an estimated sample size of 214 participants was needed for this effect size to achieve 80% power. During study development, an interim analysis was prospectively planned once 100 participants successfully completed the study activities. Given the small effect size noted in preliminary efficacy data, the goal of this interim analysis was to evaluate the study progression and to determine where there was any clear evidence of a clinically important difference between intervention groups that was or was not trending towards statistical significance.

Study Locations and Study Criteria

Participants were recruited from 1 of the 4 participating inpatient rehabilitation centers: Gaylord Specialty Healthcare,

Wallingford, CT (site 1); MedStar National Rehabilitation Hospital, Washington, DC (site 2); Spaulding Rehabilitation Hospital Cape Cod, Sandwich, MA (site 3); and St. Luke's Rehabilitation Hospital, Spokane, WA (site 4). Site 1 was the primary coordinating site for study activities.

To be eligible, participants had to be admitted for inpatient rehabilitation following either an ischemic or hemorrhagic stroke of any laterality or location. Patients were evaluated by physical therapy within the first 72 hours of admission at each recruitment site, at which point an initial BBS was obtained as appropriate. To be eligible, patients had to have a BBS score of ≥21/56. The BBS was chosen as the primary eligibility criterion as it was the standard functional balance measure used across all sites.

Patients were ineligible to participate if they did not meet any one of these criteria or presented with one or more of the exclusion criteria shown in Textbox 1. To increase recruitment, the progression of patients with a BBS of <21 at admission was tracked; if at any point those patients later progressed to a BBS of ≥21/56, they were rescreened for study inclusion. If the patient met the study criteria, did not meet the exclusion criteria, and had a set discharge date of 10 days or longer from the time of recruitment, they were consented into the study.

Textbox 1. Exclusion criteria.

- Cognitive deficits that would disrupt the ability to provide informed consent
- Active enteric infection control precautions
- Ongoing orthostasis
- Uncontrolled hyper- or hypotension
- Active seizures
- Spinal stabilization with the use of a halo-brace or halo-gravity traction
- Unstable skin structures (ie, skin grafts)
- Chest tubes
- Unstable rib or lower extremity fractures
- Severe osteoporosis
- Subjects where pressure around the abdomen, thighs, groin, or shoulders is contraindicated
- New limb amputations
- Vestibular disorders that may impact balance
- Premorbid conditions that may impact balance
- Patients requiring more than 50% high flow oxygen as consistent with inpatient therapy guidelines.
- Subjects who weigh more than 450 pounds, per the structural limitations of the ZeroG system.
- Anyone belonging to a vulnerable population, including individuals aged <18 years and who are or might be pregnant.

Functional Outcome Instruments

The primary end point for this study was the BBS [28], with the Activities-Specific Balance Confidence (ABC) scale [29], and the self-selected 10 Meter Walk Test (10MWT) as secondary outcomes [30]. The BBS is an objective clinician-reported balance measure with a scale of 0 to 56 (0 being the lowest function and 56 being the highest function), the ABC scale is a subjective patient-reported balance confidence measure with a scale of 0% to 100% (0% being the least confident and 100% being the most confident), and the self-selected 10MWT is used to evaluate gait speed in meters per second ($m\ s^{-1}$), which has been shown to correlate to balance and fall risk [31].

The BBS evaluation that was collected within 72 hours of admission was used as the baseline assessment (ie, before assessment) during data analysis. If eligible and willing to participate, participants were consented and enrolled into the study within 48 hours of admission.

After consent was collected, and before the study-related therapy sessions began, the ABC scale and 10MWT were administered by site investigators. Within 48 hours of the last study session or prior to discharge, whichever occurred first, a post-intervention assessment (ie, after assessment) was collected for all measures.

BWSS Equipment

For this study, the ceiling-track-mounted, Food and Drug Administration–listed ZeroG Gait and Balance BWSS and the ZeroG Training Responses in Postural Rehabilitation balance perturbation module (Aretech LLC) were used to complete this study. All study locations already had the ZeroG BWSS with Training Responses in Postural Rehabilitation module installed prior to study initiation. The study sites were not sponsored or supported by the manufacturer to conduct this study.

Standard Care Protocol and PBT Interventions

To minimize disruptions to participants' standard therapy regimens, and to maximize the generalizability of the study protocol in real-world settings, the pragmatic decision was made

XSL•FO
RenderX

to integrate study-related sessions directly into the participants' standard care routines. As part of their normal care, participants received a minimum of 3 hours of multidisciplinary inpatient physical, occupational, or speech rehabilitation appropriate for their condition, and as was prescribed by their attending physician. This standard of care did not include additional PBT.

As appropriate, participants' standard of care therapy regimen included, but was not limited to, functional mobility training targeting specific activities of daily living and instrumental activities of daily living needs, endurance training, balance retraining, coordination retraining, strengthening, high-intensity gait training, range of motion training, patient education with durable medical equipment, and family training prior to discharge. Referrals and treatment by other specialties (ie, therapeutic recreation, dietary, and neuropsychology) continued as normal.

Study-related therapy sessions were conducted individually. Each session lasted a minimum of 15 minutes and a maximum of 30 minutes. Data were collected from all participants who completed at least 2, and up to 6, study-related therapy sessions. Data from a range of completed sessions were purposefully collected to accommodate "real-world" short or unexpected changes to discharge timelines due to insurance authorization or other disturbances. This allowed us to examine the effect of sessions completed on outcome measures recorded. Based on the average length of stays of the study sites, once consented and enrolled in the study, participants received an average of 3 study sessions per week, approximately one every other day, until discharge.

During the BWSS only control group sessions, participants conducted a series of standard balance exercises, including: marching, side-stepping, retroambulation, step taps, and step-ups. Standard gait exercises were also completed, including: overground ambulation, going up and down stairs, and sit-to-stand transitions. For each participant, only 4.54 kg (ie, 10 pounds) of body weight was unloaded as this is the minimum requirement to activate the BWSS. As this is an active clinical comparison, clinical parameters and progression, other than those described earlier, were determined by the treating clinical investigator (ie, use of assistive devices and bracing) to ensure the participant's safety, success, and appropriate challenge.

The BWSS-P group completed the same balance and gait exercises as the control group; they differed only in the inclusion of 8 total balance perturbations, 2 in each cardinal direction (lateral left, lateral right, anterior, and posterior). Perturbations occurred while static (lateral, anterior, and posterior) and dynamically while ambulating (anterior and posterior). Eight perturbations were selected based on the findings of the previous pilot study [13] and to minimize fatigue effects. In that study, we found that 1 perturbation every 2 to 4 minutes during the 15-to-30 minute study-related session was enough to challenge participants without overtaxing them and allow for a wider range of participants with varying tolerances, while also allowing them to conduct other elements of their physical therapy regimen.

Perturbation intensity was determined by participants' tolerance and ability to recover from perturbations at baseline. At the start of the study, a baseline BWSS-P perturbation level was individually set for each participant by incrementally increasing the level to balance loss or near loss without recovery. The perturbation level then was decreased by 1 level for treatment. All 8 perturbations were set to this level until it was clinically appropriate to progress to maintain a sufficient challenge to the patient. The intensity of the perturbation ranged from level 1 (minimum) to level 10 (maximum), as set by the manufacturer. Note, while both groups had access to assistive devices during ambulation as appropriate to ensure participant safety, their use was minimized and was not used at all during balance perturbations. Furthermore, the BWSS group did not receive any balance perturbations, including manual perturbations delivered by the treating clinician.

Treating clinicians were licensed physical therapists who were all trained on best practices in using the specific BWSS and perturbation module. To ensure consistency, an initial virtual training session was led by site 1 to review best practices for delivering all study outcome measures. A virtual training session was agreed upon as COVID-19-related travel and visitation restrictions limited the lead site's ability to conduct in-person site initiation visits. Following this, site 1 led a monthly steering committee meeting that consisted of each study site principal investigator, representatives of the treating clinical teams, and the study's acting data and safety monitor. The goal of this meeting was to review if any safety events or harm had occurred, discuss protocol adherence, answer any clinical or technical questions, discuss recruitment, and address any other items as needed.

Participant Recruitment, Enrollment, and Randomization

Each study site was responsible for screening, recruiting, and consenting qualifying participants from their individual locations. Once consented, participants were randomly assigned to either the BWSS standard intervention (ie, control) group or the BWSS-P intervention (ie, experimental) group according to a pregenerated assignment sheet provided by the coordinating site. Each sheet was generated using block randomization using the random list generator tool found at Random.org. A block size of 4, 2 BWSS, and 2 BWSS-P assignments per block were used. Depending on anticipated recruitment numbers, 12-to-20 assignments were generated for each site at a time to allow for balancing as needed.

Given the nature of the intervention (ie, whether or not a baseline perturbation level was needed), clinical staff and participants were unable to be blinded to the randomly assigned group assignments.

Data Analysis

Data were analyzed using GraphPad Prism (version 10; GraphPad Software) and RStudio (version 4.2.2, Posit Software) using the *car*, *lme4*, and *emmeans* packages [32-34].

Descriptive data were reported as mean (SD). If hypothesis testing was done, data were reported with a *P* value, and significance was set at α=.0054 using the O'Brien-Fleming correction for interim analysis [35]. The primary outcome measure was the BBS. Secondary outcome measures included

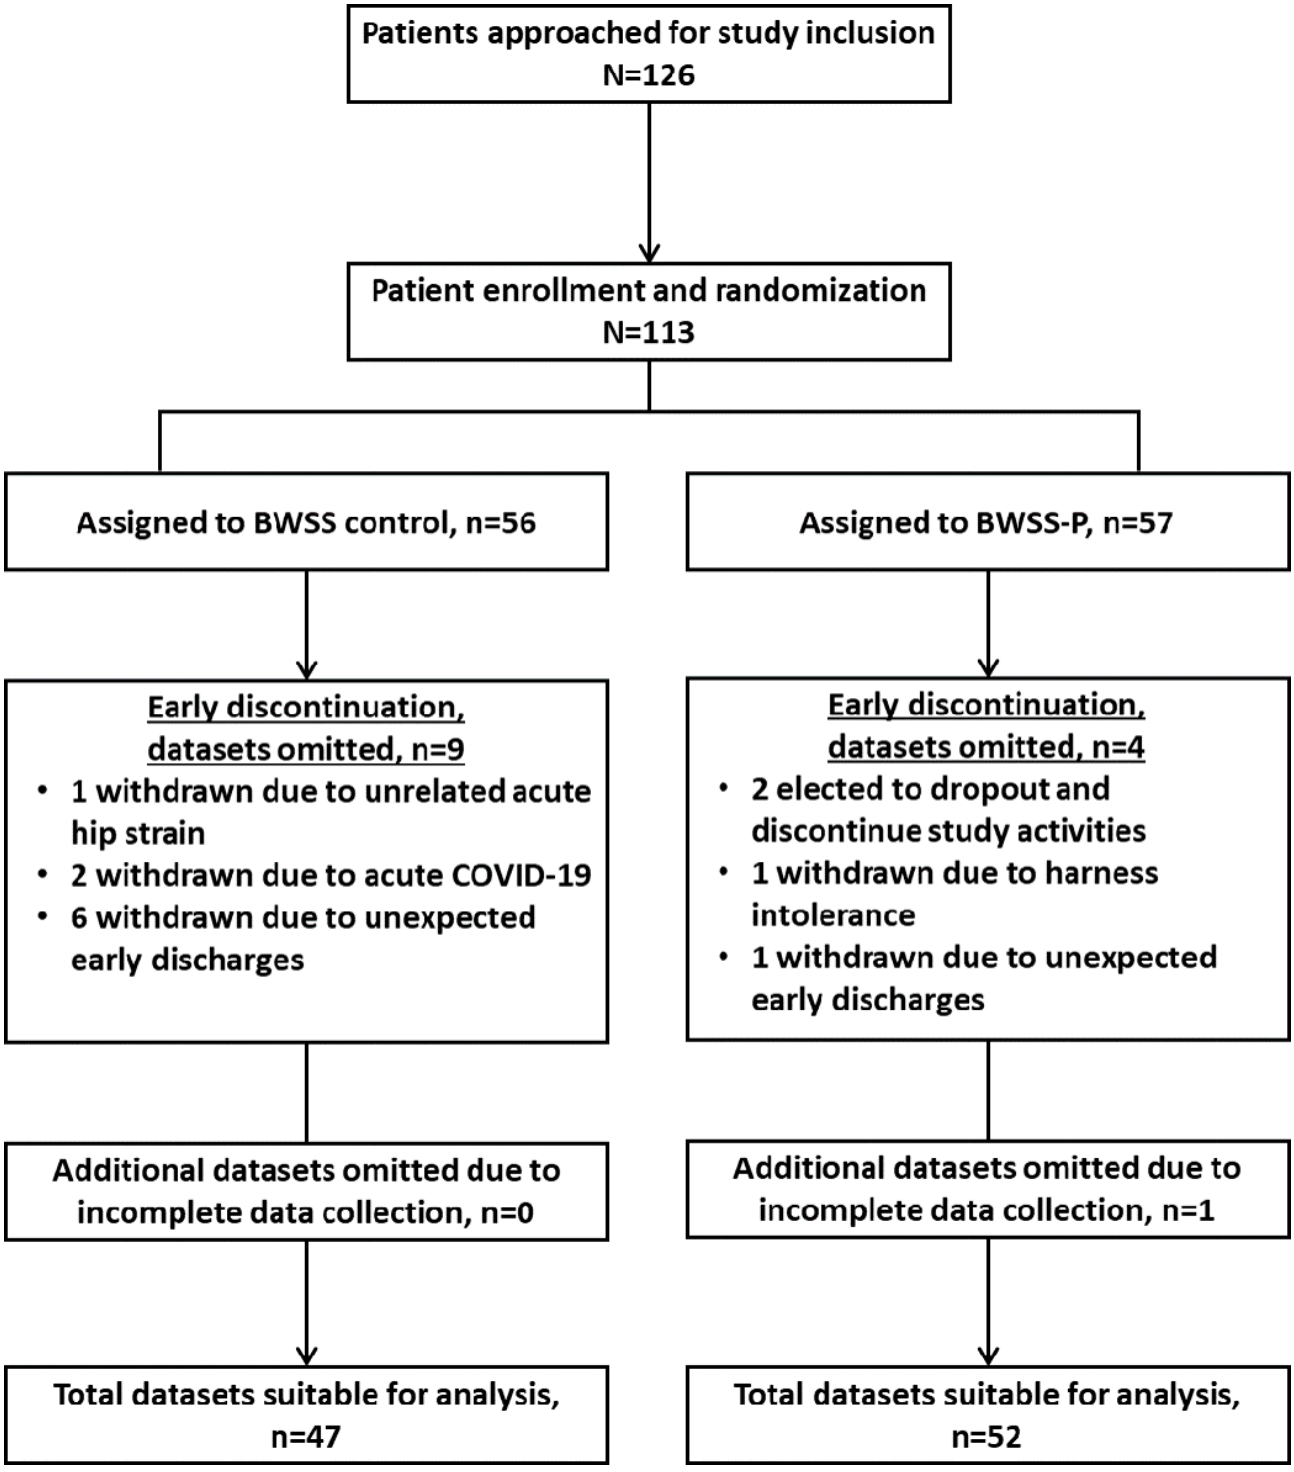
XSL•FO
RenderX

the ABC and 10MWT. Data were determined to be missing completely at random and were dealt with via complete case analysis for the total outcome measure change [36].

Pairwise categorical data were analyzed using chi-square testing. Unpaired 2-tailed *t* tests or Mann-Whitney *U* tests were used as necessary to evaluate pairwise between-group differences in continuous outcome variables. 2-way ANOVA or mixed-effects analysis was used to evaluate pairwise pre- and postoutcome measure data.

Intervention effect on outcome measure data was analyzed using a linear mixed effects model. In the models, outcome measures were the dependent variable, with fixed effects for timepoint, group assignment, sessions completed, study location, and timepoint x group assignment interaction term. Participant was included as a random effect. Type III Wald *F* test with Kenward-Roger degrees of freedom was used to evaluate the significance of all the fixed effects. Model assumptions were assessed through visual inspection of residual plots and model diagnostics.

Results



Participant Characteristics

The study's initial target was a final sample size of 214 participants. However, based on the results of the planned interim analysis following the recruitment and completion of 100 participants, the study team made the decision to end study recruitment early and proceed with full data analysis using an appropriately adjusted α. In total, 126 participants were approached for study inclusion, 113 were consented, enrolled, and randomized, with 99 participants yielding sufficient data for analysis (Figure 1). No major or serious adverse events were noted during the study period.

Of the 99 participants with complete data, 47 were assigned to the BWSS only control group, and 52 were assigned to the BWSS-P group. No trends related to sex, age, or any other demographic were observed between groups (Table 1). Participants began study activities a mean of 16.00 (SD 8.01) days following their stroke and a mean of 1.99 (SD 1.99) days following collection of the BBS preintervention assessment.

Participant Outcome Measures

The outcome measures collected included baseline and post-intervention assessments of BBS, ABC, and 10MWT (Figure 2). The effect of the BWSS-P intervention was analyzed using linear mixed effects models with a type III Wald *F* test with Kenward-Roger degrees of freedom for all outcome measures collected. With a corrected α level of .0054, the intervention did not show any significant impact on our main outcome measure, the BBS. This was shown by the *time x assignment interactions* ($F_{1,97}$=1.57; *P*=.21). Similarly, no significant intervention effects were observed in either the ABC ($F_{1,94.99}$=0.36; *P*=.55) or 10MWT ($F_{1,97}$=4.15; *P*=.04; Table 2).

[a]Results from linear mixed effects models. Fixed effects were tested using a type III Wald *F* test with Kenward-Roger degrees of freedom. Random effects are shown as variance with SD.

[b]BBS: Berg Balance Scale.

[c]In BBS, random effects of participant: variance 26.80 (SD 5.28) and residual: variance 26.30 (SD 5.13).

[d]ABC: Activities-Specific Balance Confidence.

[e]In ABC, random effects of participant: variance 342.3 (SD 18.50) and residual: variance 198.6 (SD 14.09).

[f]10MWT: 10 Meter Walk Test.

[g]In 10MWT, random effects of participant: variance 0.12 (SD 0.35) and residual: variance 0.03 (SD 0.16).

[h]Significance was set at α=.0054 using the O'Brien-Fleming correction for interim analysis.

Time effects were significant across all outcome measures. BBS scores showed significant improvement from admission to discharge across both groups ($F_{1,97}$=181.01; *P*<.001), along with ABC ($F_{1,95.29}$=42.91; *P*<.001) and 10MWT ($F_{1,97}$=23.71; *P*<.001).

Assignment effects were nonsignificant across all outcome measures. BBS showed the most suggestive evidence of differences between groups ($F_{1148.14}$=5.55; *P*=.02), with ABC ($F_{1132.74}$=1.09; *P*=.30) and 10MWT ($F_{1110.82}$=0.57; *P*=.45) outcomes showing less evidence of a difference.

The number of sessions completed (ie, 2-to-6) did not have any evidence of a significant effect on the outcome measures. BBS showed the most difference in regards to the number of sessions completed ($F_{1,93}$=6.23; *P*=.01), with ABC ($F_{1,93.25}$=3.29; *P*=.07) and 10MWT ($F_{1,93}$=0.57; *P*=.45) showing smaller differences.

Location had similarly suggestive, but inconclusive, evidence of an effect on outcome measures. BBS ($F_{3,93}$=3.12; *P*=.03) and 10MWT ($F_{3,93}$=3.03; *P*=.03) had the most evidence of a location effect, while ABC did not ($F_{3,92.83}$=0.01; *P*=.99).

Model estimated marginal means (SE) for the BBS showed that at admission, both the BWSS (30.02, SE 1.15) and BWSS-P

XSL•FO
RenderX

(33.44, SE 1.13) groups had similar scores. This finding was also true at discharge, with BWSS (43.45, SE 1.15) and BWSS-P (45.42, SE 1.13) ending at a similar level. Similar patterns were noted in the model estimated means of the secondary outcome measures, as well as the observed unadjusted means for all outcomes (Table 3).

Table . Outcome measure pre- and post-assessment scores.

Discussion

Principal Findings and Alignment With Literature

The goal of this study was to compare the effects of a BWSS-integrated PBT training module on poststroke balance and gait rehabilitation as compared to BWSS training alone. Specifically, participants completed a regimented neurological rehabilitation program that included 2-to-6 BWSS sessions with or without 8 balance perturbations per session. Participants in both groups demonstrated similar within-group improvements with no significant between-group differences in BBS, ABC, or 10MWT. Furthermore, there was suggestive, but inconclusive, evidence of minimal site-specific effects. While these observations are nonsignificant and confirm the null hypothesis that the BWSS-P intervention is not different than the BWSS only control, these data still provide us with meaningful observations that support past publications.

First, similar to past observations [37], the number of sessions that participants completed greatly varied due to several extenuating and pragmatic factors, including insurance continuing stay authorization [37]. While not ideal, these data and the protocol are reflective of what are feasible and realistic

XSL•FO
RenderX

best practices in these inpatient settings in the current environment.

Our findings are also in alignment with other past studies that tested the effect of traditional PBT intervention in the poststroke population [17,19,20,38-44]. Many of these studies used the same outcome measures that were used in this study. Of these, 6 studies used the BBS to evaluate balance [19,20,39,40,42,43], 2 studies used the 10MWT to assess gait speed [17,41], and 2 studies used the ABC to measure participants' balance confidence [17,41]. Similar to our findings, little to no between-group differences were observed for each of these outcome measures.

As noted by Brown et al [44], these past studies all varied in training duration, frequency, and interventions used. Study sessions ranged from 1 to 24 sessions, and the number and type of perturbations also varied and included treadmill delivery, therapist-applied perturbations, waist pull perturbations, and slip training, in addition to other commercially available systems. Few studies, however, have examined the impact of overhead gait robotics that facilitate balance perturbation. These studies and others report encouraging results; however, the impact of PBT on stroke balance rehabilitation remains inconclusive [20,22,44].

In addition to unifying study interventions, Mcrum et al [22] have also indicated the need for further dosing studies to examine optimal dosing within sessions or within training programs in addition to examining the effect of bidirectional and multidirectional perturbation training to provide recommendations for clinicians. Following this study, 1 observation that we made is that the level of perturbation experienced by the end user can be defined in many ways, including the magnitude and duration of the applied force that disrupts the user's balance. This can be controlled by factors like the force applied, the direction of the force (eg, forward, backward, and lateral), and the timing of the perturbation during the gait cycle. In addition, the level of body weight support provided by a harness can also influence the perceived perturbation level, as less support means greater impact from the applied force, and more support may result in the patient being able to complete greater repetitions. These factors all need to be taken into account when planning future dosing studies of this technique.

Limitations and Lessons Learned

As this was the first multisite randomized-controlled trial to evaluate this novel BWSS-integrated PBT technology, we can identify several limitations that must be considered when interpreting the data and planning future studies.

First, since the study was conducted in the inpatient rehabilitation setting, the study activities were only a small part of the participants' overall treatment strategy. Several factors, including therapy outside the study and natural recovery progression, likely contributed to improvements in participants' status and function. Despite attempting to unify the delivery of the study intervention, treatment strategies outside of study activities may have been variable across study sites. For example, in seeking possible explanations of the suggestive location effect, it was found that site 2 had implemented an institution-wide high-intensity gait training program as part of their site's standard of care, which was not used by the other study sites during the study.

Second, BBS score changes may have been limited due to ceiling effects. To address this, an upper BBS score should be considered as part of the study criteria in all future studies on this topic. For example, a BBS score of 45/56 has been suggested to describe patients with normal functional ability [28]. Similarly, incorporating a dynamic gait assessment that more closely resembles functional movement patterns and reactive balance-specific outcome measures may be beneficial to understanding the full implications of this new BWSS-P module [45,46].

Third, several participants (8/99, 8%), constrained by short lengths of stay, only completed 2 sessions, the minimum number to be included in the study. This limited dose may not have been enough to elicit a clinically significant change in balance and balance confidence as may have been hypothesized. Short lengths of stay were due to several factors, including industry trends of decreasing lengths of stay in the cerebrovascular accident (ie, cerebrovascular accident, stroke, and brain injury) population; inclusion of participants with BBS scores of 45 or greater; and the impact of COVID-19. Specific to COVID-19, many patients opted to discharge home as soon as they could safely navigate the home environment with assistance, meaning some patients did not remain long enough to receive more than 2 study sessions. In addition, many patients who were eligible for the study could not participate due to a positive COVID-19 diagnosis and droplet precautions, while others were withdrawn and their data omitted from analysis due to breakthrough infections requiring isolation.

Fourth, the number of balance perturbations provided to the BWSS-P group was strictly kept to 2 balance perturbations in each cardinal direction per session (ie, 8 total). This was maintained even if the first or second perturbation in a particular direction did not elicit a strong balance response. Further, a target of 6 study sessions was based on the preliminary efficacy data collected during the pilot study; this may not have been as optimal as previously thought [13]. In future studies, it will be essential to expand upon this work and complete a dedicated dosing study to determine the optimal number of BWSS-P sessions and number of balance perturbations per session [22].

Fifth, the study end points may have been impacted by the variability in the timing of when outcome assessments were collected. To reduce the burden on the study participants from having to complete the same assessments repeatedly in a short period of time, the study team made the decision to use recently collected data to serve as study end points when available and collected in close proximity to study activities. Although some assessments were then not collected immediately prior to starting the study intervention, the authors felt the period of time between admission assessments, study enrollment, and study initiation was sufficiently short enough, and completed consistently enough, to be representative and with minimal variation.

XSL•FO
RenderX

Conclusions

PBT therapy is an important treatment modality for the rehabilitation of gait and balance following a stroke. As it becomes more accessible and widely adopted, ceiling-track-mounted BWSS with an integrated PBT module allows therapists to more safely add PBT into patients' rehabilitation sooner and in ways that are more representative of their functional environment. Our goal was to determine if neurological rehabilitation paired with this technology could significantly improve poststroke gait, balance, confidence, and functional outcomes compared to using a BWSS alone. Ultimately, both were found to be similarly effective interventions, resulting in similar improvements in patient gait, balance, confidence, and functional outcomes. Given the safety it provides to clinicians and patients alike, conducting PBT with such a device provides a safe option for conducting gait and PBT in the inpatient setting, especially for patients who are unable to safely ambulate without assistance.

Acknowledgments

The authors would like to thank all of the clinicians and supporting staff who made this study possible. Abstract

Background: Venous thromboembolism (VTE) is a common vascular disorder requiring extended anticoagulation therapy postdischarge to reduce recurrence risk. Home rehabilitation management systems that use electronic health records from hospital care provide opportunities for continuous patient monitoring. However, transferring medical data from clinical to home settings raises significant concerns about privacy and security. Conventional methods such as manual data entry, optical character recognition, and dedicated data transmission lines face notable technical and operational challenges.

Objective: This study aims to develop a QR code–based security transmission algorithm using Avro and byte pair encoding (BPE). The algorithm supports the secure creation and transfer of out-of-hospital health records by enabling patients to scan QR codes via a dedicated mobile app, ensuring data security and user privacy.

Methods: Between January and October 2024, 300 hospitalized patients with VTE were recruited at the Sixth Medical Center of the Chinese PLA General Hospital. Post discharge, participants used a home rehabilitation app tailored for VTE management. The QR code–based security transmission algorithm was developed to securely transfer in-hospital electronic health records to the out-of-hospital app. It uses BPE, Avro, and Gzip for optimized data compression and uses ChaCha20 and BLAKE3 for encryption and authentication. Specifically, BPE tokenizes medical text, while Avro serializes JSON (JavaScript Object Notation) objects, contributing to data encryption. A proprietary tokenizer was trained, and compression efficiency was evaluated using a "Performance Benchmark Dataset." Comparative analyses were conducted to assess the compression efficiency of JSON serialization methods (Avro and ASN.1 [Abstract Syntax Notation One]), and tokenization algorithms (BPE and unigram).

Results: The dataset consisted of JSON files from 300 patients, averaging 240.1 fields per file (range 89 - 623) and 7095 bytes in size (range 2748 - 17,425 bytes). Using the BPE + Avro + Gzip algorithm, the average file size was reduced to 1048 bytes, achieving a compression ratio of 6.67. This was 1.82 times more efficient than traditional Gzip compression (average file size: 1907 bytes; compression ratio: 3.66; $P<.001$). For Chinese medical text tokenization, BPE outperformed unigram with a compression ratio of 4.68 versus 4.55 ($P<.001$). Avro and ASN.1 demonstrated comparable compression ratios of 2.57 and 2.59, respectively, when used alone ($P=.30$). However, Avro combined with BPE and Gzip significantly outperformed ASN.1, achieving compression ratios of 6.67 versus 5.21 ($P<.001$). Additionally, 84.7% (254/300) of patients needed to scan only 1 QR code, requiring an average of 3.1 seconds.

Conclusions: The QR code–based security transmission algorithm using Avro and BPE efficiently compresses and transmits data in an encrypted manner and authenticates the identity of the scanning users, ensuring the privacy and security of medical data. Delivered as a software development kit, the algorithm offers straightforward implementation and usability, supporting its broad adoption across various applications.

Introduction

Venous thromboembolism (VTE) is a leading cause of death and disability worldwide [1,2]. Patients with VTE require prolonged anticoagulant therapy after discharge to prevent the recurrence of thrombosis, and extended home rehabilitation management effectively reduces the incidence of VTE events [3]. To enhance the efficiency of home rehabilitation management for patients with VTE, we developed a home rehabilitation mobile health app to assist doctors in managing patients' recovery outside the hospital. According to guidelines and consensus, home anticoagulation management for VTE is complex, requiring not only professional medical knowledge but also accurate patient information, such as coagulation indicators, biochemical markers (eg, liver, kidney, and heart function), underlying diseases, and bleeding risks [4]. Therefore, establishing comprehensive health records is the first step in effective home rehabilitation management. However, due to the multitude of information fields, manual entry by patients is difficult and leads to low user engagement.

Using patients' electronic health records (EHRs) during hospitalization can improve the success rate of out-of-hospital health record creation [5]. Hospital Information Systems are typically deployed within internal (intranet) environments, while out-of-hospital services operate on public internet infrastructure. Industry standards such as HL7 Fast Healthcare Interoperability Resources have been proposed to enable cross-institutional data exchange. However, in practice, the deployment of Fast Healthcare Interoperability Resources or other application programming interface–based approaches faces multiple constraints. Their implementation depends on dedicated network connections via front-end machines or network gateways. This implementation approach introduces the following significant issues: (1) high hardware deployment and maintenance costs; (2) increased exposure of hospital intranets, elevating security risks; (3) low efficiency of cross-departmental collaboration, leading to slow service response; and (4) complete incompatibility with closed-network environments. Consequently, such protocols have not been widely adopted in domestic settings.

Some alternative approaches attempt to use optical character recognition on printed reports. However, the recognition accuracy (75.86% - 92.46%) is highly affected by scan quality and layout [6], generally requiring manual validation [7], making it difficult to scale for widespread use. Other solutions use QR code–based transmission [8-14], either transmitting in plaintext—posing leakage risks—or relying solely on traditional compression algorithms such as Gzip, which offer limited compression efficiency and fail to make full use of QR code capacity. In real-world scenarios, a single QR code typically holds only 500 - 1500 bytes, further highlighting the importance of efficient encoding. Additionally, certain implementations require specialized screens and camera equipment, failing to balance medical privacy protection with end user convenience.

To address these challenges in cross-network medical information exchange, this study proposed a secure QR code–based transmission algorithm. The algorithm encrypts, compresses, and partitions JSON-formatted (JavaScript Object Notation) health records into multiple QR codes. Patients can safely, easily, and accurately complete the creation and transfer of out-of-hospital records simply by scanning the QR codes using a dedicated mobile health app.

To comprehensively demonstrate the advantages of the proposed solution in terms of recognition accuracy, data privacy, network exposure risk, and deployment cost, Table 1 presents a comparative analysis between this method and existing typical solutions (including optical character recognition–based solutions and dedicated channel solutions) in cross-network scenarios.

In this study, we have designed the algorithm framework in detail, described the compression and encryption processes, and constructed a training dataset. Finally, we validated the algorithm's performance using real-world clinical data.

Table . Comparison of this proposal and existing medical information exchange solutions in cross-network scenarios.

Dimension	OCR-based[a] solution	Dedicated channel (FHIR[b] or other API[c])	Proposed scheme
Accuracy	Low. Affected by image quality and layout; accuracy ranges from 75.86% to 92.46%, manual verification required	High. System-level integration with clear structure and minimal errors	High. Structured data embedded in QR code; stable decoding, unaffected by image quality
Data privacy	Low. Plaintext image transmission with high leakage risk	Medium-high. Relies on physical isolation and encryption; security depends on implementation	High. End-to-end encryption and authentication; supports zero-trust access
Network exposure risk	None. Typically offline image transmission, no network exposure	High. Requires open interfaces; increases attack surface and risk of intrusion	None. Offline QR transmission; no exposed network entry
Deployment cost	Low. No system changes needed, but high manual verification overhead	High. Requires gateway systems and dedicated channels; complex implementation and maintenance	Low. Lightweight SDK integration; high compatibility and easy deployment

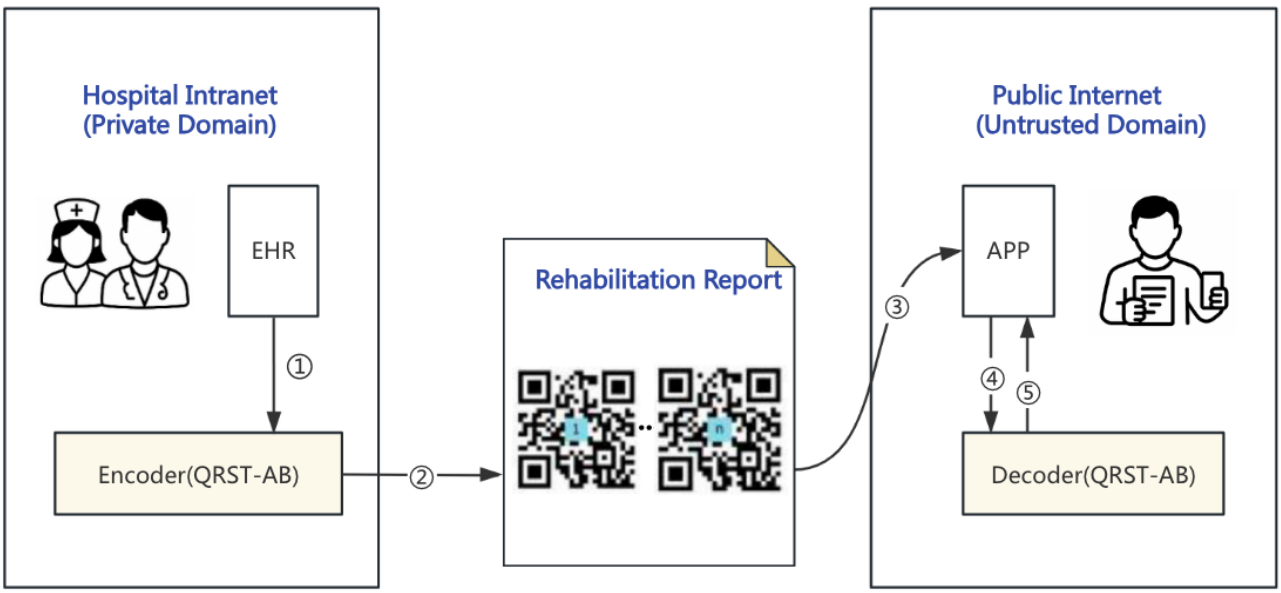
[b]FHIR: Fast Healthcare Interoperability Resources.

[c]API: application programming interface.



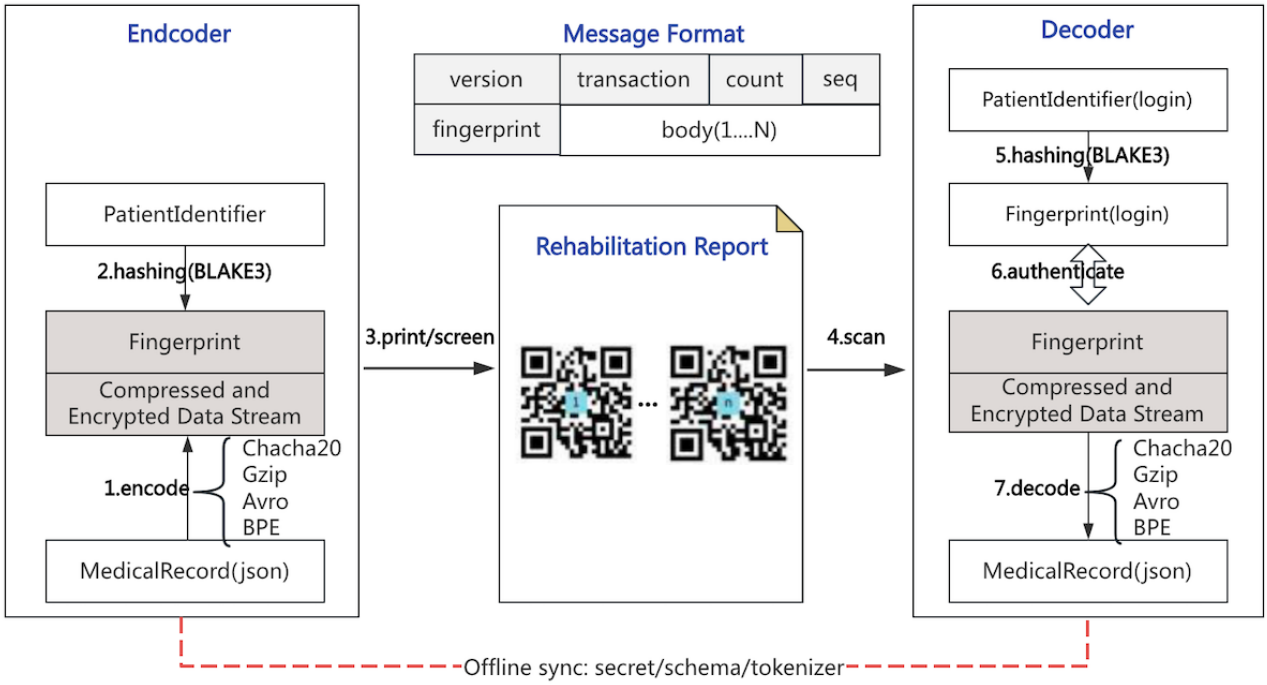
Methods

Algorithm Design

Overview

We propose a QR code–based secure transmission algorithm using Avro and byte pair encoding (BPE), which supports the secure creation and transfer of out-of-hospital health records for inpatients after discharge. The application scenario of the QR code–based secure transmission algorithm using Avro and byte pair encoding (QRST-AB), as illustrated in Figure 1, involves the following workflow: (1) health care providers access the patient's EHR; (2) the encoder module applies the algorithm to generate one or more QR codes, which are embedded into a printed rehabilitation report and physically delivered to the patient; (3) the patient scans the QR code using a mobile app; (4) the app uploads the QR code content to a server-side module; and (5) the decoder performs verification and decryption, with results presented to the user. In this process, the encoder operates within the hospital intranet (trusted domain), whereas the decoder resides in the public internet (untrusted domain), enabling secure cross-network transmission.

Figure 1. Application scenario of the proposed QRST-AB, illustrating the data flow of rehabilitation reports in cross-network environments. EHR: electronic health record; QRST-AB: QR code–based security transmission algorithm using Avro and byte pair encoding.



Algorithm Framework

The QRST-AB algorithm efficiently compresses and encrypts patient medical records in JSON format, divides them into multiple QR codes for secure transmission, and authenticates users through encrypted digital fingerprints, ensuring privacy and data security. The algorithm consists of 2 components: an encoder and a decoder. The encoder and decoder periodically synchronize the secret, schema, and tokenizer through offline

XSL•FO
RenderX

methods. The details of the framework and processing flow of the QRST-AB algorithm are shown in Figure 2 and Textbox 1.

Figure 2. The framework and processing flow of the QRST-AB, illustrating how patient medical records are compressed, encrypted, split into QR codes, and securely transmitted and authenticated. BPE: byte pair encoding; JSON: JavaScript Object Notation; QRST-AB: QR code–based security transmission algorithm using Avro and byte pair encoding.

Textbox 1. Textbox 1. The processing flow of the QR code–based secure transmission algorithm using Avro and byte pair encoding (BPE).

1. The patient medical record is deidentified and separated into 2 parts: the patient identifier and the limited data set. The data is processed through a multistage encoding pipeline consisting of BPE, Avro, Gzip, and ChaCha20, to generate a compressed and encrypted data stream, which serves as the message body. The data stream is then divided into multiple subpackets (body1...N) based on the predefined maximum size of the QR code. BPE tokenizes and vectorizes the texts in the medical record; Apache Avro serializes the JSON (JavaScript Object Notation) objects into a binary format; Gzip compresses the binary data stream; Chacha20 encrypts the compressed data to ciphertext.
2. Every subpacket and patient identifier is hashed using the cryptographic function (BLAKE3) to generate a digital fingerprint and is encapsulated within the message header. This header is combined with body1..N to form multiple QR codes.
3. The QR codes are printed on A4 paper as part of the home rehabilitation report and handed to the patient, or displayed directly on a hospital computer screen for the patient to view.
4. The QR codes are scanned by a dedicated app on the smartphone, and the scanned content is uploaded to the server (decoder).
5. Upon receiving the QR code content, the decoder first generates a new digital fingerprint based on the logged-in user's identifier.
6. Next, the calculated fingerprint is authenticated against the digital fingerprint in the QR codes, and only if the authentication passes, the decoding process is executed.
7. In the presence of multiple QR codes, a merging operation is conducted to form a complete information body, which is then converted back into a JSON object through the decoding process. The specific steps include the following: Chacha20 decrypts the ciphertext; Gzip decompresses the binary data; Avro deserializes the binary data back into a JSON object; and BPE restores the string representation of the JSON object from its numerical form.

Protocol Package Format

Within each QR code, the data content is divided into 2 parts: the message header and the message body. The header consists of 5 fields: version, fingerprint, transaction, count, and seq. The specific definitions of each field are shown in Table 2.

XSL•FO
RenderX

Table . Definition of the message header fields in each QR code of the QR code–based secure transmission algorithm using Avro and byte pair encoding.

Field	Definition	Value formula	Description	Len (bits)
Version	Version identifier, a predetermined fixed value	Constant	Used for compatibility with historical versions after updates.	8
Fingerprint	The message fingerprint	H(Message‖IdentityID)[1:n]	H() represents a cryptographic hash function. n represents the length of the digest in bytes, ranging from 1 to 64.	16
Transaction	Transaction ID for the current transmission	Tadm+Ttag	T_{adm} represents the patient's admission date, and T_{tag} is a predefined date for a specific tag, such as "2020-01-01".	16
Count	Number of QR codes the record is split into	[LbodyLqr−Lheader]	L_{body} is the total length of the compressed and encrypted body, L_{qr} is the maximum length of a QR code, and L_{header} is the fixed length of the message header	4
Seq	Sequence number of each QR code	Sprev+1	Starts from 0 and increments by 1.	4

Response Status Codes

When users receive information contained in the QR codes, the operation is simple—scanning each QR code sequentially using the dedicated app. The program provides friendly prompts based on the parsing results. The explanations for different response status codes are listed in Table 3.

Table . Response status codes and their explanations for users scanning QR codes with the dedicated app in the algorithm.

Result code	Explanation
finished	All QR codes have been successfully scanned, and decoding is complete.
waiting	Current QR code has been successfully scanned, please continue scanning others.
duplicated	Current QR code has been scanned repeatedly, please continue scanning others.
tag_error	Tag error, not a QR code format supported by the program.
auth_failed	Authentication failed, please verify authorization.
exception	Other exceptions, please contact technical support for assistance.

Algorithm Scalability

In this algorithm, each version can define the length of individual fields in the message header. Different versions correspond to different encoders, each with its own secret, schema, and tokenizer. On the decoder side, a multiversion manager enables support for various encoders, allowing compatibility with multiple data centers.

By leveraging the flexibility of the flexible structure of Avro Schema, it is easy to extend the system to support different JSON formats. In addition to the VTE electronic medical records discussed in this paper, the algorithm can be adapted to other disease types and even to nonmedical application scenarios, demonstrating strong scalability and versatility.

Data Compression

JSON Serialization

JSON serialization refers to the process of converting data structures or objects into a string or binary form for the purpose of storage or transmission. The opposite process is deserialization, which restores the serialized data back to its original structure or object.

Within serialization methods, common types include schema-driven serialization and schema-less serialization. The former includes methods such as Abstract Syntax Notation One (ASN.1) using Packed Encoding Rules, Apache Avro, Microsoft Bond, Cap'n Proto, FlatBuffers, Protocol Buffers, and Apache Thrift. These methods rely on predefined schemas to ensure the structure and type of data, typically achieving higher space efficiency. Previous studies have shown that ASN.1 and Apache

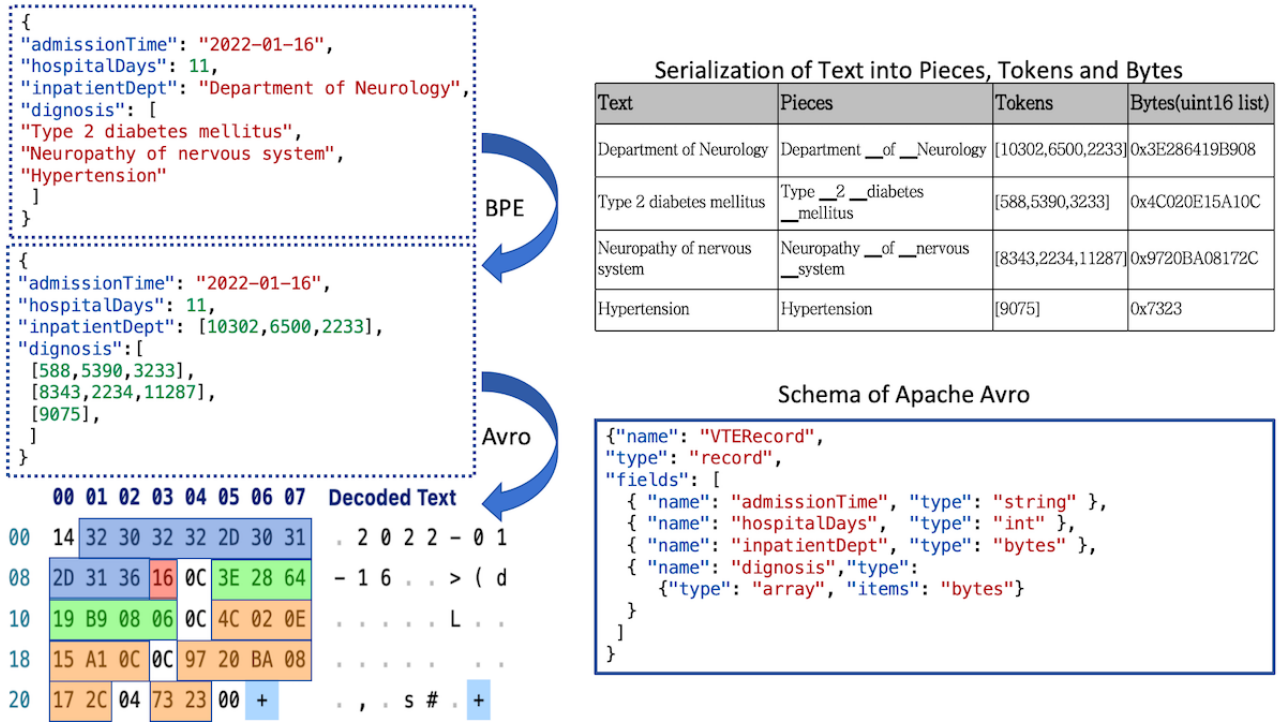
XSL•FO
RenderX

Avro perform particularly well in compression efficiency [15,16].

After comparative validation and in combination with the Gzip method, we found that Apache Avro outperforms ASN.1 in terms of compression efficiency, and Avro's syntax definition is more compatible. Therefore, in our algorithm, we adopted Apache Avro as the serialization method.

Tokenization

Tokenization is a technique that converts text sequences into numerical sequences, serving as a foundational step in natural language processing tasks. It bridges the gap between raw text and language models. Existing tokenization methods, such as BPE, originate from the field of data compression. Some scholars believe that BPE is effective because it compresses text into fewer tokens, allowing the tokenizer to be trained more efficiently on specific datasets [17-19].



The prevalent tokenization techniques in the field of natural language processing include BPE, unigram, and WordPiece. These techniques are adopted by different large language models: BPE is used by the LLaMA series and GPT series, while unigram and WordPiece are used by bidirectional encoder representations from transformers and its variants. Given that our study focuses on Chinese medical texts, which lack explicit delimiters and cannot directly use WordPiece, we have selected BPE and unigram for comparing tokenization compression efficiency.

In our dataset, we compared the compression efficacy of 2 tokenization methods: BPE and the unigram. Experimental results indicated that the BPE method demonstrated superior compression performance within the algorithmic framework proposed in this study. Therefore, we ultimately selected the BPE tokenization strategy [20,21].

Data Compression Process

To demonstrate the proposed data compression approach in practice, we present the following illustrative example using a simplified JSON record of patient information. The JSON file contains 4 fields: admissionTime, hospitalDays, inpatientDept, and diagnosis, as shown in Figure 3.

Figure 3. Explanation of the compression process using BPE and Avro, where BPE tokenizes using the tokenizer and Avro serializes JSON based on schema. BPE: byte pair encoding; JSON: JavaScript Object Notation.

Tokenization is performed on 2 free-text fields: "inpatientDept" and "diagnosis". For example, "Type 2 diabetes mellitus" is split by the tokenizer into "Type _2 _diabetes _mellitus" and further converted into a list of numerical values corresponding to tokens [10,302, 6500, and 2233]. It is noteworthy that due to differences in training corpora and hyper-parameter configurations, different tokenizers may generate varying segmentation results and tokens. This transformation not only contributes to compression but also provides a degree of information hiding, as the original text is not human-readable without the corresponding tokenizer.

Furthermore, Apache Avro is used to transform the JSON into a binary format to complete the serialization operation. As shown in the figure, the blue-marked bytes represent the value of the admission date "2022-01-16," the red-marked bytes represent the length of hospital stay "11" (using variable-length zig-zag encoding, 11(integer)=22(zig-zag)=0×16(octet)), the green-marked bytes represent the hospital department, and the orange-marked bytes represent the 3 disease names of the diagnosis.

It is important to note that the Avro-encoded binary data does not contain type information or field names, which significantly reduces the size of serialized data. However, this also means

XSL•FO
RenderX

that the receiving end must use the same schema as the sending end to correctly read the Avro data. In our algorithm, the Avro schema is not transmitted via the QR code, making it particularly difficult for third parties without the schema to read the Avro data.

In summary, the exclusive tokenizer and Avro schema definitions held by the server and client provide a robust defense for data security. In the example mentioned above, the original JSON data occupies 185 bytes, and after processing with the BPE tokenization and Avro serialization, the space is reduced to 38 bytes, with a compression ratio reaching 4.87, thereby demonstrating its excellent compression performance.

Encryption and Authentication

Modern authenticated encryption adopts the authenticated encryption with associated data approach. National Institute of Standards and Technology recommends standard algorithms such as AES-GCM, AES-CBC+HMAC, and ChaCha20-Poly1305, which ensure both data confidentiality and message integrity [22]. However, these methods require additional overhead, including a 16-byte authentication tag and 8/12/24-byte Nonce or IV fields. AES-CBC further requires 16-byte block alignment, leading to significant message expansion that limits transmission efficiency in space-constrained QR codes.

This work adopts a symmetric authenticated encryption with associated data scheme, where both encoder (sender) and decoder (receiver) share a 256-bit secret key. ChaCha20 is used for encryption and BLAKE3 for authentication, resulting in only 2 bytes of overhead. ChaCha20 is an IETF-standardized stream cipher that uses a 256-bit key and 64-bit nonce, producing a keystream via 20 rounds of permutation. It does not require alignment, keeps the same ciphertext size, and works fast in software even without special hardware, making it suitable for mobile and low-latency scenarios. BLAKE3 is an advanced cryptographic hash function with higher performance than Secure Hash Algorithm 256 bit and Secure Hash Algorithm 512-bit. It supports variable output lengths, allowing flexible adaptation to different application requirements [23].

Compared with other transmission methods, QR codes printed on paper are harder to steal and are difficult to brute-force due to their low propagation efficiency. In our proposed algorithm, BLAKE3 is configured to produce a 2-byte hash, resulting in a brute-force probability of 1/(2^16), which is acceptable for practical authentication. ChaCha20 encryption, with a 256-bit key, offers a brute-force resistance of 1/(2^256), meeting the National Institute of Standards and Technology Level 3 security standard.

Dataset

During the algorithm development phase, this study constructed a “Chinese Medical Text Dataset” for training a proprietary tokenizer. The dataset was sourced from the EHRs of approximately 80,000 historical patients from a hospital. The extracted fields included department names, surgical procedures, medication names, disease diagnoses, indicator names, and imaging examinations, among others, and were saved in text. The access control layer integrates time-based one-time password using a 6-digit random code, reducing the probability of unauthorized access to below 10^{-6}.format.

In the algorithm validation phase, the study built a “Performance Benchmark Dataset” to verify the overall compression performance of the algorithm. This dataset was derived from the EHRs of 300 inpatients with VTE at the Sixth Medical Center of the Chinese PLA General Hospital between January and October 2024 and was saved in JSON format. These medical records comprehensively documented the patients’ basic information, surgical history, diseases, radiological examination results, laboratory test data, risk assessments, and medication upon discharge. Specifically, the basic information included the patient’s age, gender, height, weight, department, and length of hospital stay; surgical details recorded the name and timing of the surgery; disease classification encompassed the name and category of the diseases; radiological examination results detailed the date of the examination, the name of the procedure, the body part examined, and the conclusions; laboratory test data listed the name of the indicator, its value, unit, risk indication, and the normal range; medication upon discharge recorded the name of the medication, the daily dosage, and the frequency of administration; and the risk assessment section included the assessment scale, risk level, and risk factors.

Performance Metrics and Validation Methods

The compression ratio in this study is defined by the formula: CompressionRate=OrigDataBytes/CompressedDataBytes.

In terms of algorithm design, we strive not only to optimize overall performance but also to ensure compatibility with various worst-case scenarios. Therefore, when analyzing the byte size of JSON files and the number of fields in the “Performance Benchmark Dataset,” we used statistical methods for calculating the mean, as well as the minimum and maximum extreme values.

We compared the efficiency of our compression algorithm with the traditional Gzip compression algorithm. In addition, we compared the efficiency of the 2 most effective JSON serialization technologies in real patient datasets, as well as the compression efficiency of 2 mainstream tokenization algorithms on specific datasets. All of the above comparisons used mean statistical methods and used *t* tests to calculate *P* values.

Furthermore, we used cumulative distribution function graphs to analyze the distribution of the number of QR codes scanned by patients and tested the time required for creating patient records via QR codes using various models of mobile phones.

Ethical Considerations

This cohort study was approved by the Medical Ethics Committee of the Sixth Medical Center of Chinese People’s Liberation Army General Hospital (approval number: HZKY-PJ-2022-21). A waiver of informed consent was granted because this was a retrospective, data-only study, and all data were fully deidentified in accordance with institutional and national guidelines. Patients using the home rehabilitation service app provided informed consent at registration. QR code information constitutes a deidentified limited dataset with no personally identifiable information included; personally

XSL•FO
RenderX

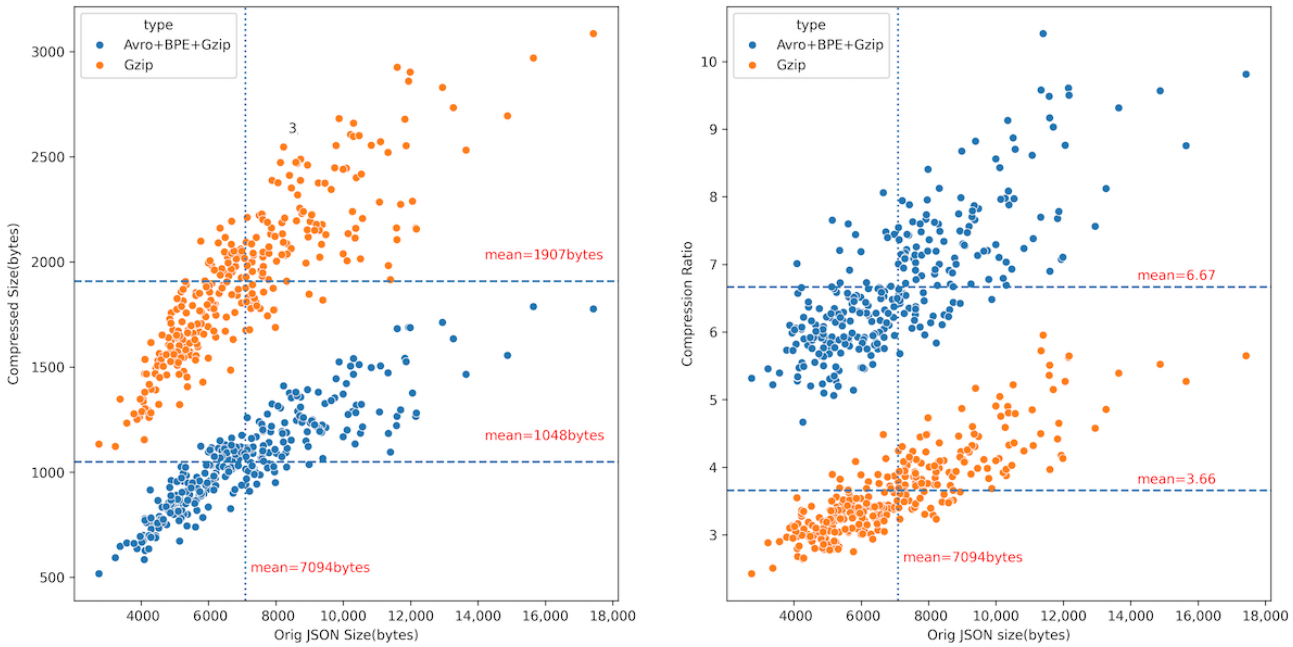
identifiable information is used only locally for authentication and is never transmitted. Encrypted QR codes are accessible only by authorized patients, ensuring data security and access control. All procedures complied with institutional policies, the Declaration of Helsinki, and relevant data protection regulations.

Results

Statistical Characteristics of the Performance Benchmark Dataset

We conducted a detailed statistical analysis of the fields and their storage sizes in the JSON files of the "Performance Benchmark Dataset," which is summarized in Table 4. The average number of fields in the raw JSON files was 240.1, ranging from 89 to 623, with an average storage byte size of 7095, varying from 2748 to 17,425. In terms of the number of fields, laboratory test data constituted the highest proportion at 67.5%, followed by risk assessment data at 9.6%. Regarding storage byte size, laboratory test data also represented the largest proportion at 61.4%, with radiological examination result data following at 14.4%.

Table . Characteristics of the performance benchmark dataset in this study.



Patient (n=300)	Field (num), mean (min-max)	Field (%)	Size (bytes), mean (min-max)	Size (%)
Total	240.1 (89-623)	—[a]	7095 (2748-17,425)	—
Base	10 (10-10)	4.2	261 (242-270)	3.7
Operate	1.1 (0-32)	0.5	77 (23-1269)	1.1
Image	17.1 (4-56)	7.1	1022 (153-3944)	14.4
Lab	162 (46-496)	67.5	4354 (1269-13,365)	61.4
Ass	23 (10-35)	9.6	584 (212-1181)	8.2
Disease	12.2 (2-48)	5.1	419 (80-1537)	5.9
Drug	14.6 (0-85)	6.1	379 (28-2042)	5.3

[a]Not applicable.

Overall Compression Efficiency Analysis

The average size of the original JSON data was 7095 bytes. After compression using the traditional Gzip algorithm, the average size was reduced to 1907 bytes, with an average compression ratio of 3.66. By applying our developed BPE+Avro+Gzip combined compression algorithm, the average size was further reduced to 1048 bytes, improving the average compression ratio to 6.67. The compression efficiency of our algorithm was 1.82 times that of the traditional Gzip algorithm (P<.001). The scatter plot distribution in Figure 4 shows that the larger the original JSON file, the more significant the compression effect.

Figure 4. Comparison of the compression efficiency between our Avro + BPE + Gzip combined method and traditional Gzip in the performance benchmark dataset. BPE: byte pair encoding; JSON: JavaScript Object Notation.

RenderX

Comparative Analysis of Avro and ASN.1

According to previous research, ASN.1 and Avro demonstrated the best compression performance among JSON serialization technologies. For our "Performance Benchmark Dataset," Avro achieved a compression ratio of 2.59, while ASN.1 had a compression ratio of 2.57, with no significant difference (P=.30). However, Avro significantly outperformed ASN.1 when combined with BPE or Gzip methods (Table 5 and Figure 5). Specifically, the compression ratio for Avro+Gzip reached 4.72, compared with 4.12 for ASN.1+ Gzip (P<.001). Further, when the BPE method was introduced, the compression ratio for Avro+BPE+Gzip was 6.67, while for ASN.1+BPE+Gzip it was 5.21 (P<.001).

Table . Comparison of compression ratios between Avro and Abstract Syntax Notation One (ASN.1) in different combinations with byte pair encoding (BPE) and Gzip.

Name	Median (IQR)	Min	Max
ASN.1[a]	2.59 (2.45-2.77)	1.78	3.09
Avro	2.57 (2.43-2.75)	1.78	3.07
ASN.1+Gzip[b]	4.12 (3.63-4.46)	2.92	6.92
Avro+Gzip	4.72 (4.18-5.15)	3.35	7.73
ASN.1+BPE[c]	5.01 (4.83-5.23)	4.07	5.81
Avro+BPE	5.14 (4.94-5.37)	4.16	5.99
ASN.1+BPE+Gzip[d]	5.21 (4.95-5.45)	4.12	6.62
Avro+BPE+Gzip	6.67 (5.93-7.20)	4.67	10.41

[b]ASN.1+Gzip versus Avro+Gzip; P<.001.

[c]ASN.1+BPE versus Avro+BPE; P<.001.

[d]ASN.1+BPE+Gzip versus Avro+BPE+Gzip; P<.001.

Figure 5. Analysis of compression performance for Avro and ASN.1 in different combinations with BPE and Gzip, where "Serial" indicates the use of Avro or ASN.1 for JSON serialization. ASN.1: Abstract Syntax Notation One; BPE: byte pair encoding; JSON: JavaScript Object Notation.

Comparative Analysis of BPE and Unigram

Our constructed dataset consisted of a total of 1,146,532 records, with a total size of 122.5 MB and an average sentence length of 38.3 Chinese characters, corresponding to an average byte length of 106.8. We divided this dataset into a training set and a test set at a ratio of 9:1.

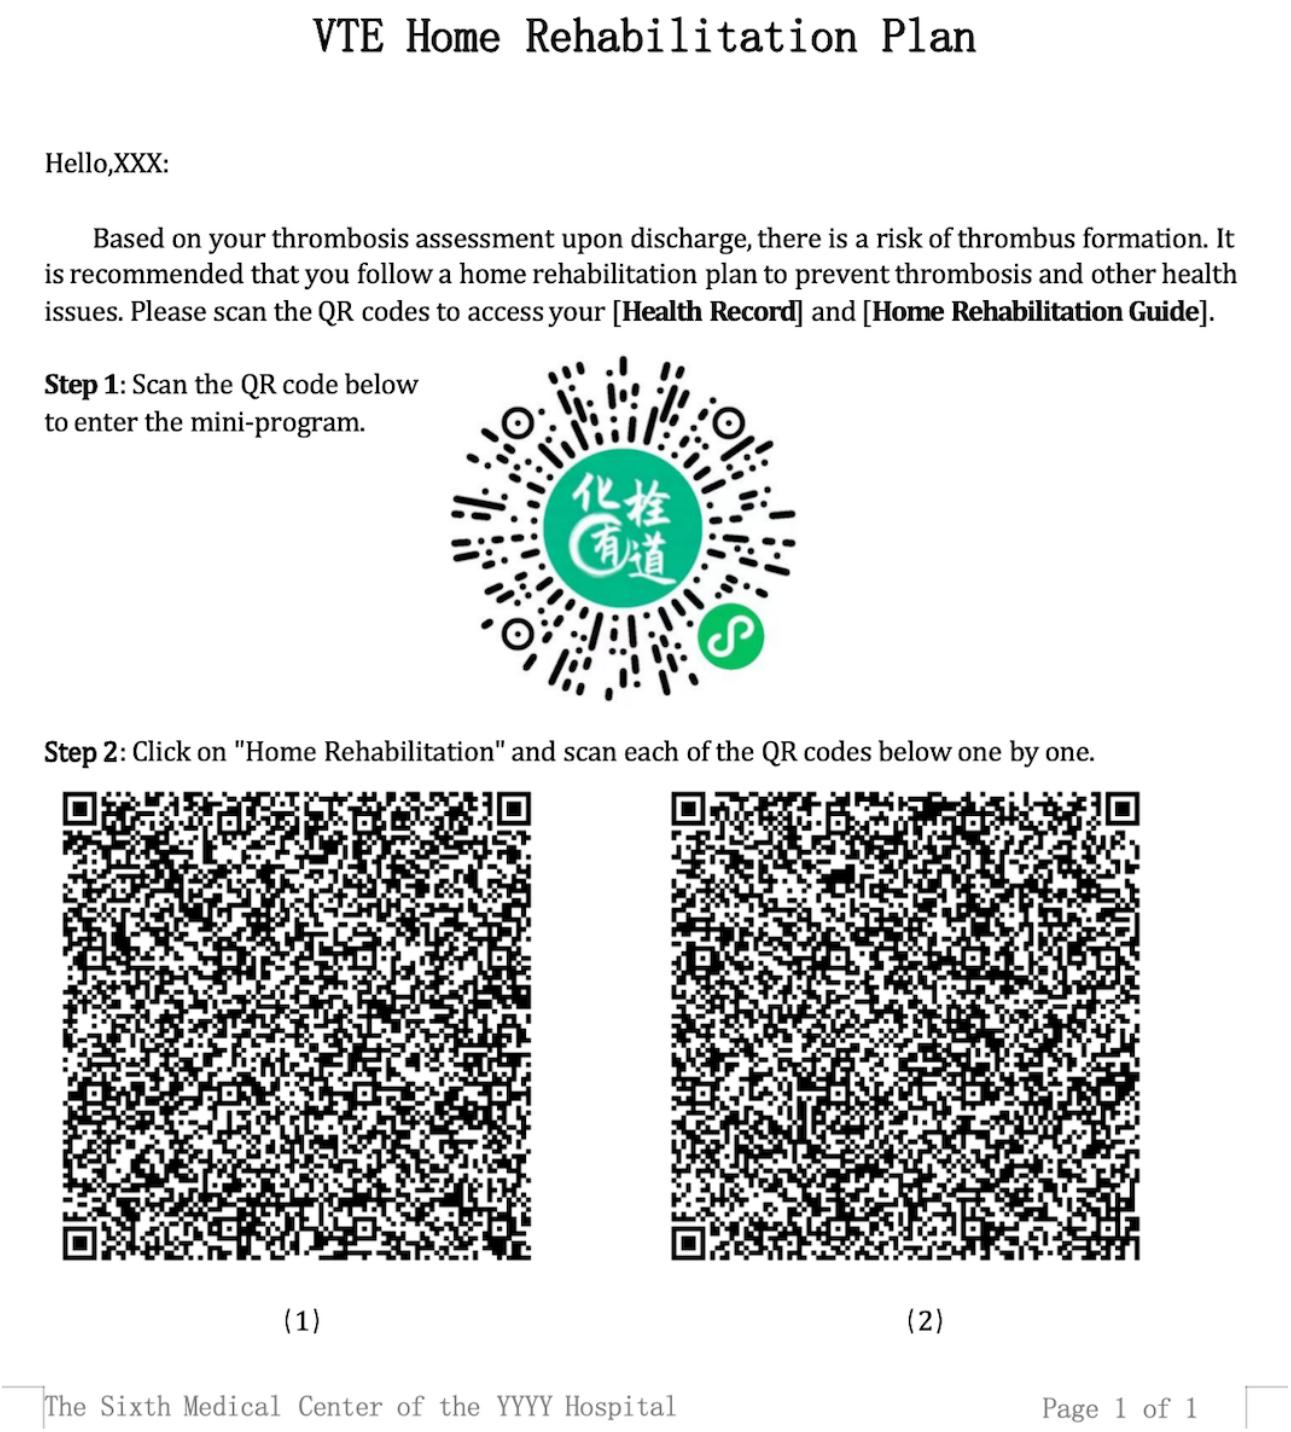
Using Google's open-source project SentencePiece for tokenizer training, we trained and validated 2 tokenization methods: unigram and BPE171819, with a vocab_size of 65,535, allowing each token to be represented by a 2-byte unit. In terms of training duration, unigram took 65.91 seconds, while BPE took 360.2 seconds, with unigram being faster. In terms of compression ratio, on the training set, unigram and BPE

XSL•FO
RenderX

achieved compression ratios of 4.7 and 4.83, respectively (P<.001); on the test set, they achieved 4.55 and 4.68, respectively (P<.001), showing that BPE is more efficient than unigram (Table 6).

Table . Comparison of compression ratios for byte pair encoding (BPE) and unigram with different serialization methods in the Chinese medical text dataset.

Dataset	Sentences (n=1,146,532)	Unigram	BPE	*P* value
Train	1,031,697	4.70	4.83	<.001
Test	114,835	4.55	4.68	<.001



QR Code Distribution and Scanning Time

Based on previous research, when each module size is set to 4×4 pixels, 100% readability can be achieved on A4 white paper [24]. For the largest QR code size, the number of modules contained is 177×177 [25]. With a border width of 4 and an estimated resolution of 200 dots per inch for a standard printer, even the largest QR code would occupy a space of 3.7 inches (9.39 cm) in both length and width on A4 paper.

Considering the response speed of mobile phone scanning and the redundancy requirements of QR codes, we selected the version 25 QR code with 117×117 modules, which has a theoretical size of 2.5 inches (6.35 cm). Taking into account the differences in dots per inch, ink density, and default print margins across different hospital printers, we reserved a 20% redundancy, resulting in a designed QR code size of 7.62 cm × 7.62 cm (approximately 3×3 inches), with 2 QR codes per row. The specific layout is shown in Figure 6.

XSL•FO
RenderX

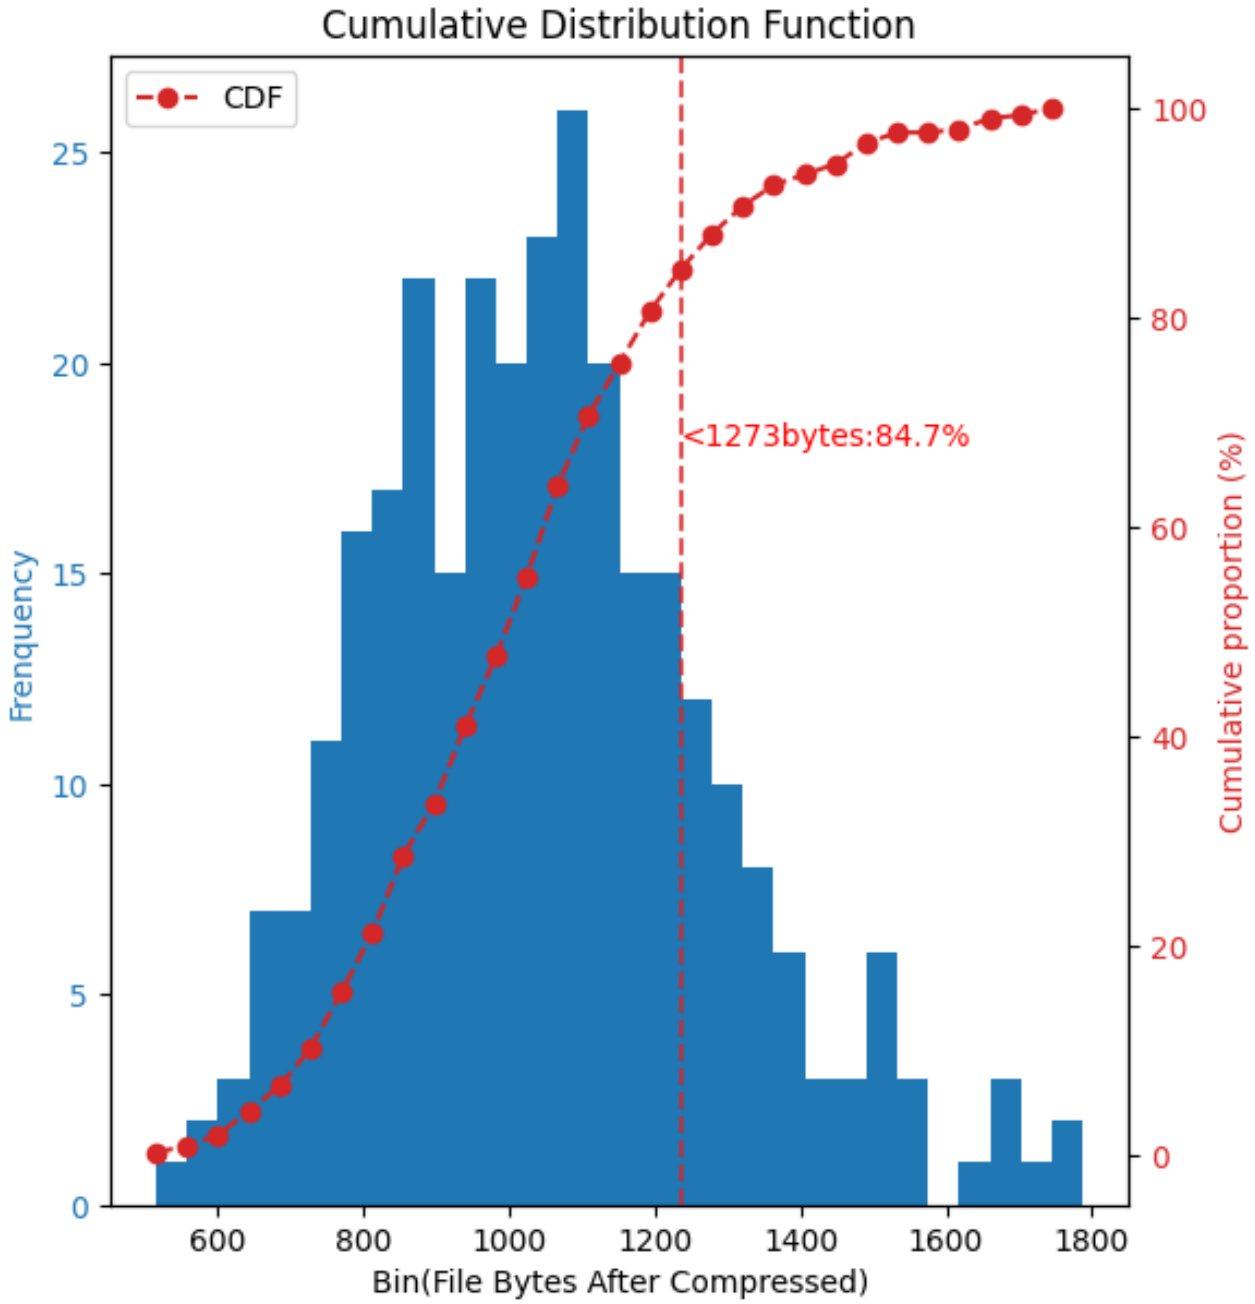


Figure 6. Example of a home rehabilitation report given to patients upon discharge for scanning QR codes. VTE: venous thromboembolism.

We used version 25 QR codes with an error correction level set to L, each supporting a maximum binary capacity of 1273 bytes [25]. As shown in Figure 7, following a cumulative distribution function [26] analysis of the compressed file sizes for 300 patients, we found that 84.7% of the patients needed to scan only one QR code, while 5.3% of the patients required scanning 2 QR codes. Only an extremely small number of patients may need to scan more than 3 QR codes.

XSL•FO
RenderX

Figure 7. CDF analysis of file sizes for 300 patients after compression, showing that 84.7% of patients require scanning only 1 QR code with a file size less than 1273 bytes. CDF: cumulative distribution function.

Based on the size of the compressed files, we selected 3 patients for a scanning test, corresponding to 1, 2, and 3 QR codes, respectively. The test timing started when the patient clicked the scan button and ended when the record creation was completed. Testing with different models of mobile phones showed that, on average, scanning 1 QR code took 3.1 seconds, scanning 2 QR codes took 7.30 seconds, and scanning 3 QR codes took 8.73 seconds. ANOVA was used to test the differences, with a *P* value <.001.

Based on the size of the compressed files, we selected 3 patients for a QR code scanning test, corresponding to 1, 2, and 3 QR codes, respectively. The timing started when the patient clicked the scan button and ended when the registration was completed. Different smartphone models were used for the tests, and the results showed that, on average, scanning one QR code took 3.1 seconds, scanning 2 QR codes took 7.30 seconds, and scanning 3 QR codes took 8.73 seconds (Table 7). ANOVA was used to test the differences, with a *P* value <.001.

Discussion

Main Findings

We developed a QRST-AB, which assists patients in creating home rehabilitation records after discharge while ensuring the privacy, security, and efficiency of medical data transmission. The primary outcomes of our study are as follows. (1) We proposed a QR code authentication and encryption mechanism that leverages ChaCha20 encryption and the BLAKE3 hash function, reducing message inflation to as low as 2 bytes and enabling noninteractive cross-domain verification and data security in a zero-trust environment. (2) We developed an efficient combined data compression method, where the BPE+Avro+Gzip compression approach is 1.9 times more efficient than traditional Gzip compression, allowing a single patient's medical record to be compressed into 1 - 3 QR codes, thus improving the practicality and efficiency of QR code transmission in medical data scenarios. (3) The algorithm is provided in software development kit form, making it easy to deploy and use, which facilitates broader adoption.

Comparison With Prior Work

In previous research, there have been instances of embedding medical data, as opposed to URL information, into QR codes for transmission. Specifically, Lin et al [8] encoded patients' prescription information into QR codes, facilitating the use of these codes by patients at different pharmacies. The QR code encompassed information across 17 fields, including the patient's name, identification, age, type of disease, name of medication, and date, among other critical data. Additionally, Nakayama from Japan [9] and Mathivanan from India [10,11] have successfully embedded electrocardiogram data into QR codes. Lauriot [12] adopted the approach of directly embedding the data results of imaging reports into a single QR code. Mao et al [13], on the other hand, used a different strategy; they segmented a file containing medical data and embedded the segmented data into consecutive QR codes, which were dynamically and continuously displayed in a streaming video. Users could capture this video stream with a smartphone and subsequently recover the relevant medical data from the QR codes.

However, in previous practices, despite the use of signal sampling and private encryption algorithms to enhance security when embedding electrocardiogram data into QR codes, medical texts are still embedded in plaintext, which may expose the data to interception by unauthorized third parties, leading to potential leakage of patient privacy information. Moreover, these cases generally lack user authentication mechanisms and exhibit low compression efficiency.

Prior to this work, several studies have proposed solutions for securing data transmission in untrusted environments. For example, [27] introduces authentication and encryption measures for military communication protocols to prevent man-in-the-middle and replay attacks. In [28], blockchain technology is used to establish a decentralized trust mechanism—for instance, similar to the framework described in [29], one can refer to its on-chain authentication and consensus processes to enhance data integrity and immutability when transmitting QR-embedded information. In the health care domain, [30] emphasizes the need to balance data security and privacy protection in telemedicine interoperability, which informs our design of QR code data encryption and client authentication. Moreover, [31] addresses deepfake disinformation strategies from a holistic cybersecurity perspective, offering guidance on ensuring the integrity and trustworthiness of data embedded in QR codes. Finally, [32] presents a hesitant fuzzy decision-making approach for usable-security assessment, which can be applied to optimize the usability of our underlying authentication workflow.

To address these security risks and efficiency issues, we have taken the following improvement measures. First, we have proposed a complete solution and an end-to-end communication mechanism, defined the protocol specifications, and added authentication information to the protocol header. We use cryptographic hash algorithms to verify the identity of the scanning user, preventing unauthorized users from scanning the QR code. Additionally, we use encrypted transmission, which remains secure even if a third party understands the principles of our algorithm, as they do not possess the ChaCha20 secret key, the Avro encoding schema, and the BPE tokenizer, and thus cannot decipher the contents of the QR code.

Second, we have proposed an efficient compression algorithm for patient medical record data, organically integrating JSON

XSL•FO
RenderX

serialization technology, tokenization techniques based on large language models (including subword tokenization methods like BPE), and binary data compression technology. The combination of BPE+Avro+Gzip has achieved optimal compression performance. To date, there is no precedent for compressing electronic medical records using this combination. Although the transmission efficiency of QR codes is inherently limited and slow, our effective compression algorithm can significantly reduce the size of medical record data, thus greatly enhancing the practicality of QR codes in the transmission of medical information. Furthermore, our solution supports the transmission of multiple QR codes in a single transaction, thereby enabling the carriage of larger volumes of medical records and information.

Through our improvements and real-world data validation, the QRST-AB possesses the characteristics of encryption, authentication, efficiency, robustness, and scalability. This makes it well-suited for home rehabilitation registration scenarios and other situations requiring the transmission of patient privacy data.

Limitations

There were some limitations to this study. First, due to the limited project timeline, validation was conducted using single-center data only. However, the algorithm was designed with flexibility for multicenter deployment and support for diverse disease types, which will be further validated in future studies. Second, when patient records are large and QR codes contain substantial data, poor network conditions may lead to delays in the decoder's real-time response. Thirdly, the solution relies on manual scanning, and the patient's digital health literacy may affect the user experience; however, most users are capable of performing scanning operations, which helps mitigate this issue.

Future Work

We plan to conduct multicenter validation and extend support to other disease types, as well as optimize the algorithm to reduce response delays caused by large patient data volumes.

Conclusions

The QRST-AB algorithm efficiently compresses and transmits data in an encrypted manner and authenticates the identity of the scanning users, ensuring the privacy and security of medical data. Delivered as a software development kit, the algorithm offers straightforward implementation and usability, supporting its broad adoption across various applications. All code is publicly available through the QRST-AB GitHub repository.

Abstract

Background: The integration of artificial intelligence (AI) in rehabilitation technology is transforming traditional methods, focusing on personalization and improved outcomes. The growing area of AI in digital rehabilitation (DR) emphasizes the critical role of end-user compliance with rehabilitation programs. Analyzing how AI-driven DR tools can boost this compliance is vital for creating sustainable practices and tackling future challenges.

Objective: This study seeks to assess how AI-based DR can improve the end-user compliance or adherence to rehabilitation.

Methods: Following the updated recommendations for the Cochrane rapid review methods guidance and PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, a systematic literature search strategy was led in PubMed, which yielded 922 records, resulting in 6 papers included in this study.

Results: The reviewed studies identified 6 key ways in which AI enhances end-user compliance in rehabilitation. The most prevalent method (in 4 studies) involves motivating and engaging users through features like exercise tracking and motivational content. The second method, also noted in 4 studies, focuses on improving communication and information exchange between health care providers and users. Personalized solutions tailored to individual cognitive styles and attitudes were highlighted in 3 studies. Ease of use and system usability, affecting user acceptability, emerged in 2 studies. Additionally, daily notifications, alerts, and reminders were identified as strategies to promote compliance, also noted in 2 studies. While 5 studies looked at AI's role in improving adherence, 1 study specifically assessed AI's capability for objective compliance measurement, contrasting it with traditional subjective self-reports.

Conclusions: Our results could be especially relevant and beneficial for rethinking rehabilitation practices and devising effective strategies for the integration of AI in the rehabilitation field, aimed at enhancing end-user adherence to the rehabilitation regimen.

KEYWORDS

artificial intelligence; AI; rehabilitation; digital rehabilitation; compliance; adherence; PRISMA; Preferred Reporting Items for Systematic Reviews and Meta-Analyses

Introduction

Increased population growth in the global south, aging demographics in the global north, and rising numbers of individuals in both contexts with chronic conditions highlight the growing need for multidisciplinary rehabilitation worldwide. Rehabilitation is defined as "a set of interventions designed to optimize functioning and reduce disability in individuals with health conditions in interaction with their environment" [1]. Access to rehabilitation services plays a crucial role in providing comprehensive care and support for individuals in need. However, traditional rehabilitation services present significant limitations, including time constraints, long distances to travel, high costs, lack of human resources, and limited availability of clinical facilities, leaving a large unmet need and subsequent lack of participation [2,3].

The growing trend toward digitized health care, the use of portable technology, and events such as the COVID-19 pandemic have exacerbated the challenges that rehabilitation services face. The social distancing measures implemented during the COVID-19 pandemic provided a considerable push for the expanded use of digital rehabilitation (DR) modalities

XSL•FO
RenderX

by numerous types of health care professionals [4]. DR has the potential to advance end-user (patient) and therapist collaboration to enhance the outcomes, improve performance challenges and quality of life, decrease health care costs, and tackle other key rehabilitation obstacles [5,6]. DR involves incorporating digital technologies into the rehabilitation process, which encompasses, but is not limited to telehealth and remote rehabilitation apps and services, a range of sensor and information and communication technologies, artificial intelligence (AI)–driven and robot-assisted tools, wearables, as well as email, video, speech, and SMS text messaging solutions [3,4].

The application of AI is revolutionizing almost all subfields of health care, including rehabilitation [7]. AI is described as the capacity of a machine to do a functional task under the intelligent supervision of humans [8]. AI tools are becoming more adept at learning from extensive and intricate data, using algorithms to acquire knowledge, analyze, and subsequently aid in different clinical and rehabilitation procedures [9].

Rehabilitation technology supported by AI signifies a groundbreaking and revolutionary method in the rehabilitation sector, which can be used to customize and complement the overall quality of traditional rehabilitation strategies [10]. AI has become a crucial component of DR, transforming and improving evaluation, screening, therapy, and monitoring through identifying patterns within vast quantities of health care data [10]. These patterns can then be used in designing tailored and personalized rehabilitation strategies and treatment regimens and comprehensive care planning [10-12]. AI tools support the automation of many rehabilitation tasks, injury prevention, prompt referral decisions, remote rehabilitation, monitoring and forecasting the end-user progress, and the creation of assistive technologies [12,13].

AI technologies provide efficient and enhanced rehabilitation access with optimized outcomes, which have the potential to improve client adherence and motivation [4,10,12]. Some of these technologies include AI-based digital and personalized rehabilitation mobile apps, AI-driven virtual reality and augmented reality rehabilitation, sensors, robotic devices, and AI-powered gamification and telerehabilitation [4,10].

Despite the key benefits of these technology-driven interventions—such as improved accessibility, affordability, and their availability from the convenience of homes—most of the AI-based rehabilitation applications are in the early stages of development [12,14-16]. However, the application of AI in redesigning rehabilitation to tackle upcoming challenges will intriguingly grow [4].

Compliance or adherence to long-term treatments, including rehabilitation, poses a significant health care challenge when managing chronic illnesses and is crucial for the success of rehabilitation and end-user recovery. While it signifies the end user's readiness to engage in and dedicate themselves to the treatment and prescribed therapeutic routine, this commitment aims to prevent complications and the reoccurrence of the disease by enhancing daily activities, quality of life, and overall outcomes [17]. Although the terms compliance and adherence are different in some ways, the 2 words are used interchangeably by medical professionals [18]. Compliance or adherence guarantees that there is willing, cooperative, and engaged interaction between the client and the health care provider [19].

Several factors and explanations contribute to the complexity of compliance or adherence to rehabilitation. In medical and rehabilitation settings, adherence refers to how well individuals follow the clinical recommendations that have been mutually established [20]. In this study, we refer to rehabilitation adherence as the end user's (patient's) compliance or adherence to, engagement in, and acceptability of the rehabilitation program. Reasons for the end user not adhering to rehabilitation plans may include skepticism about treatment benefits, concerns about side effects, financial limitations, the complexity of the treatment plan, and insufficient support from family and peers [19,21]. Prior studies have indicated that patients who adhere more closely to treatment plans tend to experience improved outcomes [22]. However, there is an overall lack of evidence in the area of compliance or adherence, and in what ways AI can improve end-user rehabilitation compliance or adherence is unknown. AI in DR is an emerging field, and considering that end-user compliance or adherence to a rehabilitation regimen plays a significant role, comprehending how AI-based DR can impact the end-user rehabilitation compliance or adherence is crucial for establishing sustainable DR practices and meeting the challenges ahead. The aim of this rapid review (RR) lies in understanding the impact of AI-based DR tools on the improvement of end-user rehabilitation compliance or adherence. This review answers the following research question: "How can AI-based DR improve end-user compliance or adherence to rehabilitation?"

Methods

Study Design

A Cochrane RR is "a form of knowledge synthesis that accelerates the process of conducting a traditional systematic review through streamlining or omitting specific methods to produce evidence for stakeholders in a resource-efficient manner" [23]. It primarily provides prompt evidence for decision-making regarding urgent and high-priority health issues [23].

RR is a type of systematic review that aims to balance time limitations with the need to address bias [24]. However, RRs may not include all elements of a systematic review, with differences in the dimensions of time, resources, and searches. For example, Cochrane RRs should take no longer than 6 months; they may be less comprehensive, and a small number of databases are selected for searches; they may exclude hand-searching and gray literature; and some limits such as years and language may be applied in RRs [24,25].

This review is in compliance with the updated recommendations for the Cochrane RR methods guidance and the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) recommendations (Checklist 1) [24,26]. The Cochrane RR guidance consists of 24 specific recommendations supporting the conduct of RRs to enhance the efficiency of the review process [24].

Literature Search

PubMed was searched in May 2024, and a combination of MeSH terms and keywords on the following themes was used: AI, DR, and end-user compliance or adherence. A copy of the PubMed search strategy is included as Multimedia Appendix 1.

Study Selection

Titles and abstracts were initially screened through applying the eligibility criteria by 2 reviewers (MM and MLW) independently. The only software that was used to facilitate this process was Microsoft Excel to aid in the display and tabulation of the information. For retained papers, full texts were obtained, and again, a subset of full texts was screened by 2 researchers (MM and MLW). Differences and discrepancies were discussed, and dual screening was continued until convergence was reached.

Studies were included when they encompassed the following elements in line with the population, intervention, comparison, and outcome framework for evidence-based practice:

- Population: Adults (≥18 years of age) undergoing formal rehabilitation.
- Intervention: Any type of AI-based applications and tools, used by end users or health care providers, in inpatient, outpatient, or community-based settings.
- Comparison: For interventional studies, the control group is defined as those not receiving AI-supported rehabilitation.
- Outcome: End-user rehabilitation compliance or adherence.
- Study types: Any study design.
- Other: English language studies published from January 1, 2012, onward.

Protocols, books, theses, editorials, conference abstracts, and non-English language studies were excluded. Studies focusing on psychiatric rehabilitation were intentionally excluded since distance- and digital-based mental health interventions have been widely available, even before the internet age with counseling being done via telephone. Studies focusing on robotics and AI were also excluded, as this is a sufficiently large field that would require a separate review. Considering the recent use of AI applications in the health care field and a surge of advancements in AI in 2012, it was deemed not necessary to review papers published before 2012.

Data Extraction and Management

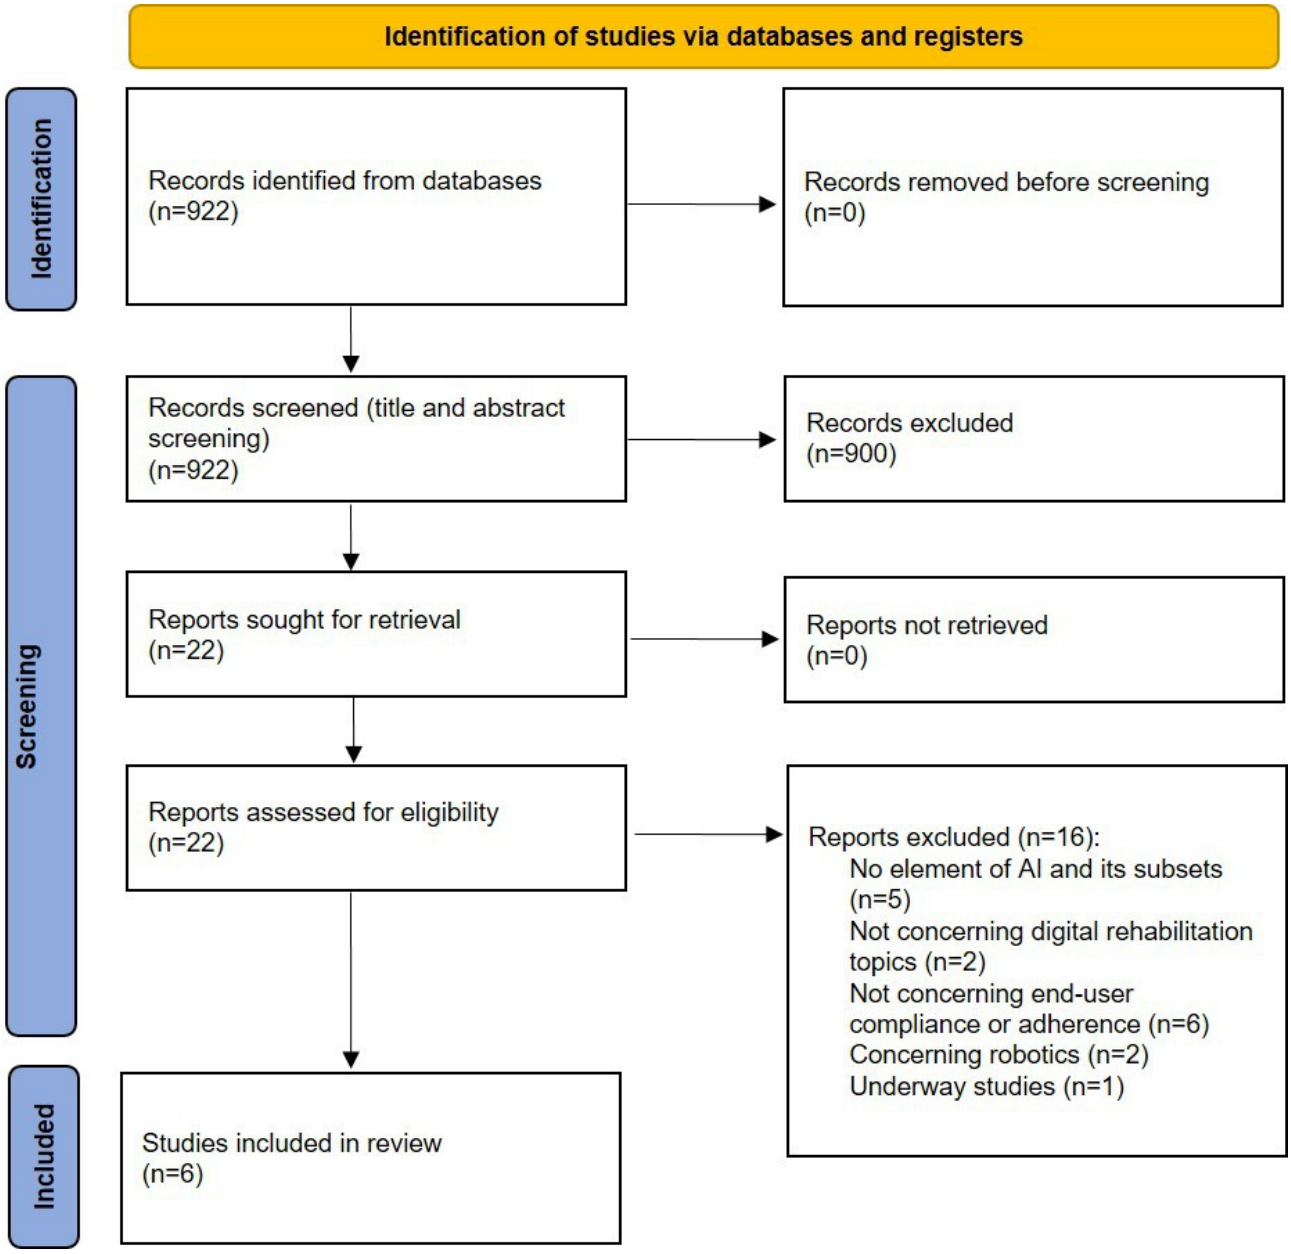
Data extraction was conducted by a single researcher and then verified for consistency, accuracy, and completeness by a second independent researcher. It included population characteristics, rehabilitation field and setting, intervention details including AI subset or algorithm, purpose of the device and the technology used, the study aims and its characteristics evidencing drawbacks and advantages reported by respective authors, major findings, and the way AI impacts the end-user compliance or adherence.

Quality Assessment

The Cochrane Risk of Bias tool 2.0 [27] was used for randomized controlled trials (RCTs) to assess the quality of studies. The tool inquires about various aspects in 5 domains where bias could potentially arise. The five domains include (1) bias from randomization, (2) bias from deviations in interventions, (3) bias from missing outcome data, (4) bias in outcome measurement, and (5) bias in reported result selection.

Data Synthesis

Due to the diversity in study designs and outcome measures, the results were synthesized in a narrative format.



Results

Overview

In the initial paper search, 922 unique papers were identified. After screening, 6 papers met the eligibility criteria and were included (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart of the results from the literature search. AI: artificial intelligence.

Study Characteristics and Interventions

Characteristics of the included studies and their relevant interventions are presented in Table 1. Of the 6 publications, 3 were RCTs [28-30], 2 were pilot studies [31,32], and 1 was a proof-of-concept study [33]. The number of participants recruited into the included studies ranged from 6 to 500 participants. Studies were conducted in Canada (n=1), Israel (n=1), the Republic of Korea (n=1), Thailand (n=1), Italy (n=1), and the United States (n=1).

XSL•FO
RenderX

Table . Characteristics of the included studies and their interventions.

Reference (year, country)	Study design	Rehabilitation field and setting	Sample characteristics	Intervention
Chae et al (2020) [29] (Republic of Korea)	RCT[a]	Upper limb rehabilitation, home-based	End users with chronic stroke, intervention: n=17; mean age 58.3 (SD 9.3) years; control: n=6, mean age 64.5 (SD 9.6) years	Performing the home rehabilitation exercises while using wearable sensors embedded in a commercial smartwatch
Aharon et al (2022) [28] (Israel)	RCT	Cardiac rehabilitation, clinic-based	End users discharged from a cardiovascular event, intervention: n=95; mean age 61.3 (SD 14.6) years; control: n=500; mean age 65.4 (SD 10.4) years	Using the Well-Beat system, ongoing personalized text messages for each end user were generated to create continuity and reinforce desired behaviors
Burns et al (2018) [33] (Canada)	Proof of concept	Shoulder physiotherapy, home-based	Healthy adult participants, n=20, mean age 28.9 years; range 19 - 56 years	Performing 20 repetitions of 7 shoulder exercises bilaterally while using a smartwatch device with embedded inertial sensors
Thiengwittayaporn et al (2023) [30] (Thailand)	RCT	Physical therapy, home-based	End users with primary knee osteoarthritis, intervention: n=42; mean age 62.2 (SD 6.8) years; control: n=40; mean age 63.0 (SD 9.7) years	Receiving information regarding knee osteoarthritis disease background and exercise instruction through mobile app self-directed exercise guidance
Capecci et al (2023) [31](Italy)	Prospective, pre- or postintervention pilot study	Motor and respiratory rehabilitation, home-based	Participants with post–COVID-19 condition and Parkinson disease, n=21; mean age 61.1 (SD 10.5) years	Using ARC Intellicare, a telerehabilitation solution based on the use of multiple wearable sensors, a mobile device, and algorithms of AI[b]
Ramkumar et al (2019) [32] (United States)	Pilot study	Total knee arthroplasty, home-based	End users undergoing primary total knee arthroplasty, n=25; mean age 64.3 years	Performing daily exercises and a weekly survey while using a knee sleeve paired with the end user's iPhone and a mobile app

[a]RCT: randomized controlled trial.

[b]AI: artificial intelligence.

There were diverse rehabilitation settings, and most were home-based. Only in 1 study was the rehabilitation in a clinical setting. The treated conditions included stroke, cardiovascular disease, osteoarthritis, post–COVID-19 condition, and Parkinson disease. While 4 studies used wearable sensors as an intervention, in 1 study, end users received information regarding the disease background and exercise instruction through a mobile app, and in the other study, ongoing personalized SMS text messages for each end user were generated to create continuity and reinforce desired behaviors.

Outcomes and Results Summary

Outcome measures and results summary of the included studies are presented in Table 2. The outcomes measured in the included studies fell into 3 categories: feasibility, accuracy, and usability of the rehabilitation system; end-user compliance or adherence, engagement, and acceptability; and clinical outcomes (eg, functional improvements, range of motion, and quality of life). However, our focus is on the second category of outcomes.

XSL•FO
RenderX

Table . Outcomes and results summary of the included studies.

Reference	Outcome measures		Results summary
	Primary measures (end-user compliance or adherence)	Other measures (feasibility, accuracy, and usability or clinical outcomes)	
Chae et al [29]	Dropout rate and home exercise performance average time as measures for the end-user compliance or adherence	Accuracy of the developed rehabilitation system, functional assessment test, shoulder range of motion	A decreased dropout rate, increased home exercise performance average time, a significant increase in functional recovery and shoulder flexion
Aharon et al [28]	End-user rehabilitation adherence	None	Significant improvement in end-user adherence and participation in the rehabilitation program
Burns et al [33]	The frequency and duration an end user is engaged with exercises as measures for the end-user compliance or adherence	Classifier performance in the measurement of frequency and duration of an end-user engagement in prescribed exercises	Feasibility of robust and highly accurate classification of sensor data in the measurement of frequency and duration of an end-user engagement in prescribed exercises
Thiengwittayaporn et al [30]	Ability to correctly perform the rehabilitation exercises as measures for the end-user compliance or adherence	Range of motion, Knee Injury and Osteoarthritis Outcome Score, and Knee Society Score	Improved accuracy of rehabilitation exercises, as measures for the end-user adherence, stronger overall functional outcomes, better daily life, ability to do sports and recreation, higher satisfaction and expectation, and a significantly better quality of life
Capecci et al [31]	Adherence to the rehabilitation program	Safety, usability, and acceptability of the rehabilitation program, clinical effectiveness (disability in basal activity of daily living, respiratory outcomes, endurance and fatigue, mood, and quality of life)	Improved end users' adherence, improved system usability scale score, clinical outcome measures, and no side-effect reports
Ramkumar et al [32]	Rehabilitation compliance	Feasibility validation, mobility, knee range of motion, patient-reported outcome measures, opioid use	Improved rehabilitation compliance, the provision of a continuous stream of data without any loss, improved mobility and patient-reported outcome measures, and stopped opioid use

Risk of Bias Summary

Three of the studies [28-30], which were RCTs, were assessed using the Cochrane risk of bias tool [27]. One of the studies had an overall risk of bias of "some concerns" [30], and 2 studies had an overall high risk of bias [28,29]. In total, 1 study had a high risk of bias arising from the randomization process [29], all 3 studies had a risk of bias of some concerns in the domain of bias due to deviations from intended interventions, and in the domain of bias in measurement of the outcome, 1 study had a high risk of bias [28], and 2 studies had a risk of bias of some concerns [29,30].

The Role of AI

Summarized information regarding the system and technology used by interventions in the included studies and the role of the used AI subset is presented in Table 3.

XSL•FO
RenderX

Table . Characteristics of the systems used in interventions: technology type, artificial intelligence (AI) subset, and role.

Reference	AI subset	System and technology type	Purpose or role of the AI-based device or system
Chae et al [29]	Machine learning (ML) algorithm implemented by a convolutional neural network ascertaining what types of sensor data can detect home exercise activities most accurately via a cross-validation test	Activity monitoring using wearables (smartwatch, smartphone, and apps [Android Studio 2.3, Google])	The AI-based rehabilitation system connected end users and therapists at a distance and made it possible to share end users' home exercise data with therapists at remote locations. The system assisted participants in the intervention group to record their exercise time, obtain their own home exercise results, and communicate with a clinician, yielding visible improvement and acting as a motivation—features that were not available to those in the control group.
Aharon et al [28]	A real-time ML algorithm processing the digital questionnaires	Well-Beat platform, which created a profile for each end user by processing a digital questionnaire assessing end users' initial state	After processing the questionnaires, the system created a profile for each end user and presented it on the health care providers' toolbar. The toolbar included the end user's persistence level, readiness for change level (maturity), self-efficacy level, main motivational driver, and barrier, as well as what the health care provider should watch out for in communication with them. Based on this information, the engine recommended the personalized end-user dialogue to use, in terms of the tone, the style, and motivation factors, as well as what to avoid saying.
Burns et al [33]	Supervised ML approach	Exercise recognition using wearables, that is, smartwatch device with embedded inertial sensors (Apple Watch [series 2 and 3] with the PowerSense app, sampling at fs=50 Hz)	The AI-based system assessed the feasibility of performing shoulder physiotherapy exercise recognition with inertial sensor data recorded from a wrist-worn device to enable objective measurement of home shoulder physiotherapy adherence.
Thiengwittayaporn et al [30]	Rule-based and AI techniques (eg, determining the disease stage based on decision tree)	Education and assessment for the stage of disease via Love-Your-Knee mobile app (Android)	The AI-based system was used as a personalized solution and recommending the appropriate exercise types and the number of sets for each end user by assessing the stage of the disease, monitoring disease progression, and promoting physical therapy and rehabilitation exercise.
Capecci et al [31]	Algorithms of AI (patent pending), a neural network was used to recognize the performed exercise and segment the data into single repetitions	The ARC Intellicare system (an AI-powered and inertial motion unit-based mobile platform) consisting of a set of 5 inertial sensor inserted in slap supports, a tablet with a dedicated app, and a charging station	The AI-based system allowed rehabilitation professionals to prescribe exercises according to specific therapeutic needs and to monitor end users' performances and progresses remotely. The counting of the number of exercise repetitions correctly performed was the output of the developed AI algorithm. Real-time feedback was provided to the end user through the app user interface.

XSL•FO
RenderX

Reference	AI subset	System and technology type	Purpose or role of the AI-based device or system
Ramkumar et al [32]	ML algorithms	Activity monitoring using wearables (knee sleeve, personal iPhones [Apple], and mobile app termed TKR [Focus Ventures])	The system transmitted the wearable knee sleeve motion data to the smartphone, then transmitted these and all other data to the dashboard, then analyzed these data by the ML algorithms to actively record and check daily compliance in order to provide automated reminder notifications based on the end user's compliance to the program.

The Ways AI Impacts End-User Rehabilitation Compliance or Adherence

In the included studies, the role of AI in rehabilitation and how it impacts end-user compliance or adherence to rehabilitation fell into 6 categories. End-user rehabilitation compliance or adherence improvement through motivation, engagement, and encouragement of end users was the first more cited procedure that was provided by AI-based rehabilitation systems or tools in the studies [28-30,32]. This was done, for example, by exercise tracking, using interactive features, and sending motivational content to end users to keep them engaged and to motivate them to adopt more desirable behaviors.

The second most cited approach was the enhancement of end-user rehabilitation compliance or adherence by facilitating information exchange and improving health care provider-end-user interaction and communication [28-31]. Third, offering a personalized end user–tailored solution was the other strategy supported by AI-based rehabilitation systems that could influence end-user compliance or adherence to rehabilitation [28,30,31], for example, by way of identifying end users' cognition, coping styles, and attitudes. The fourth category was ease of use and simple system usability influencing end-user acceptability [31,32]. Providing daily notifications, alerts, and reminders for end users, as end users, was another procedure that AI-based rehabilitation systems used to improve end-user compliance or adherence to rehabilitation [28,32].

While 5 studies addressed the role of AI in end-user rehabilitation compliance or adherence improvement, 1 study evaluated the capacity of AI-based rehabilitation systems in objective measurement of end-user compliance or adherence [33]. Since adherence is typically assessed using subjective methods like relying on end users' self-reports for home exercises, which may lack validity due to recall bias, social desirability, and misinterpretation, AI-based solutions could more easily and objectively monitor and assess the at-home adherence of exercise protocols by measuring the frequency and duration an end user is engaged with each of their prescribed exercises.

Implications and Drawbacks

Table 4 presents summarized information on the implications for end-user rehabilitation compliance or adherence, along with the drawbacks and limitations reported within the included studies themselves.

XSL•FO
RenderX

Table . Summary of the included studies' implications and reported drawbacks.

Reference	Implications concerning end-user rehabilitation compliance or adherence	Study drawbacks and limitations
Aharon et al [28]	A dropout rate could decrease, and home exercise performance average time could increase due to using an AI[a]-based rehabilitation device, which could be considered as measures for improved end-user compliance or adherence to rehabilitation	Small number of participants, discrepancy in the number of case and control participants, and the probability of selection bias
Chae et al [29]	To increase adherence, any intervention should be tailored to the end user's preferences and behavioral profile, and this end user–tailored intervention approach could improve adherence with no change to the therapeutic regime	The potential bias related to the unblinded nature of this study with health care providers, the possible influence of the method of recruiting participants on the results
Thiengwittayaporn et al [30]	AI-based algorithms could be used to objectively monitor and assess the end-user rehabilitation compliance or adherence by measuring the frequency and duration an end user is engaged with exercises	The limited number of participants, no participants had symptomatic shoulder disorders, significantly younger age of the participants, and how well the proposed AI-based system would generalize to adherence monitoring in a clinical population is uncertain
Capecci et al [31]	An end user's ability to accurately perform the exercises at the final follow-up reflects adherence to home exercise, which could be improved due to the role of AI-based rehabilitation regimen	The end users included in this study were able to efficiently use smartphones, which may not be reflective of a larger older adult population; according to the structure of the study, it was impossible to blind the participants to their intervention, which could potentially skew self-reported outcomes, and the majority of the end users were female participants
Ramkumar et al [32]	AI-based devices allow for real-time monitoring of several aspects of adherence: both daily adherence and repetition, based on exercise recognition	The small sample size and the absence of a control group
Burns et al [33]	The AI-based remote end-user monitoring system could offer the newfound ability to more completely evaluate the end-user rehabilitation compliance	The data represented a small cohort with no broadly generalizable conclusions, a small sample size, and the potential risk for selection and recall bias by end users

[a]AI: artificial intelligence.

Discussion

Principal Findings and Interpretation

Achieving end-user autonomy represents an important objective of rehabilitation in response to the growing population, aging demographics, and higher prevalence of chronic illnesses. The integration of AI in rehabilitation technology represents an innovative and transformative approach, offering the potential to enhance and tailor traditional rehabilitation methods also for improved overall effectiveness [10]. However, adhering to extended treatment regimens, such as what rehabilitation may often require, presents a significant health care challenge in the management of chronic conditions and is essential for the effectiveness of rehabilitation and end-user recuperation. This review showcases how technology-driven interventions affect end-user (patient) rehabilitation adherence and focuses on the use of AI in enhancing end-user rehabilitation compliance or adherence by providing a general summary of the topic. This study categorizes literature according to the combination of procedures that AI impacts end-user rehabilitation compliance or adherence to support the future challenge of implementing sustainable DR practices to address upcoming issues.

According to the findings, 6 distinct areas were found to be important in assessing the impact of AI on end-user rehabilitation compliance or adherence across the independent studies [28-33]. One method that was frequently mentioned in the studies for enhancing end-user compliance or adherence to rehabilitation involved using AI-based rehabilitation systems and tools to motivate, engage, and encourage end users [28-30,32]. Motivation is a significant personal factor that strongly affects adherence to rehabilitation [32], which can be supported by AI-based technologies. Due to the significance of establishing habits and nurturing internal motivation, AI-based rehabilitation systems could potentially promote consistency and strengthen end users' desired behaviors by exercise tracking, using interactive features, music, video instruction, alerts, and awards, and sending motivational content to end users to keep them engaged and motivated [30]. Based on the findings, various aspects of AI-driven rehabilitation could enhance end-user engagement, such as real-time feedback and self-assessment features, and showcase daily progress [32].

Promoting information sharing and enhancing communication and interaction between health care providers and end users were other specific areas that AI-based rehabilitation systems could play a role in improving end-user rehabilitation

XSL•FO
RenderX

compliance or adherence [28-31]. Numerous authors believe that developing a strong therapeutic bond with end users and effective health care provider-end-user communication greatly influences end-user adherence [34,35]. Communication-driven features of the AI-based rehabilitation tools and services could potentially strengthen the health care provider-end-user interaction and enhance communication. This was achieved by identifying the most effective communication approach for end users, tailoring personalized communication, and inspiring them to take action [28]. End users could benefit from such interventions by conveniently retrieving relevant medical information offered by these tools [30]. By facilitating the information exchange between the end user and the health care provider, the AI-powered rehabilitation tools and services can potentially support remote interventions. This represents a significant advancement in delivering services to vulnerable end users who must refrain from visiting health care centers during events like the COVID-19 pandemic [28].

Offering personalized solutions tailored to individual end users was a strategy supported by AI-driven rehabilitation systems that could impact end-user compliance or adherence to rehabilitation [28,30,31]. End users' characteristics, values, and the variability among their requirements, lifestyle, habits, beliefs, and persistence should be taken into consideration in the development and implementation of interventions aimed at improving health [36,37]. Accordingly, in order to improve end-user adherence to rehabilitation protocols, interventions should be customized to align with the end user's preferences and behavioral characteristics. Tailoring an AI-based rehabilitation intervention for each end user was determined by a comprehensive assessment of their medical records and profile, including aspects such as personality, coping mechanisms, willingness to change, and other factors, in addition to their behavior. This was achieved through, for example, targeted screening to identify end users' cognitive frameworks, their attitudes and perspectives on the circumstances, the factors that inspire them, and the obstacles they face toward progress [28]. In the study of Capecci et al [31], AI algorithms allowed rehabilitation professionals to prescribe exercises according to end users' specific therapeutic needs and to monitor their performances and progresses remotely, which led to real-time monitoring of several aspects of adherence and improved end-user compliance or adherence to rehabilitation. Similarly, Thiengwittayaporn et al [30] used AI techniques as a personalized solution for assessing the stage of the disease for each end user, monitoring disease progression, and promoting physical therapy and rehabilitation exercise. Therefore, rather than aiming for a one-size-fits-all optimal intervention, AI-based rehabilitation services help health providers identify the most suitable intervention for each individual end user at a specific moment. What may be highly effective for one end user can be ineffective, or even detrimental, for another. Additionally, the same intervention that initially shows promise in the rehabilitation process may prove inadequate, as the end user's performance progresses.

Another category, which could be instrumental for the improvement of end-user rehabilitation compliance or adherence, was the usability and ease of use of the AI-based rehabilitation intervention [31,32]. Low usability, in terms of ease of use and suitability, and inadequate user-friendliness are primary factors leading to the neglect of technological systems, impacting individuals' willingness to accept digital solutions and adherence to the treatment [38,39]. With their availability from the convenience of homes and being readily usable, AI-based rehabilitation tools and services could potentially contribute to end-user engagement and satisfaction and consequently rehabilitation compliance or adherence [32]. Moreover, AI technologies are commonly being integrated into smartphone apps, offering a variety of health care services including rehabilitation. The availability and ubiquity of smartphones, easy-to-use experience of the mobile apps, and platforms that do not necessitate any extra hardware beyond an end user's own smart device have unleashed the possibilities of AI-driven rehabilitation tools and services to enhance end-user compliance or adherence to rehabilitation [32].

Additionally, the findings of this review suggest that the capability of AI-based tools and services in providing automated daily notifications, alerts, and reminders for end users had an impact on the improvement of end-user rehabilitation compliance or adherence [28,32]. Numerous studies have demonstrated the effectiveness of reminders, notifications, and alerts in improving health outcomes [40,41]. The AI-driven rehabilitation tools and services have the ability to remotely monitor end users' progress and compliance with rehabilitation protocols, offering automated daily notifications, alerts, and reminders for end users to enhance end-user adherence to the program. For example, in the study of Ramkumar et al [32], the AI-based system actively recorded end users' weekly data for the daily compliance check and provided automated reminder notifications whenever required, and the end users mentioned these notifications as reasons for their engagement with the system.

Another key finding of this review is the ability of AI-driven rehabilitation systems to accurately measure end-user rehabilitation adherence in an objective manner [33]. At present, there is a scarcity of tools and a lack of agreement on a standardized approach for accurately and objectively measuring end-user rehabilitation compliance or adherence, specifically in a home environment [33,42,43]. End-user rehabilitation compliance or adherence evaluated through subjective approaches, such as end users' self-reports for home exercises, may lack validity. A less unexplored alternative is to assess the effectiveness and functionalities of AI-driven rehabilitation tools and services, offering the potential to use these technologies for objective end-user rehabilitation adherence measurement. AI-powered devices have the potential to enable the real-time tracking of various aspects of end-user rehabilitation compliance or adherence, including daily compliance and repetition, through exercise recognition [31]. In the study of Ramkumar et al [32], the AI-powered remote end-user monitoring system could provide a novel capability to assess end-user adherence to rehabilitation using machine learning algorithms. However, studies have taken various approaches to the evaluation of end-user rehabilitation adherence. For example, in the study of Chae et al [29], home exercise performance average time and a decrease in dropout

XSL•FO
RenderX

rate were considered as measures for improved end-user adherence to rehabilitation. Burns et al [33] suggest that AI-based solutions could more easily and objectively monitor and assess the at-home adherence of exercise protocols by measuring the frequency and duration an end user is engaged with each of their prescribed exercises. Thiengwittayaporn et al [30] believe that an end user's accurate performance in executing the exercises indicates adherence to home exercise; nevertheless, this may not consistently hold true.

The application of AI in end-user rehabilitation adherence is a relatively new and evolving field of study, and this topic is still in its infancy. Nevertheless, it is evident that certain features offered by AI-based rehabilitation can contribute to enhancing end-user compliance and adherence to rehabilitation protocols. Our aim was to offer a summary of the current role of AI in assessing and enhancing end-user adherence to rehabilitation programs by examining the ways by which AI can impact end-user adherence in rehabilitation. In general, the present findings indicate that AI could contribute to the improvement of end-user rehabilitation adherence by its capacity in motivating and engaging end users, facilitating information exchange and improving communication, offering personalized end user–tailored solutions, delivering convenience and ease of system use, providing automated daily notifications, alerts, and reminders for end users, and measuring end-user rehabilitation compliance or adherence with an objective and accurate approach.

Strengths and Limitations

The evidence considered in this review was sourced from publications released within a 7-year time frame from the date of this RR, thereby enhancing the importance of the findings. Notwithstanding the methodological issues, all of the studies included in the analysis were published in peer-reviewed journals. However, it is important to address a few limitations of this review. First, we refrained from conducting a systematic literature review due to the limited number of studies available on the role of AI in measuring or enhancing end-user rehabilitation compliance or adherence. Moreover, due to the wide variety of study designs, it was deemed more suitable to perform an RR with synthesized results in a narrative format to present a comprehensive summary of the literature. Finally, the potential bias related to the unblinded nature of most of the included studies and the relatively limited number of participants complicates the definitive conclusions regarding the impact of AI-based DR on the end-user rehabilitation compliance or adherence.

Future Directions

A deeper comprehension of the effectiveness of AI-based approaches in DR is required to support the improvement and objective measurement of end-user rehabilitation compliance or adherence. Future work should concentrate on implementing AI-based DR in the real world and relevant operational settings and evaluate the clinical significance of the intervention through RCTs comparing the impacts on particular demographic groups of these innovative solutions as opposed to conventional rehabilitation methods. Additionally, further research is needed to validate the use of specific AI models and use the AI's complete capacity in the improvement of end-user rehabilitation compliance or adherence to achieve constructive change in population health, policy, and genuine medical revolution.

Conclusions

This RR offers an insight into the role of AI in the DR and the approaches that AI uses to improve and measure the end-user rehabilitation compliance or adherence. Overall, the current findings suggest that AI-based rehabilitation can contribute to improved end-user compliance and adherence to rehabilitation programs by its capacity in motivating and engaging end users, facilitating information exchange and improving communication, offering personalized end user–tailored solutions, delivering convenience and ease of system use, providing automated daily notifications, alerts, and reminders for end users, and the objective measurement of end-user rehabilitation compliance or adherence. Our findings may be of particular interest and valuable in redesigning rehabilitation and strategizing the optimal integration of AI into the rehabilitation sector to address future challenges.

Acknowledgments

This study is part of the project Co-innovation for Digital Rehabilitation in the Global Marketplace, funded by Business Finland (grant 6169/31/2021).

Authors' Contributions

All authors contributed to the conception or design of the work. Data collection and extraction were performed by MM and MLW. Data interpretation was performed by MM with MLW. The first draft of the manuscript was written by MM under the supervision of KPM, EA, MO, KK, and MLW. MM, MLW, KPM, EA, MO, and KK contributed detailed academic input to subsequent versions. All authors commented on previous versions of the manuscript. All authors read and approved the final manuscript.

Abstract

Background: Occupational therapy has highlighted the necessity for planning and executing interventions in collaboration with clients, families, and caregivers to facilitate their progress. Thus, in pediatric occupational therapy, it is essential to position the family as a primary client and to actively involve them in the intervention process. These interventions often incorporate tools that facilitate parental engagement in home-based activities. However, no tools have been specifically designed to support parents comprehensively in achieving their parenting goals in everyday situations. To address this gap, we developed a mobile app called the Children's Occupation Support Mobile System (COSMO) to support occupational therapists, children, and parents in a collaborative manner to achieve intervention goals in daily life.

Objective: The aim of the study is to develop the COSMO and validate its content in terms of legibility, visibility, and accessibility.

Methods: This study was conducted in two stages: (1) designing a prototype of COSMO and (2) validating its content using the Delphi method. The prototype was developed based on a conceptual model of parenting strategies, which was derived from interviews with mothers raising children with developmental disabilities. This study included 10 Japanese pediatric occupational therapists, who were selected using convenience sampling to ensure diversity and heterogeneity in attributes. The Delphi survey was conducted entirely through a web-based questionnaire emailed to the experts. Participants rated their agreement with each item on a 5-point Likert scale. A mean item score of ≥3.75 (75%) indicated consensus.

Results: The prototype was designed through a series of 13 one-hour meetings held monthly. The functional framework of COSMO was structured into four core components based on previous research: (1) collaborative goal setting, (2) home strategy—an action plan to achieve goals, (3) self-reflection—a record of implemented strategies, and (4) progress reports—data storage for tracking outcomes. For validating the content, the 2 Delphi rounds resulted in a total mean score of 4.44 for legibility, 4.86 for visibility, and 4.84 for accessibility. In the free-text responses, there were references to improvements in the wording and to the burden of writing the reflections. Therefore, the wording was revised to avoid jargon and use plain language. The burden of COSMO use was reduced by simplifying the use process by incorporating optional inputs for some of its functions.

Conclusions: COSMO was developed as a comprehensive tool to integrate functions while aiming to reduce the burden on parents. This may reduce resistance to app use and make it easier for more parents to use it. Future studies should evaluate the generalizability and effectiveness of the prototype as an intervention. Limitations of this study include the absence of end-user testing, a geographically limited expert panel, and a limited discussion of implementation challenges across diverse health care settings.

RenderX

Introduction

The World Health Organization emphasizes the importance of designing interventions for children with neurodevelopmental disorders, including autism, through the active participation of all stakeholders [1]. Furthermore, these interventions should be implemented at the community and social levels to enhance accessibility, inclusivity, and support [1]. Similarly, the American Occupational Therapy Association (AOTA) highlighted the necessity for planning and executing occupational therapy interventions in collaboration with clients, families, and caregivers to facilitate their progress [2]. Thus, in pediatric occupational therapy, it is essential to position the family as a primary client and actively involve them in the intervention process.

A systematic review of pediatric occupational therapy interventions recommends an activity-focused top-down approach that prioritizes collaboration with caregivers [3]. Specifically, interventions should begin with child-centered goals, incorporate real-life activities in natural settings, and use intensive repetition and problem-solving at an appropriate difficulty level [3]. Furthermore, interventions should be seamlessly integrated into daily life environments, such as homes and schools, while ensuring active family and caregiver participation [4].

Therefore, pediatric occupational therapy should emphasize family engagement and practical activity-based support in natural living environments. Several occupational therapy interventions have adopted family-centered approaches in real-life settings. Examples include Occupational Performance Coaching [5], Home Programs [6], Cog-Fun [7], Pathways and Resources for Engagement and Participation [8], and Parental Occupational Executive Training [9]. These interventions often incorporate tools that facilitate parental engagement in home-based activities. For instance, intervention booklets outline objectives and policies [10], structured documents help record strategies [8], and diaries support tracking daily progress [9]. These tools assist in setting collaborative intervention goals, reinforcing strategies, and documenting progress. However, no tools have been specifically designed to fulfill these functions comprehensively and to support parents in achieving their parenting goals in everyday situations. Everyday situations refer to parenting behaviors that occur outside the occupational therapy room, where the occupational therapist cannot be involved. Examples include self-care activities such as eating and dressing, productive activities such as learning and playing at home, and leisure activities such as sports and socializing with friends. Various activities that individuals perceive as important in their lives are referred to as “meaningful occupations” [11]. Understanding the history, interpersonal relationships, context, and development of meaning in a client’s occupations is essential to effectively support these meaningful occupations [12]. Our scoping review of home-centered occupational therapy for children with neurodevelopmental disorders found no validated tools designed to support parental caregiving as assessed by experts for reliability and validity (K Kura, MSc, unpublished data, August 2025).

To address this gap, we developed a mobile app called the Children’s Occupation Support Mobile System (COSMO) to collaboratively support occupational therapists, children, and parents in achieving intervention goals in daily life. Recently, 71.9% occupational therapists have reported using apps as part of their clinical support, and interest is growing in expanding the use of apps specifically designed for occupational therapy [13,14]. Apps used in occupational therapy typically address areas such as education, activities of daily living, instrumental activities of daily living, and play, with the target users ranging from children to older adults [13]. Accordingly, developing and implementing COSMO as a mobile app was deemed appropriate to meet these needs. This study aimed to develop and validate the COSMO content. In addition, we outlined the basic steps of the app.

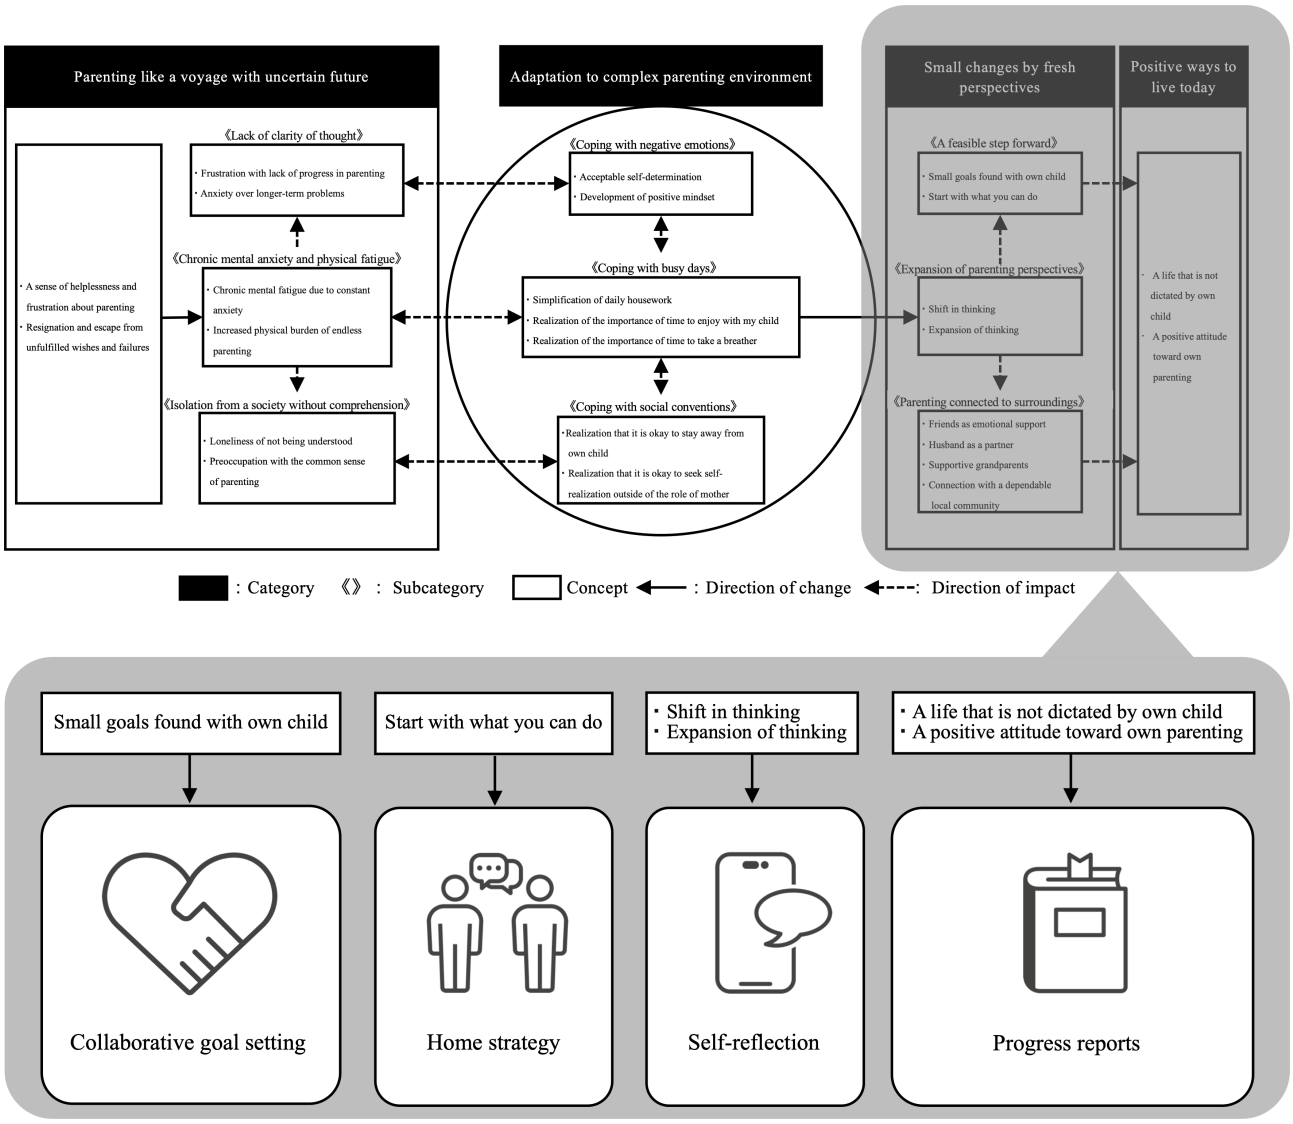
Methods

Study Design

This study was conducted in two stages: (1) designing a prototype of COSMO and (2) validating its content using the Delphi method. The Delphi method is a qualitative research approach commonly used to achieve expert consensus in areas such as medical guidelines and app development. It was selected for this study because it aligns with the research objectives of establishing expert agreement on the functional framework of the app and verifying its content validity. The first author (KK) was responsible for managing the Delphi process, including the study flow and questionnaire design, whereas the last author (KT) provided overall supervision and guidance. This study followed the 6-step Delphi framework recommended for health care research [15] and adhered to the ACCORD (Accurate Consensus Reporting Document) guidelines for reporting consensus-based studies [16].

Ethical Considerations

This study complies with COPE (Committee on Publication Ethics) guidelines and adheres to the guidelines in the Helsinki Declaration. Ethics approval was obtained from the Kitasato University Ethics Review Committee (approval 2024-020). Our protocol was registered with the University Medical Information Network Center (000057084).



Development of Prototype Apps

The COSMO prototype was developed based on the “conceptual model of effective parenting strategies for mothers with children who experience developmental disorders” formulated from parental perspectives and previous research [17]. The conceptual model was developed on the basis of interviews with 10 mothers who had implemented an individualized occupational therapy home program. The model illustrates the process of developing parenting strategies adapted to the home environment. The relationship between the conceptual model and the prototype app is shown in Figure 1. For example, “collaborative goal setting” corresponds to the theme “small goals found with own child,” “home strategy” corresponds to “start with what you can do,” “self-reflection” relates to “shift in thinking” and “expansion of thinking,” and “progress reports” connects to themes such as “a life that is not dictated by own child” and “a

XSL•FO
RenderX

positive attitude toward own parenting." End users were not involved in the process of deriving the prototype's functionality from the conceptual model. The first and last authors (KK and KT) collaboratively designed the prototype through a series of 1-hour meetings held monthly, for a total of 13 meetings. Initially, COSMO's vision was conceptually defined as "an app that supports children and families in achieving their goals within the context of parenting." The concept of COSMO was further operationally defined as "an app that grows with the child." It was designed to be downloaded to the parents' smartphones and used as a tool for occupational therapy. To enhance accessibility, terminology was chosen to resonate with parents caring for their children with neurodevelopmental disorders.

Figure 1. (A) Conceptual model [13] and (B) app function.

The functional framework of COSMO is structured into four core components based on previous research: (1) collaborative goal setting, (2) home strategy, (3) self-reflection, and (4) progress reports.

Nine functions were developed to align with the objectives of the 4 components. The functional framework and corresponding functions were developed based on theoretical concepts and input from parents. Finally, the user interface and user experience of COSMO were designed to support these 4 functional components and 9 specific functions. The details of this framework are presented in Table 1.

XSL•FO
RenderX

Table . App function, items, and contents.

Function and item		Contents
1. Collaborative goal setting		
	Listing of goal setting	The goal-setting list function displays multiple goals on the screen, allowing users to quickly review all goals upon launching the app.
	Set time frames for achieving goals	The goal time limit function lists the deadlines for achieving each goal. By displaying the remaining time for each goal, this function clarifies the necessary steps from the current state to the goal deadline.
	Framework for goal setting by who, what, when, where, why, and how	The who, what, when, where, why, and how framework function for goal setting assists in defining specific, life-related goals using the who, what, when, where, why, and how approach. It is designed to support occupational therapists with limited clinical experience and caregivers in concretizing goals.
2. Home strategy		
	Setting multiple strategies for goals	The multiple strategy-setting function allows users to assign multiple strategies to a single goal. Strategies can be set flexibly to ensure that they are realistic and feasible.
	Notification of strategy implementation time	The strategy implementation time notification function sends smartphone notifications based on the scheduled execution time of each strategy at home. Given that the implementation timing varies by strategy, this feature ensures that each strategy is executed at the appropriate time.
	Framework for strategic planning by who, what, when, where, why, and how	The who, what, when, where, why, and how framework function for strategic planning helps formulate strategies in a structured and specific manner using the who, what, when, where, why, and how approach. It aims to facilitate the development of realistic and practical strategies.
3. Self-reflection		
	Diary recordings of reflections	Diary recordings of reflections function enables users to record the outcomes of home-implemented strategies. In addition to documenting the child's daily care, this function supports tracking the child's progress and provides parents with new insights.
	Caregivers' assessment of strategies	The caregiver assessment function for strategies allows parents to evaluate the efficiency and burden of implemented strategies. This function provides a quantitative assessment of parental perspectives. The assessment timing is flexible and can be adjusted based on the occupational therapy intervention's purpose and frequency (eg, weekly, biweekly, or monthly).
4. Progress reports		
	Goals, strategies, and record keeping	The goal, strategy, and record-saving function stores past records of goals, strategies, and outcomes. This function facilitates the reuse of effective strategies for other goals, enables tracking of home implementation, and allows for modifications to goals and strategies as needed.

Process of Using COSMO

Overview

The process flow of COSMO, based on 4 components and 9 specific functions determined through the development of the prototype app, is shown in Figure 2. The app was structured into four cyclical phases: (1) collaborative goal setting, (2) design of home strategy, (3) implementing home strategy and self-reflection, and (4) discussing to achieve goals.

Figure 2. Process of using COSMO. C: child; COSMO: Children's Occupation Support Mobile System; O: occupational therapist; P: parent.

Collaborative Goal Setting

Occupational therapists, children, and parents collaboratively established goals through shared decision-making. If the child could not actively participate, the therapist and parents set goals on their behalf. Goals were defined using the who, what, when, where, why, and how framework and adhered to the Specific, Measurable, Achievable, Relevant, and Timed (SMART) criteria whenever possible [18]. COSMO does not include built-in structured interview functions; therefore, complementary tools such as the Canadian Occupational Performance Measure [19], Goal Attainment Scaling [20], and Aid for Decision-Making in Occupation Choice (ADOC)—School Version [21] can be used alongside COSMO.

Home Strategy

The next step involved designing a strategy to achieve the established goals. Strategies can be linked to specific goals, and multiple strategies can be set. Intervention strategies were developed collaboratively among therapists, children, and parents. If child participation is difficult, the therapists and parents created strategies together. Each strategy was formulated using the who, what, when, where, why, and how framework to ensure that the plan is actionable and practical. Parents received smartphone notifications for each scheduled strategy.

Implementing Home Strategy and Self-Reflection

In the context of daily parenting, parents implemented strategies designed to help their children achieve their goals. For strategy implementation, it is important that the strategy is embedded in everyday situations and is easy to use. For example, regarding strategies related to changing clothes, this could mean changing the size of buttons so that it is easy to operate or supporting a stable posture for changing clothes. In other words, strategies that avoid placing an undue burden on parents and can be implemented as an extension of normal child-rearing practices promote daily use. Such a perspective is important in positioning parents as parental caregivers rather than cotherapists. Following implementation, a self-reflection process consisting of free-text reflection and a 5-point Likert-scale evaluation was conducted. The Likert scale assessed the child's efficiency in executing the strategy and the level of burden experienced by the parents. Free-text reflection allowed parents to describe what has been done, identify the difficulties encountered, note observations, and determine the next steps based on the innovations they noticed. The efficiency rating measured how smoothly the child was able to carry out the strategy from the parents' perspective,

XSL•FO
RenderX

whereas the burden rating reflected the level of difficulty parents experienced in supporting the implementation.

The recorded goals, strategies, and reflections, including free text and Likert-scale outcomes, were stored as data that could be accessed at any time through the app. It is important to note that only this phase, in which the home strategy and self-reflection were implemented, was conducted independently by parents.

Discussing to Achieve Goals

During occupational therapy sessions, therapists reviewed progress based on the parents' recorded reflections and data. The review process emphasized that unsuccessful strategy implementation is a natural part of progress, and therapists provided coaching and guidance accordingly. If necessary, goals and strategies could be modified by returning to phases 1 and 2. If no modifications were required, the family continued to implement the strategies until the goal was achieved. Given that pediatric occupational therapy in Japan is typically provided on an outpatient basis (every 2 weeks to once a month), COSMO is designed to complement these sessions by supporting parents between visits.

Delphi Method for Content Validation

After developing the app prototype, content validation was conducted to assess the legibility, visibility, and accessibility of COSMO's 4 functional frameworks and 9 functions. The COSMO is designed for use by parents with the support of pediatric occupational therapists with diverse clinical experience. Therefore, the study participants were selected using convenience sampling to ensure diversity and heterogeneity in attributes, such as age, clinical experience, educational background, and employment status.

The sample size for the Delphi method typically ranges from 5 to 20 participants [22], with no rigid rules, depending on the study's purpose and complexity [23]. In this study, 10 Japanese pediatric occupational therapists were included based on prior research that used a similar sample size for app development in occupational therapy [24] and based on the complexity of the 4 functional frameworks and the 27-item web survey addressing 9 functions.

Participants who provided informed consent were given a 15-minute web-based briefing via a videoconferencing platform. This session covered the study background, objectives, procedures, and functions of COSMO, followed by a question and answer session to address any questions. The participants were also assured that they could withdraw from the study after receiving this explanation.

The Delphi process was conducted entirely through a web-based questionnaire (Google Forms) emailed to the experts. As the responses were collected on the web, the participants submitted their answers individually.

The questionnaire assessed the user interface or user experience design of the 9 functions within COSMO's 4 functional frameworks, comprising a total of 27 questions. These questions evaluated 3 key aspects: legibility (clarity of text expression and display), visibility (ease of viewing text and screen layout), and accessibility (ease of functional use). Participants rated their agreement with each item on a 5-point Likert scale (1=strongly disagree and 5=strongly agree). A mean score of 3.75 (75%) or higher indicated consensus on an item [15].

To allow for qualitative feedback, the questionnaire also included open-ended questions in which participants could freely express their opinions. A summary of the results was emailed to the participants, and a detailed statistical report, including summaries of questionnaire items and responses to open-ended questions, was provided in a PDF document.

Each Delphi round had a specified response deadline. If the participant did not submit a response on time, a reminder email was sent to encourage completion.

Results

Overview

The demographic attributes of the 10 study participants are summarized in Table 2. The sample included 6 male and 4 female participants. In total, 4 participants were in their 20s, 4 were in their 30s, and 2 were in their 40s. In terms of educational background, 4 participants held bachelor's degrees, 3 held master's degrees, and 3 held doctoral degrees. The occupational therapists had an average of 7.9 (SD 3.2; range 2-12) years of clinical experience.

XSL•FO
RenderX

Table . Participant demographics.

Participants	Sex	Age (years)	Employment	Degree	Time in profession (years)
A	Male	43	Regular	PhD	12
B	Female	28	Nonregular	Master	7

J	Female	29	Regular	PhD	3

Delphi Method Results

In the first round of the Delphi method, the mean score for all 27 items exceeded the consensus threshold of 3.75, with an overall average of 4.50. Research participants suggested modifying the language to make it easier for the intended users to understand and making input items optional to reduce the burden of use. These comments were reviewed and addressed by the research team, considering the degree of variation in participant feedback and outcomes of team discussions. Based on feedback from the open-ended responses, modifications were made to the app design, and a second round was conducted using the revised questionnaire. In this round, the average score increased to 4.84. Across all 27 items (comprising 9 items each for legibility, visibility, and accessibility), the mean scores for each evaluation category increased by 0.20 to 0.45 points between rounds. Furthermore, the IQR was reduced from 0.00 - 2.00 in the first round to 0.00 - 1.00 in the second round, indicating a decreased level of response variability. Because only minor revisions were suggested in the free-text comments, these were incorporated, and the Delphi process was concluded. The results of each round are presented in Table 3. Detailed comments from study participants and corresponding responses from the research team are presented in Multimedia Appendix 1. The findings are described below according to 3 evaluation criteria: legibility, visibility, and accessibility.

XSL•FO
RenderX

Overall score	4.44 (0.82)	5.00 (4-5)	4.66 (0.56)	5.00 (4-5)	4.39 (0.78)	5.00 (4-5)	4.82 (0.44)	5.00 (5-5)	4.86 (0.35)	5.00 (5-5)	4.84 (0.36)	5.00 (5-5)

Legibility

The results of the first round showed that the average score for all 9 items was 4.44. Regarding legibility, the participants suggested modifying the wording and standardizing expressions. Specifically, on the goal-setting screen, the phrase “the occupational activity you want to be able to do” was changed to “what (the activity you want to be able to do).” This adjustment avoided the use of the technical term “occupational activity” and adopted language that was easier for parents to understand. Additionally, “what” was added at the beginning of the sentence to align with the who, what, when, where, why, and how framework. There was a suggestion to change “deadline” in the goal list screen to “duration.” However, this modification was not implemented because “deadline” aligns with the time-related component of the SMART criteria in goal setting. On the strategy-setting screen, “what” was added to “in what way” to ensure consistency. In the self-reflection efficiency and burden evaluation screen, the subject of evaluation was clarified by modifying the phrasing to “How smooth was this strategy for the child?” and “How easy was this strategy for the parent or guardian?” These changes were made to enhance clarity.

The results of the second round showed that the average score for all 9 items increased to 4.82. Additionally, the terminology used to describe guardians was revised, as the participants noted that the original wording was unfamiliar to the general public in Japanese.

Visibility

The results of the first round showed that the average score for all 9 items was 4.66. Regarding visibility, the participants suggested improving the consistency of screen displays. Specifically, there was a recommendation to unify goal- and strategy-setting screens, given that the goal-setting screen provides a free-description framework for each who, what, when, where, why, and how component, whereas the strategy-setting screen lacks this feature. After discussion, the research team decided not to implement this change because the 2 screens serve different purposes. The goal-setting screen includes a who, what, when, where, why, and how framework to facilitate goal setting based on the SMART criteria, whereas the strategy-setting screen allows flexible descriptions, as the content of strategies may vary among households. This reasoning was explained to the participants during feedback. There was also a request to include example sentences on the strategy-setting screen. However, because of screen space limitations and the number of characters displayed, this suggestion was not implemented. Instead, example sentences were included in the user guide under development.

The results of the second round showed that the average score for all 9 items increased to 4.86. In addition, the participants suggested increasing the font size for better readability. Based on this feedback, the text size was adjusted to improve the readability for children and parents.

Accessibility

The results of the first round showed that the average score for all 9 items was 4.39. Regarding accessibility, participants raised concerns about the difficulty of setting goals using the who, what, when, where, why, and how framework, the burden of free-text input in self-reflection, the sequence of outcome assessments, and the need for additional data storage options. One concern was the difficulty in completing all the who, what, when, where, why, and how components on the goal-setting screen. Based on participant feedback, each who, what, when, where, why, and how framework was made optional, allowing goal setting to be completed even if some components were left blank. To reduce participant burden, free-text input and outcome evaluations were made optional, ensuring that the data could still be stored even if only one of these components was completed. The participants also suggested reordering the self-reflection process by placing free-text reflections after the outcome evaluation of efficiency and burden. However, the research team decided not to implement this change because verbalizing and reflecting on the strategies in the free-response section first was considered beneficial for conducting a structured 5-stage evaluation. Regarding data storage, there was a recommendation to store efficiency and burden evaluations along with other data. This suggestion was accepted, and these evaluations were added to the list of stored items.

The results of the second round showed that the average score for all 9 items increased to 4.84. No further modifications were made, as there were no significant concerns raised by the participants.

Discussion

Principal Findings

In this study, the content validity of COSMO was evaluated using the Delphi method. Consequently, COSMO was designed based on expert consensus regarding legibility, visibility, and accessibility in app design. Additionally, the process of using

XSL•FO
RenderX

the developed COSMO was presented. Based on these findings, this section discusses the design of COSMO, its clinical applications, and usability.

Design of COSMO

COSMO primarily aims to support children and their families in accomplishing important tasks. More specifically, it is designed to assist parents in their daily parenting activities through practical interventions. To fulfill this purpose, COSMO was developed as a smartphone app that parents could use as part of their professional support. The coaching approach in rehabilitation emphasizes real-life activities, goal setting related to participation in daily situations, and improvements in quality of life [25]. Additionally, identifying small achievable goals with one's child and starting with what is feasible are essential steps toward reaching broader objectives [17]. COSMO facilitates goal setting through a who, what, when, where, why, and how framework, reflecting the perspectives of parents and children while ensuring that goals align with the SMART criteria [18]. The strategy-setting function allows users to develop action plans tailored to their individual goals by specifying the number of steps and content necessary to achieve them. Therefore, COSMO includes the core functionalities required for collaborative goal setting and strategy development in daily life.

Strategy implementation in real-life settings and self-reflection play crucial roles in goal attainment. A randomized controlled trial of family-centered parent-coaching interventions demonstrated that reflecting on a child's thoughts, motivations, and feelings enhanced parental self-evaluation and awareness [26]. In COSMO, self-reflection is facilitated through free-text input and a 5-point Likert scale. Free-text reflections encourage parents to verbalize their perceptions of strategy implementation, which may increase their awareness of goal progress. The Likert scale assessed 2 aspects: the efficiency of the child's actions within the strategy and the burden experienced by parents. By quantitatively measuring these aspects, COSMO helps to visualize the effectiveness of strategies and enables further refinement for improved usability.

Clinical Applications of COSMO

COSMO is expected to function as a support tool for home-centered occupational therapy. Systematic reviews of pediatric occupational therapy interventions emphasize the importance of supporting parental engagement in home settings, with collaboration between occupational therapists and parents as a key factor [3]. Existing tools used in occupational therapy include booklets outlining intervention objectives and policies [10], documents for recording strategies [8], and structured diaries for tracking daily intervention progress [9]. COSMO integrates multiple functions including goal setting, strategy development, reflection, and data storage, making it a comprehensive tool that can be flexibly applied in various intervention settings. However, careful consideration is necessary when determining whether the COSMO is appropriate for a given intervention context. A qualitative study conducted by the first author with mothers who practiced home programs suggested that using home programs and daily diaries may contribute to a positive reassessment of children's behavior and parental burden [17]. The comprehensive functions of COSMO may influence parents' perceptions of their children and themselves, motivating them toward goal achievement.

Finally, the Delphi method assessment of accessibility yielded recommendations for reducing the parental burden. Based on these recommendations, free-text reflections and Likert-scale assessments were made optional to accommodate varying levels of parental engagement. Occupational Performance Coaching, a widely used support approach in occupational therapy, sets exclusion criteria for parents with low physical or mental energy [27]. In line with this principle, COSMO was designed to minimize the parental burden wherever possible. However, some level of effort is still required for its effective use. Therefore, the decision to use COSMO should consider the physical and mental conditions of parents or guardians. Moreover, because the COSMO is only a support tool, its implementation should be assessed within the broader context of the intervention objectives, treatment plans, and social background of the target population.

If adverse effects emerge after implementation and continued use poses risks, the occupational therapist in charge should consider discontinuing its use.

Usability of COSMO

Usability for professionals and clients is essential to ensure that apps are accessible and effective. Previous studies have reported that the main purposes of using apps in occupational therapy are to enhance clients' skills, facilitate participation in daily activities, and support the therapeutic process [14]. Furthermore, apps should be matched to client needs, skills, and abilities and not the other way around [28]. The selective use of apps by occupational therapists based on individual client needs suggests that, as with other therapeutic interventions, such tools should not be uniformly applied to all clients [14,28]. Similarly, the implementation of COSMO requires the careful consideration of the intervention's goals and the unique needs of each client.

Several barriers to app usability among professionals have been identified. Prior studies have cited the most common reasons for not using apps as the inability to find suitable good apps, never thought about it, and lack of access [14]. The first 2 barriers may also apply to COSMO, highlighting the importance of building further evidence and promoting broader awareness. To address accessibility, COSMO will initially be distributed free of charge in Japan. For households without smartphones, a paper-based version offering equivalent functions will be made available via the project website. Because COSMO is intended as a supportive tool for daily life rather than a treatment device, it complies with medical app review requirements. Moreover, because COSMO is not a research app, it does not collect any personal client information via mobile networks. The app is downloaded and stored on the client's personal smartphone, minimizing the risk of data disclosure to third parties. Thus, potential concerns about data protection have been addressed.

Currently, app use in occupational therapy in Japan is generally regarded as a supplement to standard treatment. Therefore, COSMO—being freely accessible—is expected to complement existing occupational therapy and other therapeutic interventions

XSL•FO
RenderX

based on professional clinical reasoning. In Japan, several specialized apps have been developed by occupational therapists, such as Osca Writing, a Japanese handwriting app [29], and Process Analysis of Daily Activities for Dementia, which analyzes daily occupations for individuals with dementia [30]. Additionally, goal-setting apps like ADOC and ADOC—School Version have been introduced [21,31]. Although the first 2 differ from COSMO in purpose and target populations, ADOC shares some similarities with COSMO in terms of goal setting. However, ADOC focuses on shared decision-making in goal selection, whereas COSMO emphasizes goal-sharing and achievement processes. Although this study was limited to comparisons with domestic applications due to differences in social and health care contexts, future studies should include comparisons across diverse health care systems and cultures.

Limitations

This study has some limitations. First, end-user children and parents were not included in the development process of this study; this is a significant limitation. Future usability tests should be conducted with the involved parties. Second, the Delphi method involved participants from a limited number of regions, which may have influenced the development of COSMO because of the homogeneous educational and cultural backgrounds of the participants. Third, convenience sampling—where participants were recruited through the researchers' networks—was conducted to ensure diversity and heterogeneity among participants and to enhance research feasibility; however, this limits the generalizability of the findings and may have influenced the response outcomes. Fourth, the quality of COSMO as a mobile app is currently unknown. The assessment of app quality is important for its future adoption by clients and professionals. Fifth, only the Japanese version of COSMO has been developed. Future studies should examine the cross-cultural validity, including translation accuracy and adaptation, for use in other countries. Sixth, the social implementation of COSMO was initially developed for use in Japan. Consequently, the current discussion does not sufficiently address the challenges of implementation in diverse health care settings.

Conclusions

COSMO was developed to support children and their families in achieving meaningful occupations. After 2 rounds of the Delphi method evaluation, the content validity of COSMO in terms of legibility, visibility, and accessibility was confirmed through an expert consensus. As a home-centered occupational therapy support tool, COSMO is expected to be flexibly integrated into interventions, depending on the objectives of the therapy. To optimize its use, discussions among professionals, parents, and children are essential before recommending its implementation. Ultimately, COSMO has the potential to enhance parental participation in achieving children's goals and contribute to more effective occupational therapy interventions. A dedicated website has been created, including a contact page to provide ongoing technical support. Because the app was developed for iOS, updates will be made as necessary to address technical issues arising from iOS system changes. Future studies should explore cross-cultural validity, including translation accuracy and adaptation, and should assess generalizability and effectiveness as an intervention tool.

Abstract

Background: Persistent difficulties with social skills form part of the diagnostic criteria for autism and in the past have required speech and language therapy (SLT) management. However, many speech and language therapists are moving toward neuro-affirmative practices, meaning that social skills approaches are now becoming redundant. Research demonstrates that virtual reality (VR) interventions have shown promise in overcoming challenges and promoting skill generalization for autistic children; however, the majority of these focus on social skills interventions. While VR is emerging as an SLT intervention, its application for autism remains unexamined in clinical practice.

Objective: This research aimed to examine speech and language therapists' knowledge and attitudes toward immersive VR as a clinical tool for autistic children and explore the reasons for its limited integration into clinical practice.

Methods: A web-based cross-sectional survey was available from April 3, 2023 to June 30, 2023. The survey, consisting of 23 questions, focused on VR knowledge, attitudes, and the support required by speech and language therapists to incorporate VR into clinical practice. Dissemination occurred through the Royal College of Speech and Language Therapists Clinical Excellence Networks to recruit speech therapists specializing in autism.

Results: Analysis included a total of 53 responses from the cross-sectional survey. Approximately 92% (n=49) of speech and language therapists were aware of VR but had not used it, and 1.82% (n=1) had used VR with autistic children. Three key themes that emerged were (1) mixed general knowledge of VR, which was poor in relation to applications for autism; (2) positive and negative attitudes toward VR, with uncertainty about autism specific considerations for VR; and (3) barriers to adoption were noted and speech and language therapists required an improved neuro-affirming evidence base, guidelines, and training to adopt VR into clinical practice.

Conclusions: While some speech and language therapists perceive VR as a promising intervention tool for autistic children, various barriers must be addressed before its full integration into the clinical toolkit. This study establishes a foundation for future co-design, development, and implementation of VR applications as clinical tools for autistic children. This study is the first to explore clinical implementation factors for the use of VR in SLT field, specifically with autistic children. Poor autism-specific VR knowledge, and mixed attitudes toward VR, highlight that specific barriers must be addressed before the technology can successfully integrate into the SLT clinical toolkit. Speech and language therapists require support from employers, funding, a robust neuro-affirming evidence base, and education and training to adopt VR into practice. Recommendations for a SLT VR education and training program for use with autistic children, are provided.

Introduction

Virtual reality (VR) uses technology to digitally replicate real world scenarios [1] by providing artificial tactile, visual, and auditory feedback. This allows users to experience environments as if they were real. A VR system connects the user to the virtual environment through sensory modalities, providing sight, sound, and tactile feedback. This can be achieved through different technologies, such as Computer Automated Virtual Environments (CAVE) and immersive head mounted displays (HMDs). These facilitate different levels of interaction, presence, and immersion, such as the perception of being in the real world. In the context of this paper, VR refers to HMDs and

XSL•FO
RenderX

CAVE, with the idea of integrating HMDs into speech and language therapists' clinical toolkits.

Research has demonstrated that VR capitalizes on visual skills, known to be a strength of autistic children, and can facilitate safe, controlled, and customizable practice environments, without negative consequences [2]. This has led to further research suggesting VR-based interventions may be effective for improving socials skills and generalization, enhancing emotional recognition, reducing anxiety, and facilitating sensory integration [3,4]. Indeed, research has demonstrated a moderate evidence base for VR with the autistic population [5]. This is evidenced by a pre-post study by George and Shakul [6], which demonstrated that a VR reality intervention for young autistic adults effectively improved their social and communication skills, and this group preferred the VR intervention in comparison with traditional methods. Furthermore, the study provides evidence that VR-based interventions can be used to complement traditional therapies for autistic service users and suggest future studies should investigate the benefits of combining VR-interventions with speech and language therapy (SLT). While VR has the potential to host communication or language-based interventions for populations such as developmental language disorder, the need to develop neuro-affirming tools to support autistic children is pressing.

As suggested above, a critical lens must be applied to previous VR research. A large proportion of studies with autistic children target social skills training, which is a neuro-affirmative shortcoming. These studies are criticized for using deficit-based interventions that aim to reduce and normalize autistic social behaviors, potentially increasing the risk of masking, negative mental health outcomes, and in some cases, trauma [7]. A growing number of professionals specializing in communication and social skills, such as speech and language therapists, are moving toward neuro-affirming practice [8]. Therefore, this paper does not use ableist language, such as autism spectrum disorder, instead adopting the term autism throughout. This reflects the authors nonpathologizing approach to autism. Neuro-affirming practice is described as support for autistic identity through strength-based, environment first approaches that promote adaptions [9]. They seek to remove environmental and societal barriers, imposed by deficit-based neurotypical standards and facilitate autistic self-advocacy [10]. Despite this, it can be difficult to know how to use resources to meet goals for autistic children. As neurotypical resources may not capitalize on autistic strengths, alternative tools, such as virtual reality (VR), should be explored to understand their application to clinical practice for autistic children [11]. As clinicians involved in the care of autistic children relating to communication and socialization, speech and language therapists' perspectives may provide insight into clinical applications of VR. Potential neuro-affirming uses have been demonstrated across literature. For example, autistic users have reported VR could help them with (1) anxiety surrounding unknown experiences; (2) concrete, literal thinking; (3) improving self-esteem and positive self-identity; (4) repetitive practice in real-life environments; and (5) making friends [11-14]. However, particularities of autism, such as sensory changes, disassociation, and indeed individualized presentations, may pose a barrier to the use of VR. Given that, VR has not been widely adopted by speech and language therapists in clinical practice, this potential remains unharnessed.

In total, 3 key papers have established a preliminary evidence base for VR as an intervention for autistic children in the SLT field. First, literature review by Bryant et al [15] provided initial support for the use of immersive VR for "communication disability" and autism, in SLT, and indicated there is some potential for every day, functional communication skills developed in VR worlds to transfer into real-world interactions. However, they suggested that technological complexities may act as a barrier to individuals with comorbid intellectual disabilities, and that VR may create ethical and safety issues that should be considered carefully. Second, systematic review by Bailey et al [16] suggested that VR could support several social communication goals for autistic children and those with an intellectual disability. However, results varied greatly, included research with low quality methodology, and outcomes were inconsistent across VR technologies. Therefore, it was difficult to compare the findings. Finally, a study by Ghanouni et al [17] examined the effectiveness of 75 speech and language therapists' social stories focused on perspective taking. While this indicates VR may be an effective medium for 'intervention' with autistic children, it is difficult to know if research is based on neuro-affirming principles. Evidence underpinning effective and affirming VR interventions in autism requires further development. Overall, Bryant et al [15] shows that VR implementation in SLT practice is still in the early stages. Therefore it is difficult to determine "which [VR] technologies work for whom, in which contexts," how VR supports SLT tasks and objectives, and the support required [18].

The precursor to using VR in clinical practice is exploring speech and language therapists' perceptions of VR and appetite for future usage. This may help to bridge the gap between technology and practice. Studies documenting clinician perceptions of VR in adult rehabilitation are positive, but knowledge and attitudes toward VR act as barriers to adoption [19]. For example, perceptions of a lack of SLT evidence, the need for training and guidelines, workplace limitations and side effects are challenging [15,20]. It is necessary to engage SLTs as one of the end users of technology, to reduce discrepancies between their needs and VR capabilities [21]. Ultimately, this may demonstrate if VR is an acceptable tool for autistic children and SLT practitioners. Despite this, there is a gap in literature examining SLT knowledge and attitudes toward VR as a tool for autistic children. Therefore, this should be explored to understand why VR has not yet been adopted into SLT practice.

In this work, we explore speech and language therapists' knowledge and attitudes toward the use of VR for autistic children. We focused on investigating knowledge and attitudinal factors that contribute to the adoption of technology, and their specific applications to an autistic population. In addition, we explored practical steps to enhance future adoption of VR by SLTs. We sought to answer 3 questions with SLTs practicing in the autism field. First, what knowledge do speech and language therapists have about VR? Second, what are speech and language therapists' attitudes toward using VR as an intervention for autistic children? Third, what do SLTs need to

XSL•FO
RenderX

support the implementation of VR in clinical practice? With this research, we aim to create a basis for future research, co-design, and implementation of VR for autistic children in an SLT setting.

Methods

Overview

A web-based questionnaire, reported in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) checklist [22], was created to gather qualitative and quantitative data exploring speech and language therapists' knowledge and attitudes toward VR as a tool for autism. This was a cross-sectional study, with data representing a snapshot of speech and language therapists' perspectives at a single point in time.

Participant Recruitment

Recruitment used convenience sampling, and participants were eligible to participate if they (1) were a speech and language therapist who provided input for autistic children or had autistic children on their caseload and (2) worked in the United Kingdom or Republic of Ireland. The web-based cross-sectional questionnaire was disseminated via the first author's professional social networks, and Clinical Excellence Networks in the SLT field. Participants were encouraged to forward the questionnaire to other eligible colleagues, using a snowball strategy to increase engagement.

Recruitment flyers included information about the research, a QR code, and link to the questionnaire. Upon entering the questionnaire, participants were provided with a participant information sheet, which outlined the rationale for research, research questions, and ethical considerations. Following this, participants were presented with a consent form to participate in the questionnaire and provided informed consent.

Questionnaire Design and Data Collection

The questionnaire was created using Microsoft Forms to ensure response anonymity was upheld and was open between April 3, 2023 and June 30, 2023. The questionnaire consisted of 23 questions overall, including Likert scales, open-ended responses, and single and multiple-choice questions. Questions included 6 questions on eligibility and basic demographics, 4 on knowledge about VR, 3 regarding previous use of VR, 6 on attitudes toward VR, and 4 on future support needs.

Knowledge about VR involved a self-rating scale about knowledge of VR, multiple-choice questions about different VR technologies, which VR "brands" speech and language therapists had heard of and integration of VR into practice, This question was adapted from Khukalenko et al [23]. Questions regarding attitudes toward VR used a 7-point bipolar Likert scale, to explore SLT reasons for use or nonuse of VR. Facilitators and barriers to adoption of technology were adapted from Albudoor and Peña's study [24], and conclusions from Brassel et al [20]. Questions on future support needs are directly based on Brassel et al [20], where supporting VR into clinical practice emerged directly as a theme. Open ended questions allow speech and language therapists to consider what they need to support VR into practice, if they would benefit from training and ideas for future research. The questionnaire used display logic to direct participants to relevant questions based on whether they had used VR in clinical practice. Consequently, different numbers of participants answered questions. The questionnaire was not piloted before going live on the web but was deemed coherent by the first author and supervisor.

Data Analysis

Following questionnaire recruitment, data was exported into Microsoft Excel for analysis. This enabled descriptive analysis of quantitative data, through percentages and counts and was presented visually. Free-text questions were analyzed thematically by the first author, following an inductive thematic analysis approach [25]. This identifed key themes and facilitated a deeper immersion with speech and language therapists' personal experiences, enabling better understanding and interpretation. Identified themes were discussed and agreed with the supervisor. Following analysis, themes were compared with quantitative data to develop an overall understanding of results, and direct quotes from text were used to contextualize results, increasing confirmability of interpretation.

Ethical Considerations

This study received ethical approval from the School of Social Sciences, Education, and Social Work Ethics Committee at Queen's University Belfast (073_2223). All participants provided informed consent and participation was anonymous. No compensation was provided for participation.

Results

Overview

Overall, 60 participants gave consent to participate in the questionnaire; however, 7 were not eligible to participate and their data were excluded. Reasons for exclusion include not working within the United Kingdom or Republic of Ireland (n=3), not working with autistic children (n=3), or not completing more than half of the questionnaire (n=1).The low number of responses may reflect the limited use of VR clinically. Results will refer to those who have and have not used VR with autistic children.

Participant Characteristics

Of the 53 participants who met the eligibility criteria, 48 responses were from women, 4 were from men, and 1 was from a participant who preferred not to comment on their gender. These figures are representative of sex-based employment data which suggests 97% (n=51) of the speech and language therapy profession are female, and only 3% (n=3) are male [26]. Further data relating to age, sector and location are presented in Table 1.

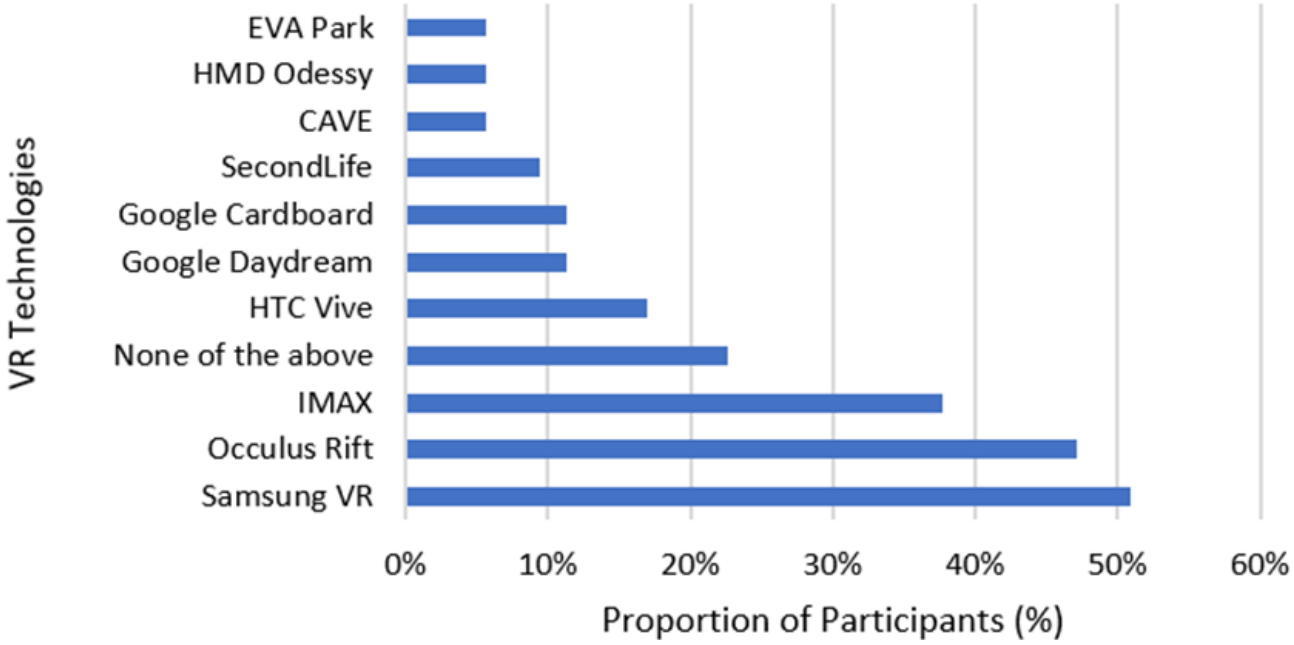
Private	22 (41.5)
Location	
England	22 (41.5)
Northern Ireland	14 (26.4)
Scotland	7 (13.2)
Republic of Ireland	6 (11.3)
Wales	4 (7.5)

Previous Use of VR



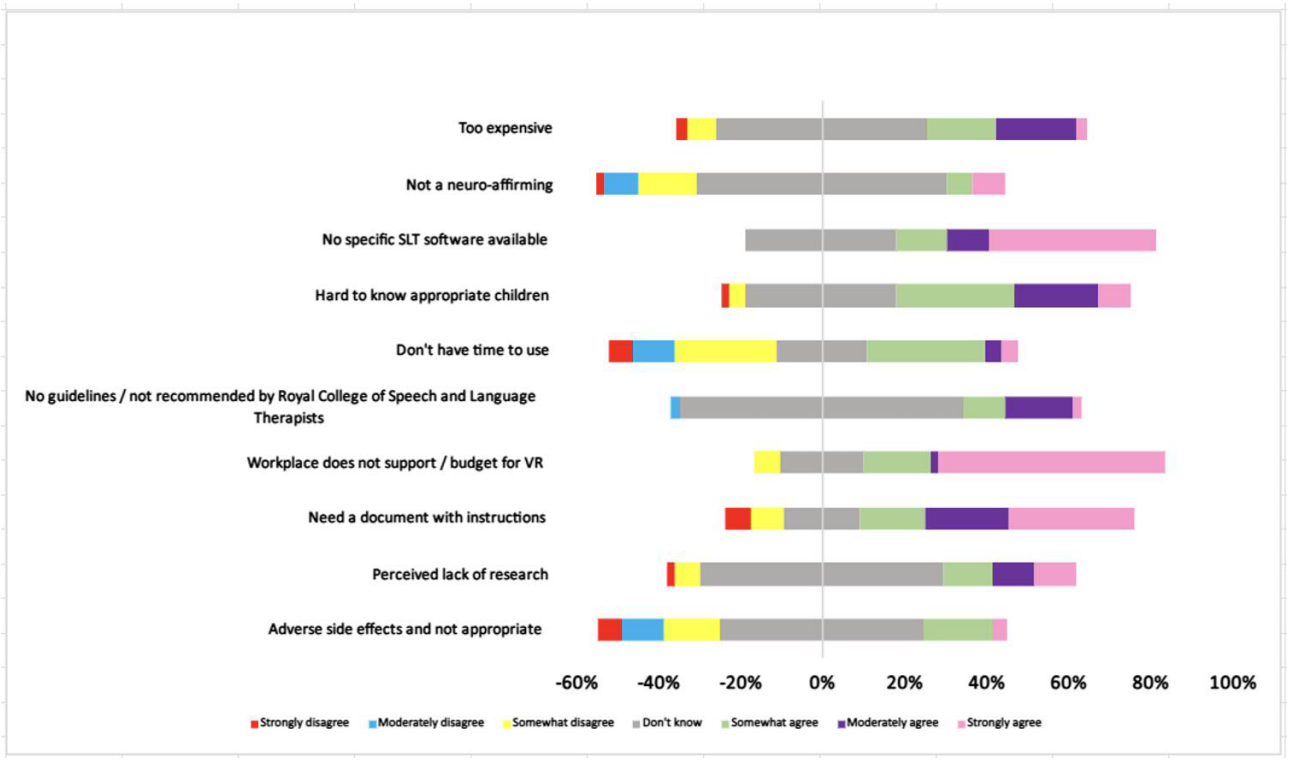
In the questionnaire, 3 questions pertained to previous VR use for SLT for autistic children. From 53 respondents, 49 had not used VR and 4 had. From the 4 VR users, 1 had used VR with an autistic child in a social skills context. In total, 3 had not used it in the context of autism but had used it to motivate children for therapy, to trial a VR Lidcombe program, and with stroke users. The Lidcombe Program refers to an SLT intervention used with dysfluency and stammering. Motivation included using gamified elements, and EVA Park had been used with people with aphasia.

Knowledge About VR

Speech and language therapists rated their knowledge on a 5-point Likert scale as excellent, good, average, poor, or very poor. Overall, they demonstrated a mixed self-reported knowledge of VR, with the majority of speech and language therapists who had not used VR, reporting poor (n=22, 41%) and average (n=20, 39%) knowledge of VR. Furthermore, a speech and language therapist exemplified this by reporting: *"My own knowledge is my main limitation."* Of speech and language therapists who had used VR (n=4), 25% (n=1) rated their knowledge as good, and 75% average (n=3). A total of 53% (n=27) of speech and language therapists who had not used VR were able to correctly identify that VR encompassed desktop computers, CAVE, and HMDs connected to smartphones or laptops. Furthermore, 70% (n=37) perceived HMDs to best describe VR. VR technology brands Samsung VR and Occulus Rift, which use HMDs, were mostly widely recognized, including by speech and language therapists who had used VR. Figure 1 outlines the recognition of various VR. Regarding the integration of VR into clinical practice, 67% (n=35) of speech and language therapists were aware of VR but had not used it in clinical practice. A further 15% (n=7) had become aware of the concept of VR from the survey and had not previously heard of it. VR was more integrated into clinical practice by those had previously used VR, with 50% (2/4) indicating their familiarity and confidence with VR, and 50% (2/4) had fully integrated VR and could creatively apply and use it in clinical practice.

XSL•FO
RenderX

Figure 1. Showing recognition of virtual reality technologies by participants. VR: virtual reality.



Attitudes Toward VR

Participants who had not used VR indicated that workplace budgeting and support, a lack of instruction and guidelines and a lack of specific SLT VR software acted as barriers toward the general adoption of VR into clinical practice (Figure 2).

As illustrated in Table 2, 55% (n=29) of speech and language therapists who had not used VR, strongly indicated that their workplace did not support or budget for VR.

I've never thought of this technology as an option – likely due to budgets and having access to the technology.

Figure 2. Showing speech and language therapist attitudes toward virtual reality when they had not previously used it in clinical practice. VR: virtual reality.

Theme and subtheme	Quotation
Training and **education**	• *"Knowledge, resource, time to upskill."*
	• *"I would like to see if it impacts sensory differences because I find when the child used it in my clinic he got really over stimulated and had more behavior problems than he did before using it."*
	• *"It should identify children who may not benefit from it ,ie, who does it work best for."*
	• *"If there are VR worlds used for autism, I'd also like to know how to keep my young people safe, because I would be worried that their social skills may put them at risk of victimization."*

[a]VR: virtual reality.

[b]SLT: speech and language therapy.

However, 43% (22) of speech and language therapists were not sure if VR was too expensive to purchase. Overall, speech and language therapists knew that their workplace did not budget for or support VR but were unsure about the cost of VR. Most of the speech and language therapists who had used VR indicated that their workplace did support or budget for VR.

In addition, 34% (n=18) of speech and language therapists who had not used VR, did not know if they needed guidelines or a document with instructions, whilst 30% (n=15) strongly agreed that they required guidelines. Overall, most speech and language therapists either wanted guidelines or were not sure. Speech and language therapists who had used VR (n=4) had mixed views. Some did not need instructions or guidelines (2/4, 50%) and some did (n=1 somewhat agree and n=1 strongly agreed). Responses to "no specific SLT software available," suggested 41% (n=21) of speech and language therapists who had not used VR, strongly agreed that there was no SLT specific software for VR. A further 37% (n=19) remained unsure. This is illustrated in Table 2. Half of speech and language therapists who had used VR did not know (2/4, 50%) if there was or was not SLT specific VR software. Others agreed (n=13, 25%) and disagreed (n=13, 25%).

Attitudes toward using VR specifically with autistic children indicated that speech and language therapists who had not used VR, were unsure about the evidence base (n=29, 55%) and adverse side effects (over 50% [n=26]).

> *I don't know enough about the applications of it within SLT, ie, in Assessment & therapy. I would need to know this and have a strong enough evidence base before I could even approach my NHS employers.*
>
> *I would be feared to implement VR, as it may encourage some of the children in my care to disassociate from the world even further.*

In total, 64% (n=33) of speech and language therapists were unsure about the suitability and screening for use of VR with autistic children as a barrier, alongside uncertainties about the neuro-affirming status of VR (n=32, 62%) :

> *I cannot see any benefits from using it with autistic children on the grounds of teaching social skills or attempting sensory desensitisation which is harmful, and does not work!!*

Notably, VR was considered to be neuro-affirming by over 30% (n=15) of speech and language therapists who had not used VR. However, 14% (n=7) felt it was not neuro-affirming, as it, "*perpetuates harmful neurotypical stereotypes that autistic children need to change.*" Of speech and language therapists who had used VR (N=4), 25% (n=1) strongly disagreed that VR could have adverse side effects, 50% (n=2) somewhat disagreed, however 25% (n=1) remained unsure. Furthermore, 50% (2/4) of speech and language therapists who previously used VR , felt VR was neuro-affirming and 50% (2/4) did not know.

Around 80% (n=42) of speech and language therapists were willing to use VR in the future and 20% (n=10) were not. Reasons for future usage included: (1) innovation in practice:

> *Always willing to explore new ways of working*

and

> *VR is in the media ALOT at the minute with the new Apple VR headset, so I think it's important that practice reality follows these new developments and isn't stuck in the past;*

(2) the motivational nature of technology:

> *It is visual and exciting, I can see the potential for use of VR with this client group*

and

> *Because lots of my clients love to use computers/ipads,*

and (3) potential therapeutic impact:

> *Another clinical tool to add to successful therapy outcomes,*

XSL•FO
RenderX

> *I think that it would support practicing areas such as self-advocacy and perspective taking in a more dynamic way*

and

> *If it could be used to improve social communication and language outcomes I would be willing to try it.*

Speech and language therapists who were not willing to use VR gave various reasons including (1) VR may not support neuro-affirming principles,

> *I would be worried about social scenarios created by neurotypical people to intervene in helping autistic people practice skills that don't come instinctively;*

(2) Concerns about sensory issues, and (3) ethical concerns and dissociations,

> *Virtual reality represents a disconnection from the real social interactions it [sets] out to improve.*

Support Needs

The 49 speech and language therapists who had not used VR were asked what they needed to support future research. Key themes emerged including an increased evidence base, workplace support, and training and education. Many speech and language therapists did not answer in full sentences, and this reflects the fragmented quotations used.

An improved evidence base for VR as an SLT tool for autistic children was required and "*having the knowledge to make an informed decision*," was a priority for many. An improved evidence base was also required to provide a more solid foundation for business cases for employers:

> *I don't know enough about the applications of it within SLT, ie, in Assessment & therapy. I would need to know this and have a strong enough evidence base before I could even approach my NHS employers to try and build a business case to support them purchasing it.*

Furthermore, speech and language therapists suggested future research should demonstrate clear quantitative evidence showing the effectiveness and efficacy of VR, clear, replicable outcomes measures for communication and generalization domains, and comparison of VR with standard SLT therapy.

Training and education were also identified as a theme across the data. In total, 83% (n=43) of speech and language therapists felt they would benefit from training, to include an overview of VR technology and guidelines for use. Speech and language therapists suggested a demonstration day, best described by one participant:

> *I personally would need a VR road show for autism where you can see what it can do, get to try it and talk with experts and other SLTs using it.*

Speech and language therapists wanted this to include education from specialists about the VR headsets available and appraisal of these, information on how to apply funding, an overview of research and practice-based learning opportunities, with peer support.

SLTs also reported that they needed a VR manual from VR "*procurement to [therapy] discharge.*" This would include a VR user guide and set up, example therapy ideas, and a frequently asked questions guide for troubleshooting and difficulties. Table 2 illustrates quotations which support the above findings.

Finally, specific areas for future research were also identified. This included neuro-affirmative uses of VR, effectiveness of a specific VR SLT tool and outcome generalization, consideration of individual needs, and involving autistic children and families in the designing VR tools. One speech and language therapist indicated that researchers should consider all future research in the current post–COVID-19 context:

> *Realise SLTs in NHS are still in battle mode post covid with severe shortages and whilst most SLTs are interested and can see potential for a range of applications, there are other interventions they are looking into and they have to prioritise. It may be the additional technology bugs/issues/learning curves slide VR into 2nd or 3rd place because we can't do it all.*

Discussion

Principal Findings

The aim of this study was to explore speech and language therapists' knowledge and attitudes toward the use of VR for autistic children. This questionnaire indicated that some speech and language therapists were willing to use VR, discussing barriers, potential uses, and support needed to facilitate the novel technology into practice. Key themes include considerations for VR use, attitudes toward VR and barriers to use, and supporting VR into clinical practice.

Despite being generally unsure about autism-specific considerations, most speech and language therapists were still willing to use VR as an intervention. This may be because some clinicians demonstrate an openness to innovation in practice, with some indicating that they liked to embrace new approaches and keep abreast of developments. Some advantages of VR were highlighted, including its motivational nature for autistic children and access to a range of communication environments, which are also highlighted in literature [11,12]. Despite this, speech and language therapists did not identify many of the other advantages of VR that are reported in literature, such as opportunities for repeated practice of increasing intensity in naturalistic environments, maximizing strong visual skills, or reduced negative social consequences. This indicates that SLTs may be willing to make a leap into VR adoption, relying on their own clinical judgment to evaluate how useful VR is in meeting the needs of autistic children. This demonstrates the perceived usefulness of VR is not only related to the evidence base and ability to facilitate adaptions, but also to its clinical relevance, applicability, and feasibility in the context of workplace, clinical, and individual demands [24].

Notably, some speech and language therapists in this study, who held more negative views toward VR, evaluated the technology from the perspective of autistic children themselves,

XSL•FO
RenderX

rather than as clinicians. This may indicate that these clinicians were supportive of neuro-affirming practice, however as demographic data was not collected on approaches to practice, the authors cannot say this definitively. Responses indicated that VR was perceived to be a tool that was based on neurotypical standards, and sought to change the skills of autistic children, rather than foster strength-based approaches and promote environmental adaptions advocated for by neuro-affirming practice [9]. This suggests that neuro-affirming perspectives may be integrated into the technology acceptance model and could be a form of subjective norms, influencing perceived usefulness of VR [27]. Neuro-affirming perspectives in technology adoption, have not yet been explored in research, and this offers an avenue for exploration.

Speech and language therapists opposed to using VR as a clinical tool for autistic children also reported concerns about adverse side effects, dissociation, and sensory impacts, similar to Bryant et al [15] and Brassel et al [20]. This suggests that speech and language therapists may be considering VR in the context of specific patient profiles. Given that autism presents uniquely in many cases, it is difficult to determine optimum autism profiles for use. Although previous research has indicated that VR can be used for sensory integration therapy and reduces stereotypical behaviors in autistic children (Marco et al [28]), this deficit-based research casts doubt over both sensory impacts and use of VR for identity affirming approaches. Indeed, autistic differences in sensory regulation may heighten dizziness and cybersickness, and although autistic children reported feeling calm when using HMDs [12], sensory stimulation impacts individuals differently. VR may allow autistic children to gain access to socializing and friendships through VR that are restricted in real life, resulting in excessive usage. This prolonged emersion may exacerbate sensory and well-being risks including dissociation [29] depression and anxiety [30] and victimization, as social communication differences may increase the risk of trolling. Therefore, VR should be supported by therapist input, and future guidelines for duration safety of use.

Education surrounding the neuro-affirming potential of VR in SLT is likely to influence the attitudes of speech and language therapists and future use of VR. Although some speech and language therapists remained skeptical about the ability of VR to support a strength-based approach that affirms autistic identity, literature indicates that VR has the potential to facilitate neuro-affirmative interventions, such as perspective taking, experience of new situations, and therapeutic interventions for anxiety and phobias [11,31]. Autistic service users felt VR could affirm their identity, facilitating educational experiences, and friendships [11,14]. As VR offers a safe place to explore and practice skills without negative consequences [32], future uses of VR may use the technology to teach skills to repair communication breakdowns, and as an advocacy tool to educate neurotypicals on communication differences.

Poor knowledge of VR was cited as a barrier to adoption, which is surprising given the increased public awareness and commercial availability of VR headsets in recent years, where VR has become a mainstream technology [33]. However, it appears that speech and language therapists struggled to extrapolate the VR represented in the media, to clinical practice applications in autism. This is reflected in literature, where clinical knowledge of VR is perceived to be a barrier to VR adoption in traumatic brain injury [19,21] and indicates the gap between knowledge and practical applications must be bridged to support adoption in autism. Despite this, personal factors such as age, gender, years of experience, and perceptions of digital skills may also impact adoption. Future research should build a clearer picture of links between demographic factors and technology adoption in SLT to understand SLT behaviors that should be targeted for change to support adoption.

Negative workplace attitudes were also highlighted as barriers to adoption of VR and similarly, these risks and barriers have also been highlighted by speech and language therapists using VR for adult communication and cognitive rehabilitation [15,19,21]. This also aligns with the technology acceptance model, by demonstrating that facilitating conditions and technological and institutional factors, play a role in technology adoption [15,24,27]. This indicates that more needs to be done to improve the ability of workplaces to support VR innovation and adoption into clinical practice. For example, grant and reward schemes for managers and trusts embedding VR therapy models.

Fostering positive knowledge and attitudes toward VR in SLT for autism, to overcome barriers, should build on suggestions for education, training, and guidelines. Previous literature in traumatic brain injury has used clinical manuals, workshops, IT support, and courses to make VR easier to use and improve practitioner confidence [21]. Although these approaches are deemed appropriate to facilitate the immersive VR use by speech and language therapists [20], the current suggestions for SLT support may improve upon this previous training model. Support for speech and language therapists using VR with autistic children should target awareness of VR technology, education and practice-based learning, and VR trials and support. Education and training strategies should work in tandem with research knowledge to translate the theoretical into practical. Both speech and language therapists who had and had not used VR, advocated for the development of VR guidelines for autistic children. Bauer et al (2023) [34] has provided detailed extended reality guidelines for paediatric autism interventions, suggesting they should be considered as part of an overall intervention program. However, they also recommend that future interventions should focus on mediation, well-being, and sensorially, social, and cognitive training, which it does not appear to be neuro-affirmative. Although these guidelines provide foundational guidance which speech and language therapists may apply to practice with autistic children, recommendations should be critically appraised on a case-by-case basis. VR SLT created guidelines for traumatic brain injury [20] that may be used as a guide to modify the guidelines by Bauer et al [34] in future research. Participatory design methods should be used in additional research [35] incorporating co-design workshops with speech and language therapists, autistic children, and parents to ensure usage recommendations reflect the needs of service users and speech and language therapists, and are underpinned by neuro-affirmative frameworks.

XSL•FO
RenderX

Overall, this research establishes emerging evidence regarding SLT knowledge and attitudes toward VR. This preliminary research is reflective of Bailey et al [16], where similar affordances and drawbacks are discussed regarding VR in SLT for communication disabilities and the technology acceptance model [27]. Knowledge of VR, subjective norms, including clinical judgment or neuro-affirming practice, and facilitating conditions such as workplace support, contributed to speech and language therapists attitudes toward VR as a clinical tool for autistic children and intention to use the technology.

Limitations and Future Directions

Limitations

Demographic variables were not analyzed in relation to adoption in this study. A fuller profile of respondents may have enabled a more nuanced discussion of VR within SLT autism practice and linked this to current practice. Studies seeking to replicate these findings should evaluate roles in autism care and professional practice. Perhaps speech and language therapists who had more clinical experience with autism, and the appropriateness of interventions, were better able to critically evaluate VR, thus reflecting their more critical attitudes toward VR. Many of these responses showed more depth than speech and language therapists who described a willingness to use VR. Future research should seek to explore the impact of previous training, years of clinical experience, location, and reflective practice on adoption of VR. A specific inclusion criterion, targeting speech and language therapists with substantial experience working with autistic children or using VR is required in future research. Authors should ensure inclusion criteria targets those aged more than 21 years as trained speech and language therapists.

In addition, the questionnaire was completed via web and self-selective, meaning respondents with adequate digital skills responded to the survey. Respondents may have an increased interest in or experience with VR, resulting in a self-reported bias. It may have been beneficial to include an adapted digital skills questionnaire to estimate SLT levels of digital competence, and how this impacted VR adoption. Results would have indicated if competence was related to technology generally, or specifically to VR. Furthermore, a questionnaire limited the depth of understanding of research questions. Focus groups may have enabled a richer exploration of clinician perspectives and future research should seek to use this methodology. Finally, it was difficult to ascertain figures for the number of speech and language therapists working with an autistic caseload in the United Kingdom and Republic of Ireland, from employment figures and therefore no power calculation was carried out. As a result, the authors are unsure if the sample size of 53 accurately sampled this population, and thus if the findings have suitable power. Given the increasing number of autism diagnoses across the United Kingdom, the number of clinicians in these roles may be higher than expected. Therefore, future research should seek to replicate this result with a larger sample size and recruit speech and language therapists from settings where they work predominately with autistic children.

Future Research

Patient specific facilitators and barriers to VR SLT interventions should be identified (eg, sensory differences, epilepsy, victimization, dissociation, intellectual disability, and gender) and external features of VR that contribute to effective SLT interventions. Given the link between epilepsy and autism, and the lack of evidence regarding seizure risk with HMDs, side effects are a pertinent area for exploration. Although the risks of HMDs are reportedly low for autistic children [12], it is necessary to establish safety protocols, such as maximum exposure time and treatment intensity required for generalization, to ensure tolerance and comfort. Limiting exposure times may also help reduce the possibility of autistic children dissociating from reality and real social interactions [15].

The neuro-affirming stance of VR was a key issue in this research. Future research should ensure VR research in autism is rooted in strength-based philosophies, given much of the current evidence base for autistic children prioritizes technology-based interventions for social skills and social cognition training [34]. This paper reiterates the need to think beyond a social skills approach, considering other linguistic, educational, and pragmatic domains within the SLT remit. This reflects the systemic change to autism management observed in the SLT literature and current practice standards [8]. However, the authors acknowledge that populations such as developmental language disorder may benefit from VR interventions designed to improve social or communication skills. Furthermore, it may be that a priority setting exercise for neuro-affirmative speech and language therapists would uncover pressing areas for research, which could guide future neuro-affirmative VR research.

SLT-specific software for autism should be designed using participatory research approaches [35] to ensure VR applications are neuro-affirmative, rooted in autistic and family priorities, and contribute to evidence-based practice in socially and ecologically valid ways [36]. This will solidify the use of VR in the care of autistic children. Frameworks such as Design Thinking [37] may facilitate future research allowing this topic to become more defined and to create new ideas to solve barriers to implementation in practice. Feasibility of VR as a clinical SLT tool may follow [38]. Additional research should compare outcomes from VR and traditional SLT clinical tools, enabling a cost benefit analysis for the benefit of clinical decision-making. Suggestions for development include VR applications that facilitate perspective changing and VR as an educational tool.

Finally, an education and training program may be developed for speech and language therapists, regarding VR as a clinical tool for use with autistic children. Key themes are outlined in Multimedia Appendix 1. Future research should explore how a SLT-specific VR training package impacts knowledge and attitudes toward VR as a clinical tool for autism and impacts adoption of VR into clinical practice. First-hand experience of and engagement with VR, may allow speech and language therapists to consider how it may be used with autistic children and for SLT goals. This may also inform future research

XSL•FO
RenderX

questions regarding implementation of dosage, minimum and maximum immersion time, and protocols for use, which contribute toward evidence-based guidelines for VR.

Conclusion

This research demonstrates mixed attitudes toward VR as a tool for autistic children among speech and language therapists. Barriers need to be carefully considered before VR can fully integrate into the SLT clinical toolkit, and this paper makes the following recommendations: (1) future research into VR in SLT should ensure a neuro-affirming approach, including autistic children in development of new software; (2) a stronger neuro-affirming evidence base regarding the use of VR for autistic children in an SLT setting, to contribute to evidence-based practice and enable access to resources; (3) development of a VR education and training program for speech and language therapists to include neuro-affirming practice; and (4) Clinical Excellence Networks should be set up to facilitate peer support among clinicians who adopt VR. From this, working groups of "VR champions" should be formed to provide advice regarding funding procurement and to engage managerial staff using success stories and outcome driven data.

Abstract

Background: Forearm, wrist, and hand impairments affect many individuals and impose a significant economic burden on health care systems. The FEPSim (flexion, extension, pronation, and supination) is designed for hand and wrist rehabilitation. It could become part of the standard care for upper extremity rehabilitation, aiming to improve range of motion, dexterity, and strength during therapeutic activities. However, the FEPSim has not yet been tested in a health care setting, highlighting the need for a trial to assess its effectiveness in upper extremity rehabilitation.

Objective: We aim to assess the feasibility of conducting a definitive trial investigating the effectiveness of adding a new device for hand therapy exercises, the FEPSim, to standard care for patients with impairments of the hand, wrist, and forearm.

Methods: Thirty-eight patients with impairments of distal upper extremities were randomly assigned either to the intervention group (FEPSim and standard care, n=19) or to the control group (standard care, n=19). Therapeutic activities to increase strength, range of motion, resistance, and dexterity were delivered by treating hand therapists using the FEPSim device for the intervention group. Outcome measures included wrist passive and active range of motion, grip strength, pinch grip force, and the Patient-Rated Wrist Evaluation.

Results: The trial retention rate (36/38, 95%) and compliance (control group: 100%; intervention group: 89%) were high. The comparisons of the change-from-baseline between groups revealed that in 63.2% (12/19) of the outcome variables, the change was in favor of the FEPSim, with statistically significant improvements in passive wrist flexion (t_{34}=−0.335, P=.008) and grip strength (t_{34}=−1.841, P=.04).

Conclusions: The FEPSim was accepted as part of standard care by therapists and patients at 2 hospitals. The trial design was feasible for hand intervention using the FEPSim device. The FEPSim positively affected grip strength, an objective measure of hand functioning.

Introduction

Impairments affecting the hand, wrist, and forearm have been found to impact everyday functioning and are associated with reduced quality of life, as well as increased levels of anxiety and depression [1]. These impairments impact a significant proportion of the global population, as they are caused by numerous etiologies such as fractures (including those caused by osteoporosis), osteoarthritis, stroke, and nerve and tendon disorders, among others [1,2].

The existing body of evidence indicates that exercise can lead to varying degrees of improvement in hand, wrist, and forearm impairments, with effects ranging from weak to moderate, particularly in cases of fractures, rheumatic arthritis, and osteoarthritis [1]. Additionally, comprehensive rehabilitation after stroke underscores the crucial role of exercising the hemiparetic hand and wrist across all stages to optimize patient

XSL•FO
RenderX

outcomes [3]. However, intervention protocols reported in the literature for exercises as part of hand therapy exhibit significant heterogeneity in conceptualization, dosage, and delivery. This limits the possibility of designing evidence-based clinical guidelines [1,4]. One reason for the observed heterogeneity in hand exercises could be the extensive variety of equipment and materials used during therapy sessions. For example, therapy putty, resistance bands, dumbbells, and jar openers are commonly used. However, these materials typically do not enable therapists to accurately determine and measure their patients' range of motion or strength during functional hand movements and exercises, which can contribute to inconsistencies in treatment protocols across therapists and settings.

Therapists in clinical settings typically use equipment falling into two main categories to enhance strength, range of motion, and resistance in the hand, wrist, and forearm [5]:

1. Low-cost and portable devices: These devices, averaging US $100, are generally small and designed to specific exercises. Examples are wheel-like or hammer-like devices to exercise pronation and supination and squeezing balls or bars to exercise grip strength. These devices lack direct measurement capabilities during hand therapy activities and are nonadjustable.
2. High-cost electromechanical devices: This category includes both portable and nonportable commercial electromechanical devices whose cost ranges from US $10,000 to US $95,000. Examples are the Simulator II (BTE Technologies) and SaeboReJoyce (Saebo). The BTE Technologies devices have been shown to be a reliable and valid tool, comparable to standard dynamometers, for measuring grip strength in healthy individuals [6,7]. The SaeboReJoyce provides a valid, quantitative, and automated alternative to standardized hand function assessments especially for patients with stroke [8]; however, its effectiveness in improving upper limb function remains inconclusive [9].

There is a clear need for a new rehabilitation device for hand therapy. Existing devices either are low-cost but lack measurement and adaptability or are prohibitively expensive for many health care settings. A versatile, cost-effective device could bridge this gap, offering precision and accessibility for more consistent hand therapy interventions.

The FEPSim (flexion, extension, pronation, and supination [10]), developed by Karma Machining & Manufacturing Ltd, is a rehabilitation device designed explicitly for hand therapy. It targets hand and wrist conditioning through various movements and offers adaptability for different grasp patterns. The device allows therapists to monitor improvements in strength, range of motion, and endurance by enabling controlled resistance adjustments. Resistance is set using a lever on a generic scale from 0 to 1, which corresponds to a torque range of 0.1 to 3.7 newton meters. In addition to resistance, the device can record the repetitions of therapeutic exercises, and is equipped with degree scales that allow therapists to observe patients' range of motion during active movements of the hand, wrist, or forearm. Thus, although the FEPSim is not an assessment tool, it serves as a useful tool for tracking patient progress in hand therapy. Its potential advantages also include compactness and portability, making it a promising option for rehabilitation of impairments of the hand, wrist, and forearm; however, the effect of using the FEPSim on hand therapy outcomes is unknown. In addition, the device is priced at less than US $3000.

In order to investigate the areas of uncertainty regarding a future definitive randomized controlled trial (RCT), this feasibility study, of which the protocol has been published previously [5], had the following objectives: (1) to assess the methods in terms of recruitment, the eligibility criteria, the type and number of diagnoses included, the length and dosage of the intervention, the data collection methods, and the outcome variables; (2) to explore the clinical effectiveness of adding the FEPSim device to the standard of care for patients with impairments of the hand, wrist, and forearm; and (3) to gather and synthesize the data, from which the sample size of a definitive RCT can be estimated.

Methods

Study Design

A pilot or feasibility study is intended to guide the planning of a large-scale investigation. As noted by Thabane et al [11], the primary objective of pilot studies is to evaluate feasibility, mitigating the risk of potentially catastrophic consequences associated with initiating a large-scale study. This precautionary measure aims to prevent the potential "drowning" of the entire research endeavor [11]. A feasibility study serves the purpose of elucidating previously unknown information crucial for designing a definitive RCT. It plays an integral role in acquiring pertinent insights into the acceptance of a novel intervention by both clinicians and patients. Additionally, this study seeks to identify potential beneficiaries of the intervention and elucidate optimal delivery methods within the context of standard care. The decision to undertake a feasibility study is rooted in the purpose of gaining insights into the acceptance and effectiveness of a newly developed hand therapy device which has not yet been tested in health care settings. Additionally, this study aims to evaluate the suitability of the designed research protocol for the clinical settings involved in the investigation.

This study was a feasibility parallel-group RCT that followed the CONSORT (Consolidated Standards of Reporting Trials) statement for randomized feasibility studies. The CONSORT statement serves as a guideline developed to enhance the transparency and quality of reporting in feasibility RCTs [12]. The trial was registered in the ISRCTN (International Standard Randomized Controlled Trial Number; ISRCTN13656014) Registry.

Ethical Considerations

This study was reviewed and approved by the University of Alberta Health Research Ethics Board - Health Panel (Pro00095587) and the Northern Alberta Clinical Trials and Research Centre. Treating therapists identified eligible participants and invited them to participate. A member of the

XSL•FO
RenderX

research team explained the study and obtained signed consent. Participants were able to withdraw from the study at any time, and this did not in any way affect their treatment or their rights as patients at the hospitals. Participants received a coffee shop gift card valued at CAD $25 (US $17.34) upon completing their participation. Personal data were deidentified. The participant names were replaced by numeric codes at the beginning of the study, and these codes were retained throughout data collection and analysis.

Materials

The FEPSim is an innovative device designed for the rehabilitation of the hand, wrist, and forearm. This study used the horizontal model depicted in Figure 1. This device features a central structure with an adjustable resistance mechanism, a degree-of-rotation scale for supination and pronation, and a small screen displaying exercise repetition counts. The device is tabletop secure and comprises 2 lateral shafts.

Various attachments facilitate exercises and the simulation of daily activities. For instance, a dowel grip attachment, installable on each shaft, is used for wrist flexion and extension exercises. Rotation and supination exercises involve a 90-degree unit rotation, enabling patients to grasp the dowel and perform clockwise and counter-clockwise rotations. Additional attachments include a key pinch attachment for lateral pinch exercises resembling tasks such as starting a car or turning a key, a T attachment simulating can opener use, a lever attachment for elbow extension or flexion exercises and simulating knife cutting and steering wheel use, and a doorknob attachment for door opening simulations.

Figure 1. The FEPSim device horizontal model. FEPSim: flexion, extension, pronation, and supination.

Recruitment

Patients receiving outpatient hand therapy at the Glenrose Rehabilitation Hospital and Royal Alexandra Hospital (Alberta Health Services) who met the inclusion criteria were invited to participate in the trial. The participants were outpatient adults (18 y of age and older) with limitations in their forearm, wrist, or hand function due to distal radial or ulnar fractures, stroke, osteoarthritis (ie, patients who had undergone wrist salvage surgery), Keinbock disease, ulnar shortening, perilunates dislocation, ganglion removal, tumor removals, triangular fibrocartilage complex injury repairs, ligament repair (torn ligament), or spinal cord injury. This study excluded patients with chronic regional pain syndrome, those who experienced unmanaged pain or edema, individuals with communication or cognitive impairments that hindered their ability to understand instructions, and those who were not able to participate in the outpatient hand program at least once a week. The participants were randomly assigned 1:1 to either the experimental group or the control group, using a permuted block-randomization approach with a block size of 4. The stratification was carried out based on diagnosis at each of the hospitals to ensure balance between the groups.

Procedures

Invitations to participate were posted at several locations in the 2 hospitals. Hand therapists at both hospitals who were unaware of the randomization blocks identified eligible participants. Then, the participants who met inclusion criteria and consented to participate were allocated into one of the groups (experimental group or control group) by the project coordinator who was off-site. This was a single-blinded study. Research assistants blinded to group allocation collected demographics (age, gender, ethnicity, employment status, highest degree or level of education, and medication taken) and outcome measures. Outcome measures were collected at enrollment and weeks 2, 4, 8, and 10.

XSL•FO
RenderX

Outcome Measures

The primary outcome measures were range of motion and grip strength. Range of motion included active range of motion and passive range of motion of wrist extension, flexion, and radial and ulnar deviation, and pronation and supination were measured using a 12-inch clear plastic goniometer (Baseline 360-degree; Fabrication Enterprises, Inc); grip strength was measured using a hydraulic dynamometer (Baseline Lite hydraulic, 200 lb; Fabrication Enterprises, Inc); pinch strength (including pulp pinch, key grip, or 3 finger grip) was measured using a pinch gauge or pinch meter—60 lb. Grip and pinch strength were measured 3 times, then the mean and SD of the 3 measures were calculated. The secondary outcome variables were the patients' perceived wrist pain and disability in activities of daily living and was measured with the Patient-Rated Wrist Evaluation (PRWE) questionnaire. The PRWE is a valid and reliable assessment tool of patient-based pain and disability in 3 components: pain; function during specific activities of daily living; and functioning during usual activities (personal care, household work, work, and recreational activities) [5]. Each item is rated from 1 to 10, and the maximum PRWE score is 100. Lower values in the PRWE scale outcome variable are desirable with hand therapy interventions.

Intervention

Overview

Both groups received standard care at each hospital, which consisted of immobilization for 7 to 8 weeks after the time of the injury or surgery (if needed), followed by hand therapy sessions for about 10 weeks. Hand therapy sessions included the management of scar tissue, sensory alterations, and edema, and therapeutic activities to increase strength, range of motion, resistance, and dexterity. For both groups the sessions' length and frequency depended on the patients' individualized needs and diagnoses, as determined by their treating therapists. The length of each session was between 30 and 45 minutes, carried out once or twice per week. The sessions were provided by occupational or physical therapists with training and experience in hand therapy.

Control Group

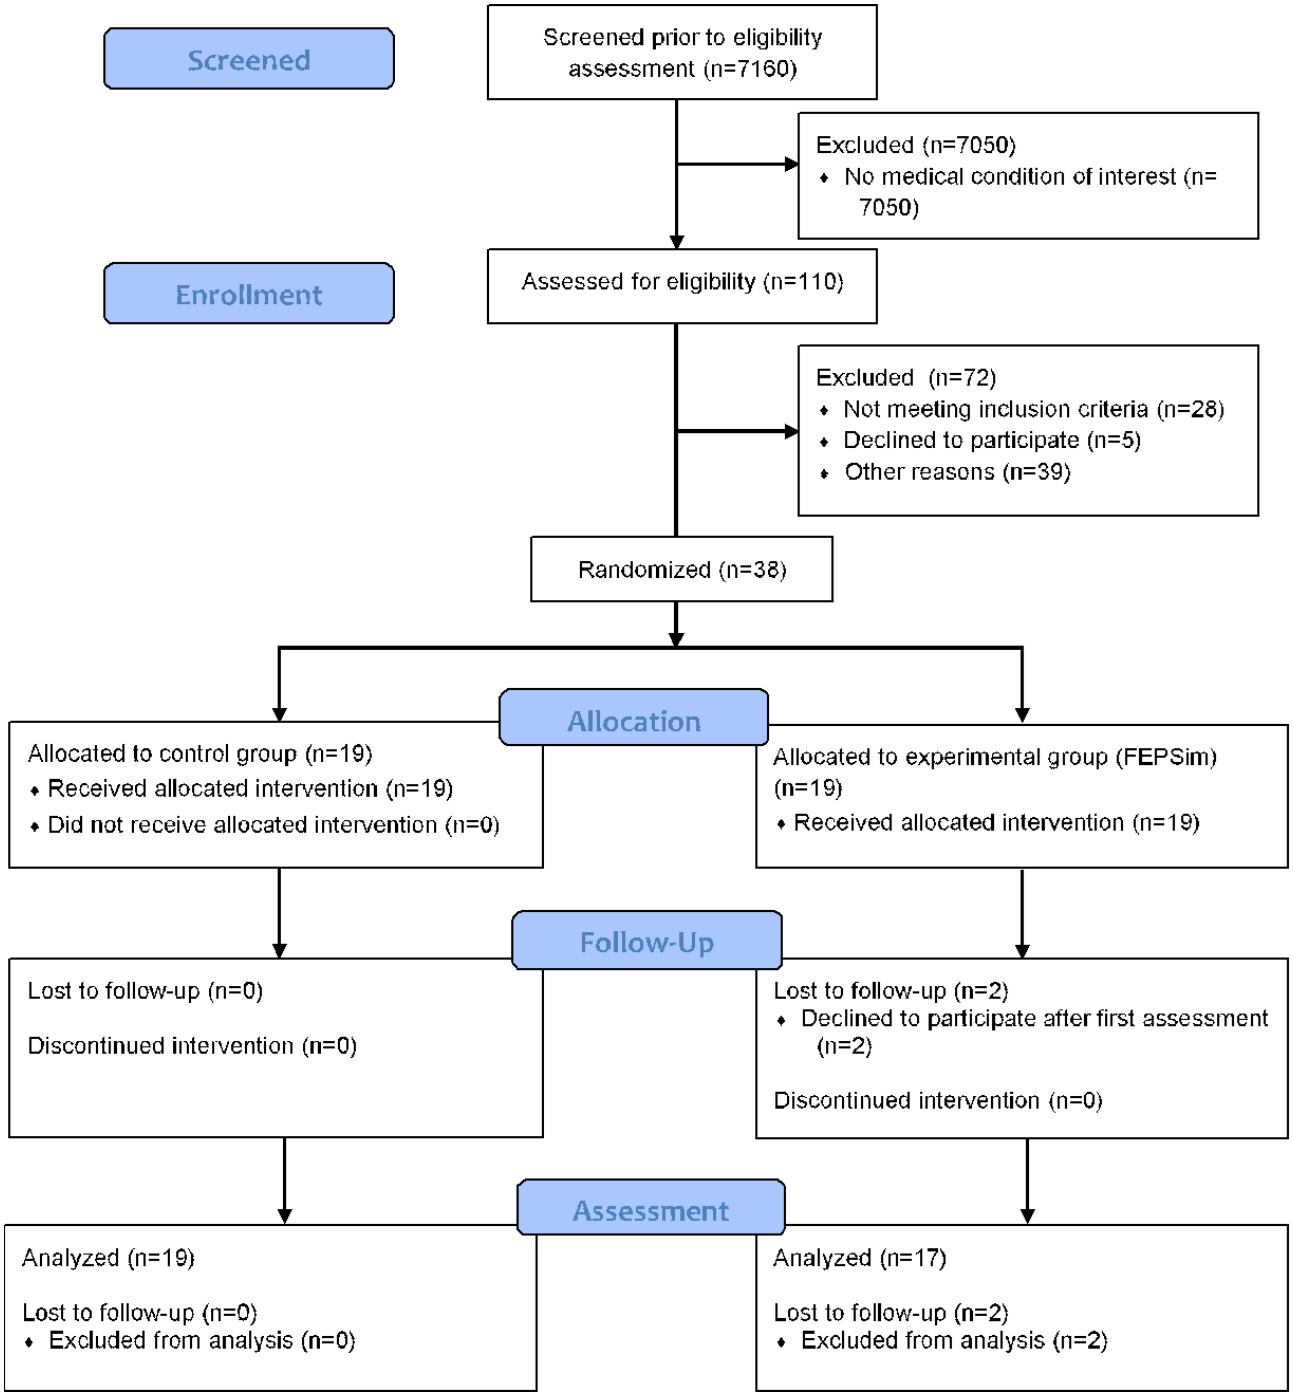
The therapeutic activities to increase grip strength and wrist or forearm range of motion were performed using available equipment and materials at each hospital. This included using weights such as dumbbells, elastic and squeezing equipment, therapy putty, bands, and other equipment that imitated the hand patterns required for daily activities (eg, jar openers).

Experimental Group

The research team worked with a group of experts to define which equipment and materials used at each hospital for hand rehabilitation could be replaced by the FEPSim device based on its features. As a result, for the experimental group, the therapeutic activities to increase grip strength, and wrist or forearm range of motion were performed using the FEPSim device instead of the equipment and materials used in the control group as described above.

Statistical Analysis

The analysis was conducted using an intention-to-treat principle. Descriptive statistics were used to characterize the groups at the pre- and posttest. Due to variations in the lengths of the interventions, as a result of various discharge times from treatment services, posttest was defined as the last measure taken once discharge from the outpatient clinic was determined by the hand therapists. Tests of normality were carried out in within and between groups comparisons across the outcome variables as appropriate (ie, 1-tailed paired *t* test or Wilcoxon signed rank test for within group comparisons; independent *t* test or Mann-Whitney *U* test for between group comparisons). We calculated 95% CIs and interpreted the level of uncertainty based on them [13]. The α level of significance was set at $P<.05$ (1-tailed). Cohen *d* values were calculated across variables, and an overall average effect size was calculated using a fixed-effects model for continuous outcomes. All analyses were conducted using SPSS (version 28, IBM Corp). In addition, the minimal clinically important difference (MCID) was calculated. An effect size of 0.2 is commonly considered equivalent to the MCID, so we estimated it by multiplying the SD of the baseline scores by 0.2 (a small effect size) [14].



Results

Recruitment

From October 1, 2020, to August 31, 2022, a total of 7160 patients received hand therapy rehabilitation at the 2 hospitals, from which 110 were eligible to enter the trial and 38 consented to participate (participation rate of 35%). The trial retention rate was 95% (36/38). The compliance for the control group was 100%, and for the intervention group, it was 89%. Two participants declined to participate after the first assessment due to disagreement with measures in place to control the spread of the pandemic. Figure 2 presents the flow diagram of the progress during the phases of this study. Table 1 presents the demographics of the 36 participants who completed this study, and Table 2 presents the participants' baseline characteristics according to group allocation.

[b]*z* score.

[c]PRWE: Patient-Rated Wrist Evaluation.

Eligibility Criteria

The trial protocol originally proposed to include outpatient adults with 3 specific diagnoses [5]. However, during the intervention sessions, therapists using the FEPSim device identified 8 additional diagnoses that could potentially benefit from its use. As a result, we amended the trial protocol to include patients with a total of 11 diagnoses, as outlined in the Methods section.

Length and Dosage of the Intervention

Mean numbers of treatment sessions received per group are highlighted in Table 3. We found no statistically significant differences in the number of weeks, the number of sessions, nor the number of days between the pre- and posttest between groups. All the participants in the intervention group received the treatment with the FEPSim. On average, the therapists used the FEPSim in 89% of the sessions in the intervention group.

Table . Treatment information per group.

Treatment parameters	Control group (n=19)		Intervention group (n=17)		Statistics	
	Minimum, maximum	Mean (SD)	Minimum, maximum	Mean (SD)	*z* score	*P* value
Number of weeks	2, 11.43	7.01 (3.19)	2, 10.86	8.54 (2.75)	−0.779	.21
Number of days (between pre- and posttests)	14, 80	49.05 (22.34)	14, 76	59.76 (19.24)	−0.779	.21
Number of sessions	4, 13	7.94 (2.95)	5, 19	10.82 (4.73)	−1.649	.05
Number of sessions with the FEPSim[a]	0, 0	0 (0)	3, 18	9.76 (4.52)	—[b]	—
Compliance (%)[c]	100, 100	100 (0)	57, 100	89.34 (14.80)	−3.09	<.001

[a]FEPSim: flexion, extension, pronation, and supination.

[b]Not applicable.

[c]Compliance was calculated as the percentage of intervention sessions completed as expected for each participant relative to the total number of prescribed sessions. Since this value varies across participants, the table reports the minimum and maximum values, as well as the mean and SD for each group. Therefore, compliance is presented solely as a percentage and not in the format n (%), as this format is not applicable to the data.

Data Collection Methods

The overall missing data was very low; from a total of 3204 values across participants and variables, 2.5% of the data was incomplete. Most of the missing values occurred in the baseline data collection phase, which was largely influenced by clinical decisions made by the therapists (ie, if conducting a measurement could compromise the healing process or worsen the clinical condition of a patient). As a result, variables such as pinch strength and grip strength were not measured for 19% (7/36) of participants, while the passive range of motion was not measured for 14% (5/36) of participants at the baseline. In addition, 25% (9/36) of participants did not respond to the “lifting a heavy object” item on the pain subscale of the PRWE at baseline. Most of the missing data were from participants with diagnoses of stroke, wrist fracture, and for ligament repair. Furthermore, the percentage of participants who were discharged from therapy increased as the trial measurement progressed (6%, 25%, and 50% at weeks 4, 8, and 10, respectively); which led the team to define posttest as the last measure taken before discharge.

Effect of the Intervention

Both groups showed better values in all outcome variables at posttest compared to pretest. The differences between posttest and pretest were statistically significant in 89% (17/19) of the outcome variables for the control group and 95% (18/19) of the outcome variables for the intervention group.

Table 4 displays the change-from-baseline outcome variables for both groups. Comparing the change-from-baseline between groups revealed that in 63% (12/19) of the outcome variables, the change was greater in the intervention group that used the FEPSim than in the control group; however, statistically significant differences between groups were observed in only two of the outcome variables 11% (2/19), specifically grip strength and passive wrist flexion, both in favor of the intervention group. The MCID was 0.96 for grip strength and 1.08 for passive wrist flexion. For the PRWE scale, including the pain and function subscales, as well as the overall summative scale, the change-from-baseline was not in the desired direction (unfavorable for the FEPSim). However, no statistically significant difference was observed for these outcome variables.

[c]PRWE: Patient-Rated Wrist Evaluation.

Sample Size of a Future Definitive RCT

The overall fixed-effects model calculated a small effect size. That is, we obtained a statistically significant test for Cohen *d*=0.189 (*z* score=2.450, 95% CI 0.038 to 0.340, *P*=.01) with an SE of 0.077. With a statistical power of 0.8, an α of .05, and the effect size of 0.189, the minimum sample size required for a future definitive RCT is 350 participants (174 participants in each group).

When estimating the effect size per group using a fixed-effects model for continuous outcomes, the overall average effect size for the intervention group had a higher value. That is, we obtained a statistically significant test for Cohen *d*=0.420 (*z* score=5.360, 95% CI 0.267 to 0.574, *P*<.001) with an SE of 0.070 and a *d*=0.310 (*z* score=4.092, 95% CI 0.161 to 0.458, *P*<.001) with an SE of 0.075 for the intervention and control groups, respectively.

Discussion

Trial Feasibility

Overall, the research design is feasible for a definitive RCT and offers valuable information for ongoing and future studies. The high trial retention and compliance showed that both the therapists and participants from the 2 hand therapy services agreed to incorporate the FEPSim into their hand therapy treatments. The therapists' acceptance of this device is also backed up by the qualitative results of another study published elsewhere [15].

Clinical Effectiveness of Adding the FEPSim Device to Hand Therapy

This study provides evidence of the potential clinical benefits of incorporating the FEPSim device into hand therapy. Both groups improved with the hand therapy treatment in around 8 weeks. However, the FEPSim group showed improvement in more outcome variables, associated with a statistically and significantly higher effect size. For grip strength and passive wrist flexion, the change-from-baseline was statistically significant in favor of the FEPSim. In the intervention group, 76.4% of participants showed a change equal to or greater than the MCID for grip strength, and 88.2% for passive wrist flexion. Grip strength is a commonly used objective proxy of hand function due to its strong correlation with overall hand performance and functionality [16,17]. Grip strength is a composite measure that reflects the integrated function of various hand muscles and joints, capturing both intrinsic and extrinsic muscle function, is clinically relevant and is associated with various health outcomes [18]. Furthermore, sufficient strength in the upper limb is related to the ability to adequately perform many activities of daily living.

The significant improvements in grip strength are clinically relevant for the most common diagnoses included in our trial. Postimmobilization following a wrist fracture often results in stiffness and muscle wasting, leading to a decrease in grip strength, which in turn affects the individuals' capacity to use the affected hand in daily activities [12]. High movement dosage after distal radius fractures has been found to be critical to increasing grip strength and range of motion. For example, repetitive wrist extension exercises have been found to facilitate regaining grip strength [19]. Additionally, wrist surgical salvage procedures aimed at alleviating osteoarthritis pain have been observed to decrease wrist range of motion and grip strength, potentially leading to long-term impairment [20]. The postoperative rehabilitation goal focuses on pain-free functional wrist motion and includes isometric strengthening exercises, followed by isotonic strengthening and progressive resistive exercises. Depending on the specific surgical salvage procedure, patients can achieve between 53% and 83% of normal contralateral grip strength [21]. Finally, following a stroke, there is a substantial reduction in maximal voluntary force within arm and hand muscles, contributing to significant upper-limb weakness during acute and chronic stages of recovery. A meta-analysis proves that graded strengthening programs improve grip strength and hand function in stroke survivors [22].

The significant improvements in grip strength can be explained by physiology. The use of the FEPSim as part of the therapeutic sessions allowed patients to repeat specific movements such as wrist FEPSim, as well as different grasp patterns with a resistance appropriate to the patient's progress at each session. This promoted muscle activation and efficiency of muscle recruitment in the wrist and hand intrinsic and extrinsic muscles, leading to an improvement in grip strength. Finally, the diverse wrist and hand movements the device facilitated might improve tendon gliding and elongation, reducing adhesions or tightness and enhancing passive wrist flexion.

The findings underscore the potential efficacy of FEPSim in augmenting grip strength among individuals diagnosed with specific conditions. The device's multifaceted capabilities, including the provision of real-time repetition counts, adjustable resistance levels, and the simulation of daily tasks impacted by hand injuries (eg, knife cutting), demonstrate its ability to enable multiple repetitions, carry out graded strengthening programs, and perform hand grasp and grip patterns used in functional activities in a controlled and safe manner. These features appear instrumental in optimizing movement dosage, thereby potentially enhancing clinical outcomes in therapeutic interventions.

Recommendations for a Definitive RCT

Based on the results of this feasibility trial, the authors make the following recommendations for a definitive RCT. First, to investigate a larger sample of diagnoses, including the emerging 8 diagnoses, from the outset to promote sample size and a more robust evaluation. Second, we recommend having 3 measurement points pretest (wk 0), posttest (immediately after discharge), and follow-up at 6 months. This recommendation is based on the observation that the percentage of participants who were discharged from hand therapy services increased during the trial, and that participants may have been discharged at different points during the proposed protocol. Third, considering that the sample size calculation showed that a total of 350 participants will be required and that we had a dropout rate of 10%, a total of 385 participants will be required to participate in a definitive RCT. Considering that the participation rate of this feasibility trial was 34.5%, for a definitive trial the required accessible population will be 1116 patients. To ensure an adequate sample size for a definitive RCT that recruits participants over a 2-year period, it is recommended that recruitment is from 10 settings. This is based on the observation that the feasibility trial admitted approximately 5 patients per month who potentially met the inclusion criteria, resulting in an estimated 47 eligible patients per month (1116 patients/24 mo). It is important to note that these conclusions were reached under challenging circumstances, as the data used to inform this recommendation was collected in hospital settings during the COVID-19 pandemic.

Study Limitations

It is worth noting that this study has some limitations. Given the limited sample size and low statistical power, caution should be exercised when interpreting the results; it is important to consider these limitations in the context of its feasibility nature and the power calculation conducted for a future definitive trial. Another important consideration is that the 2 variables showing

XSL•FO
RenderX

statistically significant differences between groups—grip strength and passive wrist flexion—had missing values in 19% and 14% of participants, respectively. These missing pretest values were imputed using the single imputation method of carrying the last observation backward. While this approach is widely used, it, as with all imputation methods, has inherent limitations. The COVID-19 pandemic had a significant impact on the trial, with different hospital policies for COVID-19 prevention and control, resulting in varying recruitment launch dates and the closure of one hospital's hand therapy service. This led to a significant reduction in the number of potential participants who met the inclusion criteria. In addition, the data collection was affected, as the trial was conducted over several months during the pandemic. A study by Ivy et al [23] investigated the pandemic's impact on hand therapy services; they reported a decrease in caseload for 98% of the 719 surveyed hand therapists, with 46% providing telehealth services. However, it is important to note that the impact of the pandemic on the results of this study may differ in a postpandemic world, where hand therapy services may have returned to prepandemic levels. Lastly, as no follow-up measurement points were incorporated in this study, the long-term effects cannot be determined; thus, the results are limited to their generalizability to the short-term.

Conclusions

To conclude, our study's findings suggest that it is feasible and acceptable to conduct a future definitive RCT to assess the effectiveness of the FEPSim device in improving impairments of the hand, wrist, and forearm. This trial had high retention and compliance, indicating that the therapists and participants from 2 hand therapy services agreed to incorporate the FEPSim in their hand therapy treatment. The FEPSim had a positive effect on grip strength, an objective measure of hand functioning. The device features appear instrumental in optimizing movement dosage, thereby potentially enhancing clinical outcomes in therapeutic interventions.

Acknowledgments

We thank the hand therapy staff at the Glenrose Rehabilitation and Royal Alexandra Hospitals, Edmonton, Canada, who treated the patients in this study. This work was supported by Alberta Innovates in 2018/2019 Accelerating Innovation Into Care (AICE; grant G2019000520).

Abstract

Background: A low-cost home exercise system called VestAid has been developed to assist participants during vestibulo-ocular reflex gaze stabilization exercises outside of clinic visits. The system includes a tablet-based app for the participant and a web-based portal for the physical therapist that provides data to make judgments about exercise accuracy and performance.

Objective: The purpose of this study was to assess the feasibility and acceptability of VestAid in a pilot study of 10 participants (mean age 45 [SD 19] years; 6 women) with various vestibular diagnoses.

Methods: All participants completed twelve 30-second horizontal vestibulo-ocular reflex exercises in a seated position (6 “easy” and 6 “hard” exercises). The exercises differed by variations in the background color, pattern, and movement. One of the exercises was repeated to assess the test-retest reliability of the measure of gaze stability accuracy and head motion compliance during the exercise. Participants rated the difficulty of the exercises (0 - 10 where 0=easy, 10=difficult) and completed usability surveys.

Results: Participants completed the VestAid session without adverse events. The responses from the usability survey demonstrate the acceptability of VestAid. The mean rating of the “easy” exercises was 2.7/10 (SD 1.9). The mean rating for the “difficult” exercises across participants was 4.8/10 (SD 2.1).

Conclusions: The consistency of the mean ratings of the participants with the exercise classifications (“easy” and “difficult”) suggests that VestAid has clinical utility.

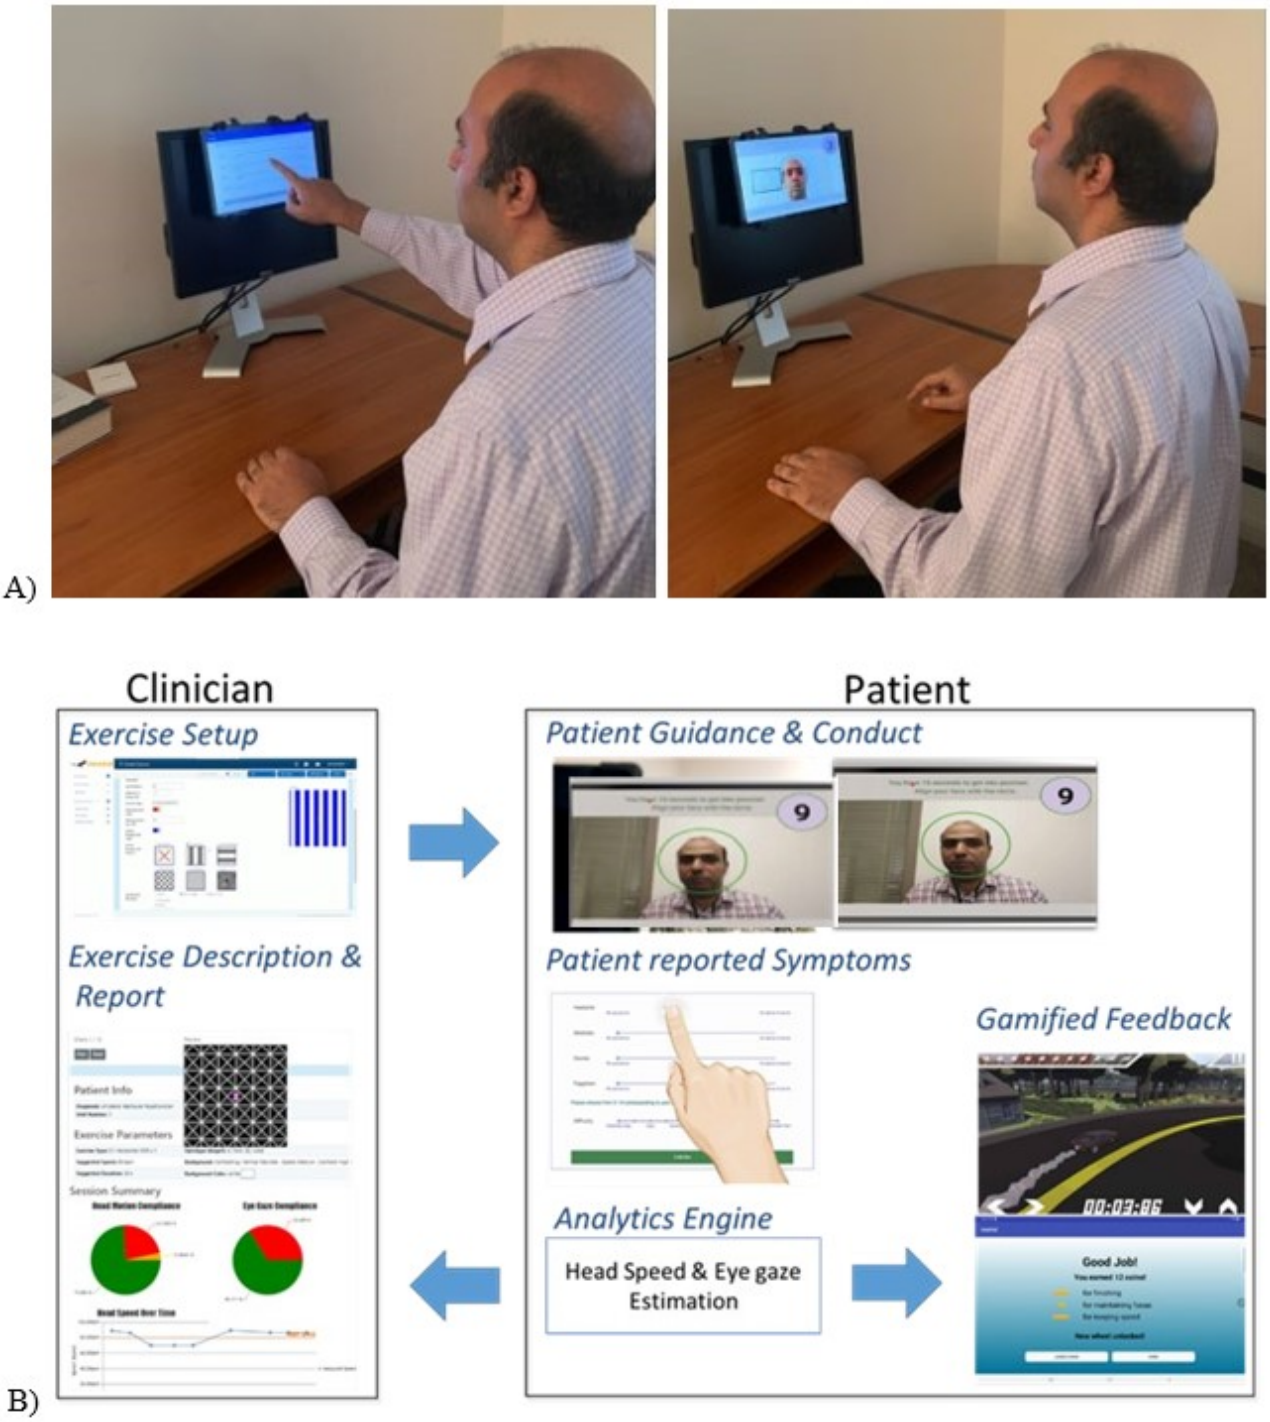
Introduction

Completion of gaze stabilization, or vestibulo-ocular reflex, exercises, such as vestibulo-ocular reflex × 1 (VORx1), have been shown to improve vestibulo-ocular reflex gain and reduce dizziness [1-3]. Prescription of gaze stabilization exercises has also been linked to decreased risk of falls [4]. Current clinical practice guidelines recommend that people with vestibular disorders complete gaze stabilization exercises at a minimum of 3 times per day for a total of at least 12 - 20 minutes each day if they have difficulty with vision or dizziness with head movement [5,6].

A retrospective chart review of 104 participants referred to vestibular rehabilitation postconcussion found that eye-head coordination exercises were the most common exercise prescribed by vestibular physical therapists, with the most common frequency and duration being 3 times per day for 60 seconds [7]. To achieve the recommended dose for VORx1 exercise during vestibular rehabilitation, most of the exercises must be completed outside of the clinic without expert supervision, which prevents participants from receiving timely individualized feedback.



Determining VORx1 exercise compliance is challenging for rehabilitation professionals. In the clinic, evaluation of gaze compliance and head speed compliance may vary based on clinician experience, and there is currently no easy, objective method to record VORx1 exercise performance.

VestAid [8] is an innovative tablet-based app for home or clinic use to objectively track exercise compliance and provide VORx1 performance feedback to both the treating physical therapist and the participant (Figure 1). Video instruction helps participants recall how to do the VORx1 exercises and a metronome guides head speed during the exercises. With the

XSL•FO
RenderX

tablet camera, facial and eye recognition software is used to analyze the accuracy of head and eye movement during the exercise. An unconstrained face detection method (where the face in the frame has arbitrary position and orientation variations) [9] combined with facial landmark detection and convolutional neural network models are used to determine the face image, refine landmark points (eye and nose positions), and capture face shape [8,10,11]. Head angles are computed using the filtered data from facial landmarks. A peak detection algorithm is used to determine head-speed compliance. The system classifies eye gaze direction as on- and off-target which is then used to determine eye-gaze compliance. The participant records their symptoms before and after each exercise which is then combined with the eye and gaze performance to provide feedback to the participant and the physical therapist.

Figure 1. VestAid tablet (**A**) and web portal (**B**).

While VestAid is thought to provide useful information to the participant and clinician, the feasibility and usability from a participant perspective is not yet known. The purpose of the study was to evaluate the usability of the VestAid technology from the perspective of the participant. Prior to using VestAid in a clinical trial, it was important for us to know whether the participants found the device easy and acceptable to use. We

XSL•FO
RenderX

hypothesized that VestAid would be both feasible and acceptable to participants with dizziness who complete VORx1 exercises.

Methods

Participants

Ten participants receiving vestibular rehabilitation for dizziness were recruited in this single-site pilot study in a tertiary balance center. All participants were 18 y or older and were diagnosed with a vestibular disorder by a neurologist who specializes in otology. Participants were excluded if they had a baseline dizziness rating of >5 out of 10 on a verbal analog scale (with 10 being the worst imaginable dizziness), visual acuity worse than 20/40, loss of protective distal sensation, or less than 5 degrees of ankle dorsiflexion. Previous experience has shown that people with severe baseline dizziness might not be able to complete the study.

Ethical Considerations

Informed consent was obtained from all participants and the study was approved by the University of Pittsburgh Institutional Review Board (STUDY19050389).

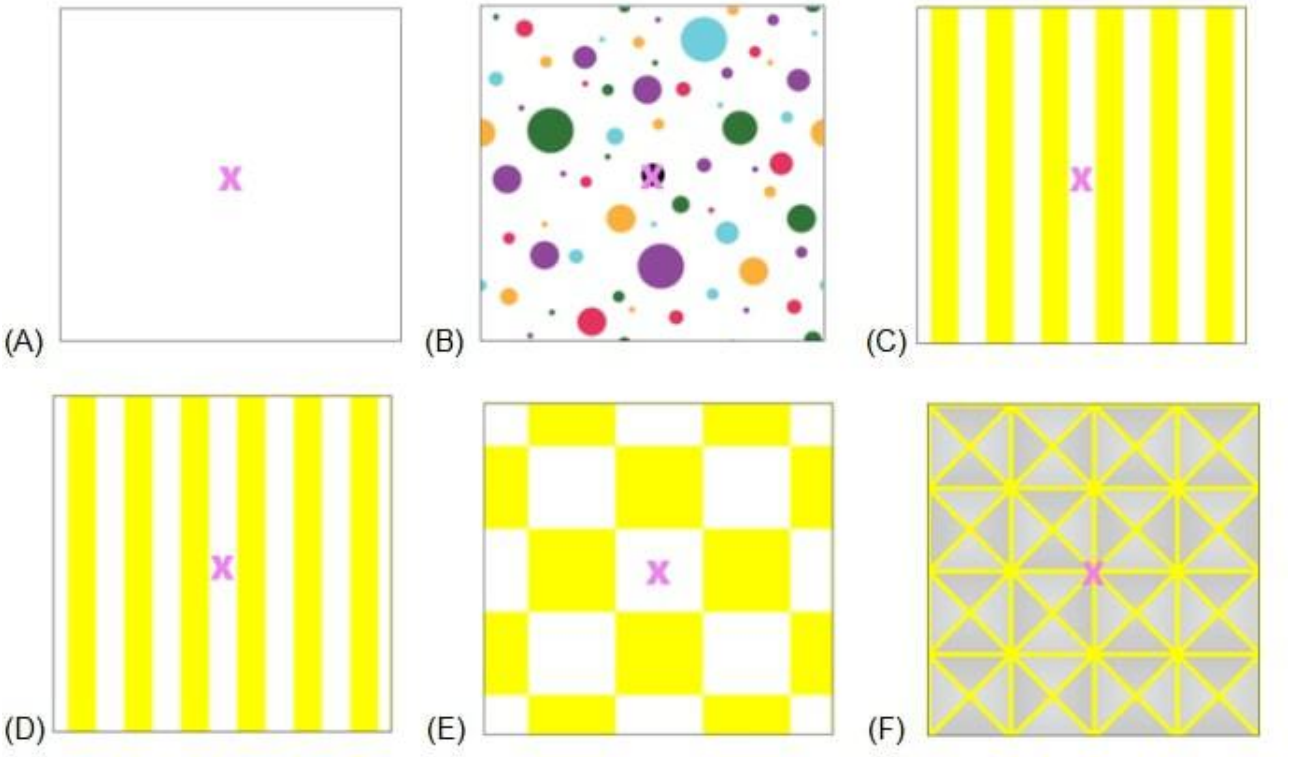
VORx1 Exercise Description

Participants performed horizontal VORx1 (a yaw head movement exercise done at 80 beats per minute while focusing on a stationary target) for a total of 12 trials of 30 seconds each during the single study session. There was a 1-minute rest break between each trial and per study protocol, the next trial was not initiated until symptoms returned to baseline. The study team chose a standardized speed for this usability study and opted for a relatively slower speed that we felt all participants could complete. Twelve trials of 30 seconds provided a total of 6 minutes of gaze stabilization exercise during the study session. If the gaze stabilization exercise is completed 3 times per day as is recommended for vestibular hypofunction, the dose of 6 minutes in our study session is on target for the recommended daily dose for gaze stabilization exercises (3 times per day for 6 minutes equals 18 min of gaze stabilization).

Each exercise varied in difficulty level by manipulating the background colors, patterns, and movement of the visual scene. The study team classified 6 of the exercises as being “easy” and 6 as being “difficult.” The exercises were selected and classified as “easy” or “difficult” based on pilot testing with study team members and the clinical experience of the research team. Insights from both the pilot testing and the team’s clinical expertise informed the final categorization, supporting appropriate exercise selection for study participants. The background of the easy exercises had low color contrast with no movement whereas the more difficult exercises had higher color contrast, and all but one trial incorporated a moving background. The 6 easy exercises were completed first in a randomized order followed by a second group of 6 difficult exercises, also in randomized order. This design was planned as we were unsure if participants would tolerate the moving and busier backgrounds and we wanted to allow for adequate comparisons of exercises completed. All exercises were completed in the seated position with the tablet positioned 3 feet away from the participant. A minimum of a 1-minute rest was given between trials. The visual fixation gaze stabilization target was viewed on the tablet screen and the exercise was video-captured and recorded by the tablet. For all 12 exercises, the optotype of the target was a pink “X” with a 30-point font size. The background patterns and movement during the more difficult exercises differentiated “easy” exercises from the “difficult” (Figures 2 and 3).

XSL•FO
RenderX

Figure 2. Background patterns of the easy vestibulo-ocular reflex × 1 (VORx1) exercises; background stationery for all 6 exercises.



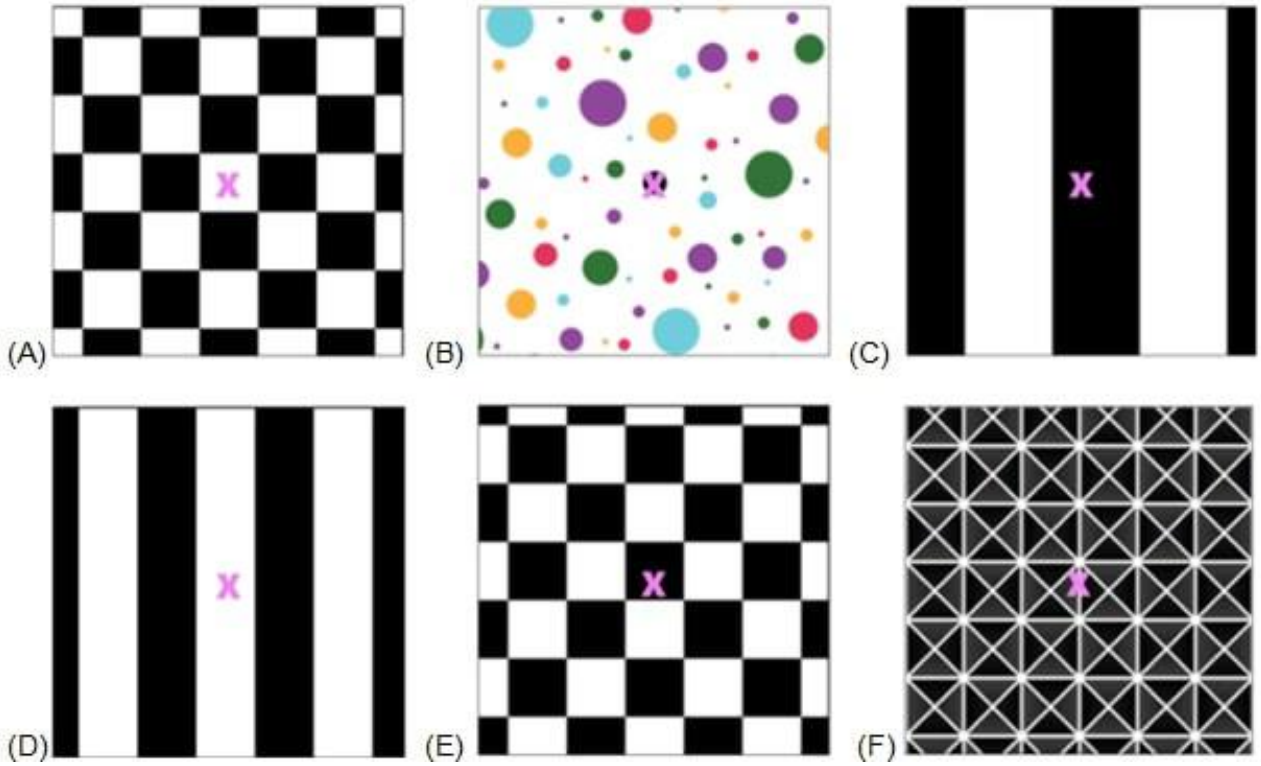


Figure 3. Background patterns and movements of the difficult vestibulo-ocular reflex × 1 (VORx1) exercises. Background movements are as follows: (A) stationary, (B) rotating clockwise, (C) moving left to right, (D) oscillating horizontally, (E) moving down to up, and (F) oscillating vertically.

Exercises are easily selected in the VestAid web portal for the desired parameters including exercise duration, head speed, target size, and background (type, color, stationary or moving speed, and direction of movement). The patient-facing tablet-based app provides written exercise instructions and an audible metronome to ensure proper head speed. Image-processing algorithms use facial recognition features from the camera in the tablet to track the patient's gaze fixation, head movement amplitude, and speed. VestAid estimates key parameters, including 3D head angles (roll, pitch, and yaw) and eye movements, in near real-time using advanced machine learning algorithms. Using these data, VestAid calculates

XSL•FO
RenderX

compliance metrics for head and eye movements, such as the percentage of the exercise performed at the correct speed. Additionally, the app collects patients' pre and postexercise symptoms (dizziness, headache, nausea, and fogginess) along with their perceived difficulty of the exercise.

Data Collection and Analysis

All participants completed the Dizziness Handicap Inventory [12] prior to the initiation of the exercises. Participants completed a 0 to 10 visual analog score rating (where 0=no symptoms and 10=worst imaginable symptoms) of their dizziness, headache, nausea, and fogginess before and after each VORx1 exercise [13]. Additionally, after each VORx1 exercise, participants rated the difficulty of the exercise on a 0 to 10 visual analog scale (VAS) (0=no difficulty and 10=most difficult) [14]. After the participants performed all 12 VORx1 exercise trials, they were asked to complete a brief usability survey with a 10-point Likert scale to note their level of agreement with 10 statements and 6 open-ended questions. The usability survey was administered on paper and asked open-ended questions such as "What did you like most in the app?" and "What did you like least in the app?" Descriptive statistics and reliability analysis were conducted using SPSS (version 28; IBM).

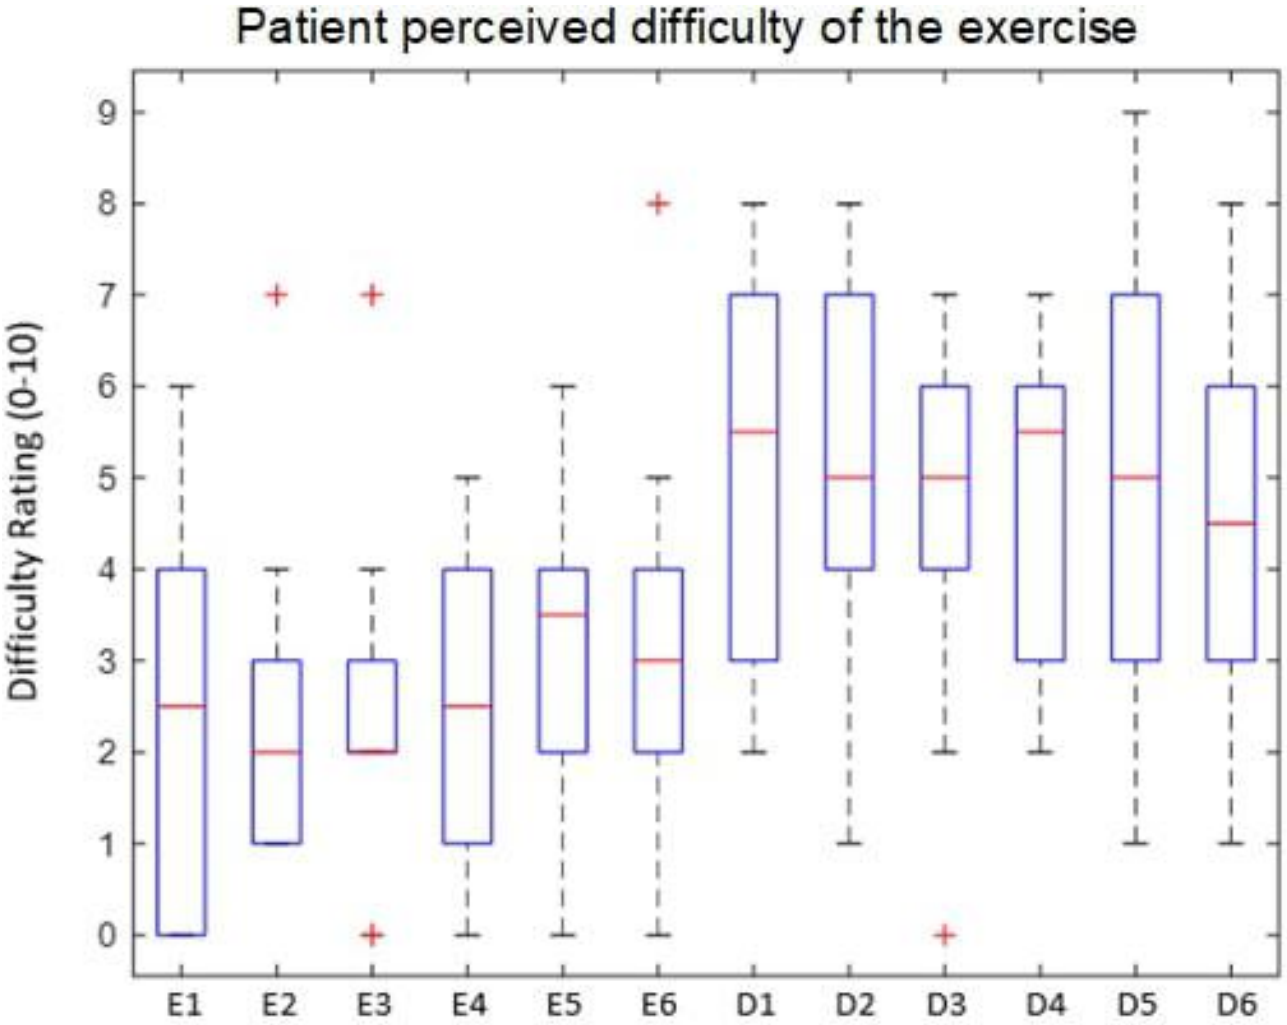
Results

The 10 participants (6 females) had a mean age of 45.3 (SD 18.7) years and a mean Dizziness Handicap Inventory score of 41.4 (26.7) indicating moderate handicap due to dizziness on average (Table 1). The number of vestibular rehabilitation visits completed prior to the study session ranged from 1 to 15 (mean 6; median 5) and the vestibular diagnoses included: unilateral vestibular loss (n=4), vestibular migraine (n=3), postconcussion (n=2), and dizziness of unknown etiology (n=1).

Table . Participant demographics.

	Age (years)	Sex	Diagnosis	Vestibular physical therapy visits completed	Dizziness handicap inventory
1	31	Male	Vestibular Migraine	10	52
2	41	Male	Postconcussion	9	64
3	31	Male	Unilateral vestibular hypofunction	3	4
4	80	Male	Dizziness of unknown etiology	2	88
5	43	Female	Vestibular Migraine	1	26
6	27	Female	Postconcussion	3	28
7	70	Female	Unilateral vestibular hypofunction	7	30
8	52	Female	Vestibular Migraine	2	74
9	24	Female	Unilateral vestibular hypofunction	15	26
10	54	Female	Unilateral vestibular hypofunction	7	22

The changes in dizziness, headache, nausea, and fogginess are summarized below. There was a total of 120 exercises (10 participants each completed 12 exercises) and while symptoms often increased following the exercise trial, all participants returned to baseline within 1 minute of rest. Exercise difficulty ratings had variable distributions on the 0 - 10 scale (where 0=easy and 10=difficult). The recorded gaze stabilization and head speed compliance varied among exercises and participants. Participants were not provided feedback on the objective output from VestAid related to their gaze stabilization accuracy and head speed compliance. The distribution of difficulty ratings is illustrated in Table 2.



XSL•FO
RenderX

Table . Frequency of reported exercise difficulty ratings for 120 exercises.

Reported difficulty rating (0 - 10)	Frequency, n
0	12
1	10
2	19
3	17
4	19
5	14
6	15
7	11
8	5

Prior to collecting data, physical therapists categorized 6 exercises as easy and 6 exercises as difficult. Figure 4 reveals that the participants rated the exercises categorized as difficult at higher difficulty ratings than those that were categorized as easy, validating the physical therapist's determination of exercise difficulty.

Figure 4. Participant perceived difficulty with the vestibulo-ocular reflex × 1 (VORx1) yaw exercises. D: difficult; E: easy

As illustrated in Table 3, 100% of the participants strongly agreed that the instructions were clear and VestAid was easy to use (usability study). Neutral responses were recorded from one respondent for statements about the size and color of the target being easy to see and the ease of rating the exercise difficulty. A common theme of "easy to use" was inferred from

XSL•FO
RenderX

the responses to the question about what was liked most in the app from responses such as, “self-explanatory,” “user friendly,” “quick to navigate,” and “could be used at home.” The responses regarding what was liked least about VestAid included “user interface for reporting the symptom and difficulty rating” (n=5), “visual appeal of the user interface” (n=1), “metronome speed” (n=1), and “distance of tablet too far away” (n=1).

Table . Distribution of responses (n=10) to statements provided on the VestAid usability survey.

Statement	Strongly disagree	Disagree	Neutral	Agree	Strongly agree
The exercise instructional video was easy to understand.	—[a]	—	—	—	10
The exercise steps were easy to follow.	—	—	—	—	10
The size of the exercise target (the X) made it easy to see.	—	—	1	2	7
The color of the exercise target (the X) made it easy to see	—	—	1	2	7
The metronome sound made it easy to turn my head at the right speed.	—	—	—	1	9
It was easy to rate my symptoms using the scales.	—	—	—	5	5
It was easy to rate the difficulty of the exercises.	—	—	1	3	6
Thirty seconds of exercise was easy to complete.	—	—	—	3	7
The break between exercises was enough.	—	—	—	3	7
The exercises I did using the app were similar to ones I have done before.	—	1	—	4	5

[a]Not applicable.

Discussion

Principal Findings

In this study, participants with vestibular disorders were able to complete the gaze stabilization exercise trials using VestAid without adverse events or complaints. Our sample was heterogeneous which is representative of the range of patients that are seen in vestibular rehabilitation clinics. The study sessions were tolerated by the participants without any major increases in visual analog symptom ratings. Only 7% of the exercises caused a greater than 1-point increase in the VAS for symptoms of dizziness. Of the 7% of the exercises that caused greater than a 1-point increase in dizziness, all but one were exercises from the “difficult” category and the ratings were from 3 unique participants. Only 3%, 4%, and 6% of the exercises caused an increase of greater than 1 point on the VAS for headache, fogginess, and nausea respectively. This provides us with information that displaying the gaze stabilization target and background on an electronic tablet (compared with being displayed on paper) is feasible. In this study, we chose to use an optotype that was pink as it was visible against white, black, and yellow backgrounds. We currently do not know how contrasting colors impact the difficulty of a gaze stabilization exercise and future work should explore this research question.

Overall, the feedback from the participants was positive and VestAid was well received. Participants reported that performing exercises with moving backgrounds was more difficult than backgrounds that did not move, and they indicated that increasing the speed of the background made the exercise more difficult. Participants reported that the exercises were easy to perform and that the instructions were easy to understand. We believe that the speed of head movement (80 bpm) and the completing the exercises while seated contributed to the ability of all participants being able to complete all 12 trials which was a goal of our study. It is important for new investigations to explore the optimal ways to increase the challenge and difficulty of the exercise. The participant’s perceived exercise difficulty data combined with symptom rating and the objective information about head speed and gaze stability may have clinical utility in determining when exercises should be

XSL•FO
RenderX

progressed, stay the same, or be made easier in future trials or sessions. While exercise prescription was not a goal of this study, the ease of inputting symptom ratings and perceived difficulty were important for our research question examining the acceptability and usability of VestAid.

Many barriers currently exist to the completion of gaze stabilization exercises at home. Inherent to all home exercise programs, the understanding of the exercise and the motivation to complete the exercises present barriers to completion. In a systematic review, Essery et al [15] identified factors that predict whether participants will adhere to physical therapy exercise programs. They reported that self-motivation, social support, self-efficacy, and previous adherence to physical therapy exercises were positively correlated with exercise adherence in the home. Not all participants adhere to physical therapy home-based programs without social support (including supervision and encouragement from friends, family, or a physical therapist) [15].

The VestAid vestibular exercises simulate supervised exercises because they provide the physical therapist with access to performance and symptom data. Recording and tracking exercise performance makes the participant accountable to the physical therapist, and this may increase exercise adherence with VestAid. Outside of the clinic, participants do not receive feedback as to whether they are successfully completing gaze stabilization exercises (ie, maintaining visual fixation on the target and moving their head at the correct speed). Additionally, it is difficult for physical therapists to discern whether participants are completing the exercise at the appropriate level of challenge outside of clinic visits. Programs such as VestAid can make it possible for physical therapists to track participant progress and provide feedback based on performance outside of in-person sessions.

There are regions of the world where access to specialized expert care is not available [16]. VestAid may assist in the telehealth management of people with vestibular disorders, similar to other conditions that physical therapists manage via telehealth [16-23]. Internet-based vestibular rehabilitation blended with face-to-face rehabilitation and in-clinic vestibular rehabilitation were superior to usual care which was provided by a general practitioner [23]. VestAid could be used exclusively via telehealth or via a blended telehealth and face-to-face vestibular rehabilitation program.

Acceptance of technology is a consideration with people with vestibular disorders. In a systematic review [24], older adults were more adherent to technology-based programs than traditional exercise programs when provided feedback. Using VestAid, exercises can be performed sitting or standing, depending on the clinician's judgment. There are obvious fall concerns with older adults performing balance exercises in the home unsupervised, so a clinician's judgment is required to ensure participant safety. In a recent meta-analysis of randomized trials on the effects of exercise on fall injuries, exercising older adults showed very low injury rates, and exercise compliance was good [25]. This meta-analysis [25] appears to support the use of at-home standing or sitting balance exercises as low-risk activities in older people with vestibular disorders.

Motivation and understanding of the exercise can impact the completion of gaze stabilization exercises at home. VestAid has the capability to monitor gaze stabilization exercise performance digitally and performance can be reviewed with the participant in face-to-face interactions. In older people post stroke, remotely connecting the physical therapist and the participant via technology improved exercise adherence [26]. Technology features within VestAid might motivate and promote adherence to the prescribed home exercise program. Additionally, technology has the potential to enhance the participant's understanding of how to complete their exercise program and should be explored in future work.

Future work should also explore the efficacy and effectiveness of using technology in vestibular rehabilitation. Clinical trials should investigate the optimal dose of gaze stabilization exercises and specific parameters that vary the challenge of the exercise [27]. Future work should also investigate the use of technology to progress or regress a customized vestibular exercise program based on symptoms, perceived difficulty, and objective performance with gaze stabilization accuracy and head motion compliance. The reliability of VestAid in recording gaze stabilization should be assessed. Additionally, the determination of acceptable scores for gaze stabilization accuracy (the ability of the eyes to stay focused on the target during VORx1 exercise) and head speed compliance (percentage of time that the head moves at the prescribed speed) need to be determined.

Conclusion

VestAid is feasible to use in a clinical setting and acceptable to people with vestibular disorders. By monitoring exercise performance and providing near-immediate feedback, the VestAid app may improve exercise compliance and increase motivation to complete home exercises. With access to detailed performance data, clinicians can better manage participant progression between visits, thus potentially optimizing vestibular rehabilitation outcomes and speeding recovery.

Acknowledgments

The study team acknowledges and thanks the University of Pittsburgh Centers for Rehab Services and specifically, Amy Cassidy, DPT, for their assistance in participant recruitment. Additionally, the team extends gratitude and appreciation for the expert consultation and guidance provided by Yadira Del Toro, DPT; Carlos Esquivel, MD; and Karen Lambert, DPT. Abstract

Background: Children with neurodevelopmental disorders, such as cerebral palsy (CP), often experience motor impairments in manual dexterity, which hinder daily tasks and social interactions. Traditional rehabilitation methods require repetitive task practice, which can be difficult for children to sustain due to low engagement. Game-based rehabilitation devices and robots offer a promising alternative by combining therapy with digital play, improving motivation and compliance. However, many systems fail to incorporate actual object manipulation, which is essential for motor learning through sensory feedback. To address this limitation, a low-cost, easy-to-use robotic manipulandum device (RMD) was developed. The RMD enables real-time object manipulation during gameplay while providing assistive force, allowing the practice of a wide range of manual dexterity skills beyond gross reaching. This system offers an engaging and effective rehabilitation approach to enhance hand function in children with CP.

Objective: This study aimed to provide evidence for the feasibility and therapeutic value of the RMD game–based exercise program for children with CP.

Methods: In total, 34 children with CP, aged 4 to 10 years, were randomly assigned to the experimental group (XG) or the control group (CG). The XG received a computer game–based exercise program using the RMD, focusing on object manipulation tasks, while the CG received task-specific training similar to constraint-induced movement therapy. Both groups received their respective therapy programs 3 times per week for 8 weeks. Semistructured interviews with parents and children, along with qualitative analysis, were conducted to evaluate their experiences with the exercise program. The following outcome measures were used: (1) the Peabody Developmental Motor Scale-2 (PDMS-2) grasping and visual-motor integration subtests and (2) the computer game–based upper extremity (CUE) assessment of manual dexterity.

Results: No dropouts occurred during the 8-week program. Both groups showed significant improvements in the PDMS-2 subtests (P<.001) and the CUE assessment of manual dexterity, including success rates (tennis ball: P=.001; cone: P<.001; medicine ball: P=.001; and peanut ball: P<.001) and movement errors (tennis ball: P=.01; cone: P<.001; medicine ball: P=.04; and peanut ball: P<.001). The XG outperformed the CG, showing greater improvements in PDMS-2 grasping (P=.002) and visual-motor integration (P=.01). In the CUE assessment, the XG demonstrated higher success rates (medicine ball: P=.001 and peanut ball: P=.02) and fewer movement errors (cone: P<.001). Parents reported an increase in the children's independence in daily tasks.

XSL•FO
RenderX

Conclusions: This study demonstrates the feasibility, acceptability, and positive outcomes of the RMD game–based exercise program for improving hand function in children with CP. The findings support further research and development of computer game–assisted rehabilitation technologies.

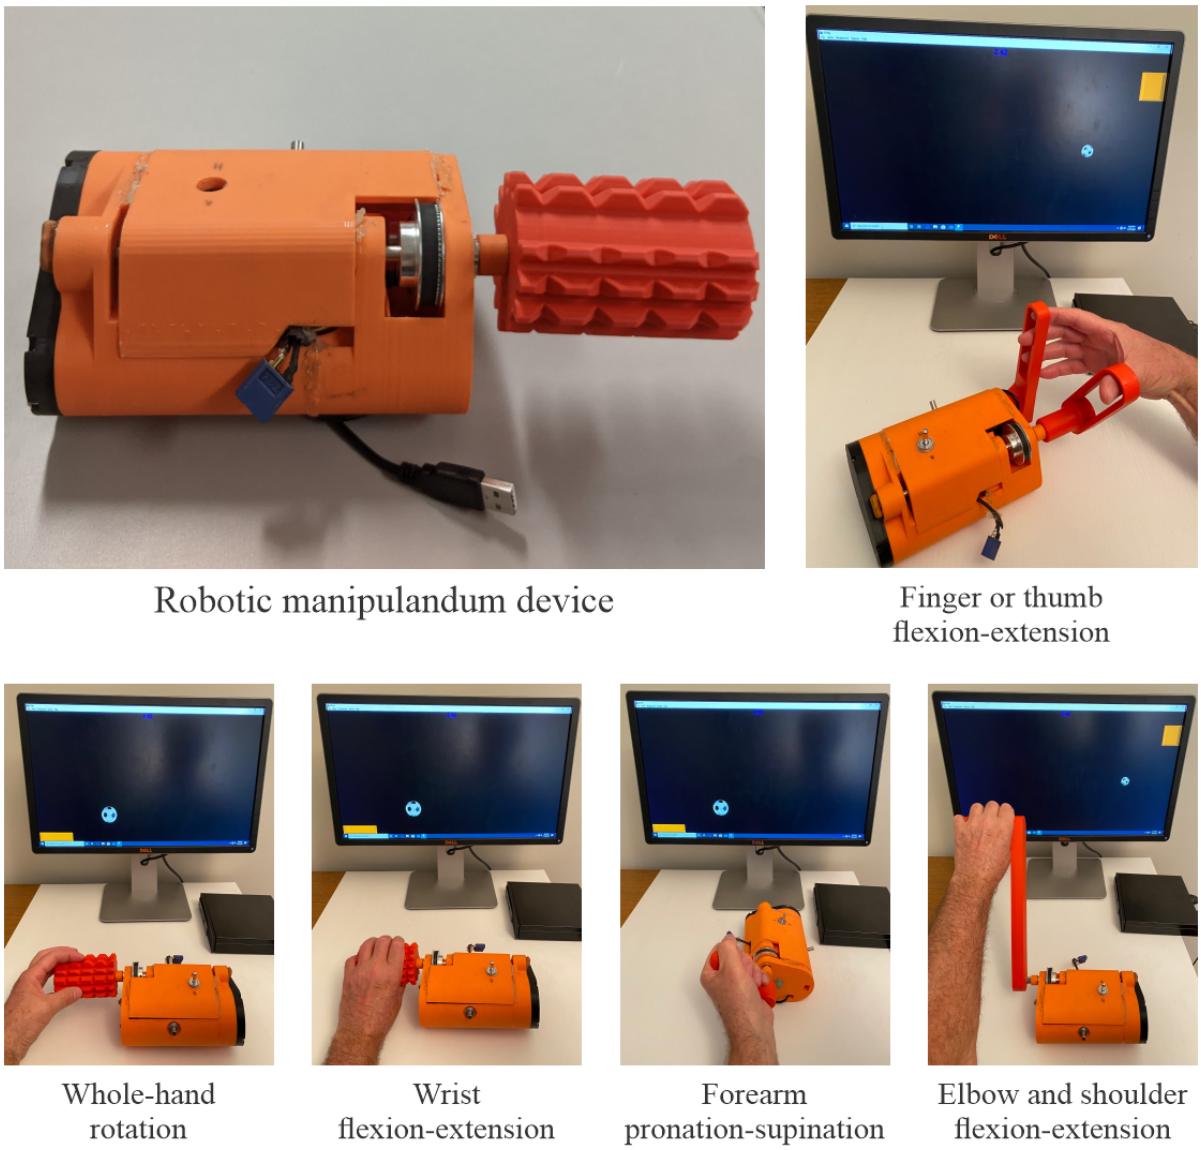
KEYWORDS

cerebral palsy; computer game–assisted rehabilitation; manual dexterity; repetitive task practice; robotic manipulandum

Introduction

Children with cerebral palsy (CP) often experience motor impairments in the upper extremity, particularly in manual dexterity [1,2]. These motor deficits make it challenging for children to handle and manipulate objects, which are essential for many daily life activities, play, and social interactions [3,4]. Such impairments in fine motor control can limit their independence and hinder participation in a variety of activities that require precision and coordination [5].

Traditional therapeutic approaches, such as constraint-induced movement therapy [6-8] and hand-arm bimanual intensive therapy [9,10], have been shown to be effective in improving hand-arm function through repetitive task practice (RTP). These therapies focus on task-specific exercises and a high volume of practice [11,12]. However, maintaining children's engagement in these therapies can be challenging due to the monotonous nature of the exercises, making it difficult to sustain motivation and adherence [13-15].



In recent years, there has been growing interest in integrating video games with rehabilitation programs to enhance engagement and motivation. These systems combine therapeutic exercises with digital gameplay, making the experience more enjoyable and encouraging adherence [16-18]. Devices like the Nintendo Wii, Kinect, Leap Motion, and inertial motion sensors have been used to track hand or arm movements and control digital avatars or objects in games [19-23]. Similarly, several studies have explored the effects of assistive robotic systems aimed at improving upper extremity function in children with CP. While many robots target the shoulder, elbow, and wrist range of motion [24-29], some focus on finger or thumb movements [30-32]. These systems use motion signals from robotic linkages (ie, body segment movements) to control digital avatars or manipulate a game paddle. However, both video game–based devices and robots often lack actual object manipulation, which provides critical tactile sensory information for detecting slip and maintaining stability, a key factor for effective motor learning [3,5,33-35].

To fill the gap in object manipulation, a game-based rehabilitation system using an inertial-based (IB) computer mouse was developed in previous studies, and its proof-of-principle was established [36-40]. The IB mouse is a miniature, wireless computer mouse that can be easily attached to any object, enabling interaction with video games through object manipulation [41]. This system allows children to practice manual dexterity tasks using real objects, with real-time feedback from video games. While effective for many children, this system does not provide movement assistance for those with limited active range of motion or poor motor control.

Taking the next step, a game-based robotic manipulandum device (RMD) was recently developed, which not only directly links object manipulation with computer games but also provides assistive force. As shown in Figure 1, the RMD consists of a small enclosure (15 cm by 10 cm by 8 cm) housing electronics, a motor, a controller, and a rotary drive shaft. A variety of 3D-printed handles of different shapes and sizes snap onto the RMD rotary drive shaft, as presented in Figure 1. These handles and their corresponding movements are designed to practice a broad range of manual dexterity skills involving (1) thumb or finger flexion-extension, (2) wrist flexion-extension and ulnar-radial deviation, (3) forearm pronation-supination, (4) elbow flexion-extension, and (5) shoulder flexion-extension and internal-external rotation. A microprocessor interfaces the RMD with computer games by reading the optical encoder on the shaft, which provides real-time angular position data to emulate mouse input. The angular position of the shaft (handle movement) is used to control the position and movement of the computer cursor or game sprite. This allows children to enjoy and engage with modern computer games, with varying levels of difficulty, speed, and accuracy, as part of a personalized exercise program. Many commercially available games also engage key visuomotor, perceptual, and cognitive skills. Specific therapeutic value can be derived from both the types of handles used (ie, different manipulation tasks) and the choice of computer games.

XSL•FO
RenderX

Figure 1. General view of the robotic manipulandum device and examples of various handles used in game-based rehabilitation for manual dexterity.

The RMD can provide unidirectional assistive force during gameplay, with the motor programmed to apply a constant force to the output shaft in a single direction. Both the magnitude and direction of this force are configurable. For many children with CP affecting the upper extremity, finger and wrist function may be more impaired in 1 direction of motion, for example, limited extension. This limitation can prevent children from positioning and opening the hand to grasp objects of varying diameters. The force assistance of the RMD allows the child to make larger game movement responses, making the system accessible to children with very limited active range of motion or poor motor control.

The purpose of this exploratory randomized controlled trial (RCT) is to enhance the development of the RMD and provide evidence of the feasibility of conducting a full-scale RCT. The objectives were to evaluate the usability, acceptance of therapeutic value, and treatment effect size of an exercise program using a game-based approach with the RMD in children with CP. The hypothesis is that an upper extremity exercise regimen using the experimental intervention will result in equal or greater improvements in hand-arm function compared to the usual outpatient physical therapy program. In parallel with this quantitative analysis, a qualitative analysis was conducted to explore the experiences of the children in the study and investigate both the difficulties with the exercises and using the technologies as well as the engagement and motivational value of the computer games.

Methods

Ethical Considerations

The study was conducted in accordance with international standards of Good Clinical Practice. Ethics approval was obtained from the institutional ethical committee at Shri Dharmasthala Manjunatheshwara University, Dharwad, Karnataka, India (approval number: 2021/Physiotherapy/MPT/07). The study was registered with

XSL•FO
RenderX

the Clinical Trials Registry - India (CTRI/2021/07/034903) before the onset of participant enrollment. Both parents and children were provided with a clear explanation of the study's objectives and methods. Written consent was acquired from the parents, while the children provided their assent to participate. All participants were informed of their right to opt out at any point without any repercussions. To ensure confidentiality, all data were anonymized, and no identifying information was published without explicit consent. No financial compensation was offered to the participants, and no images of the participants were included in the paper or any supplementary materials.

Participants

Children diagnosed with CP were recruited for this single-blind randomized clinical trial with an active control arm. For the full CONSORT-EHEALTH (Consolidated Standards of Reporting Trials of Electronic and Mobile Health Applications and Online Telehealth) V1.6 checklist, see Multimedia Appendix 1. Participants were recruited from the Pediatric Physiotherapy Outpatient Department of SDM College of Medical Sciences & Hospital.

Inclusion criteria included (1) children with a confirmed medical diagnosis of CP, a neurodevelopmental disorder, by a medical practitioner or pediatrician; (2) age 4-10 years; (3) Gross Motor Function Classification System (GMFCS) from levels 1 to 3 [42]; (4) Manual Ability Classification System (MACS) from levels 1 to 3 [43]; (5) Modified Ashworth Scale indicating spasticity in finger and wrist flexors rated from 1 to 1+ [44]; and (6) the pediatric version of the Mini Mental State Examination scored 17 and above [45].

Exclusion criteria included (1) visual or auditory impairment, such that they cannot see and interact with the computer; (2) secondary orthopedic complications due to the neurodevelopment disorder like fixed deformities of upper extremities; (3) recent botulinum toxin therapy (less than 6 months); (4) recent surgical intervention of upper extremity; (5) moderate or severe spasticity, that is, Modified Ashworth score of grade 2 and higher; (6) cognitive impairment; and (7) uncontrolled seizures.

All parents and children were informed about the purpose and protocol of the study before enrollment; written informed consent was obtained from parents and assent from the children. Successfully screened participants were randomized to the experimental group (XG) or the control group (CG) by choosing 1 sealed opaque envelope containing a letter signifying the group assignment. A graduate student not involved in the study produced the envelopes, which contained a letter for either the XG or CG. The envelopes were thoroughly shuffled before each selection.

Interventions

Participants attended 24 treatment sessions, 3 times a week for 8 weeks, at a university clinical rehabilitation research facility. Each session lasted 45 minutes.

Experimental Group

The experimental exercise program using the RMD was established based on the participants' personal goals, the degree of their hemiparesis, and functional status. Figure 1 shows a variety of 3D-printed "therapy" handles of different shapes and sizes that snap onto the RMD rotary shaft. These were designed to practice a broad range of hand function skills. A typical session involved exercises with 4-5 different handles, several computer games, and assistive forces of different magnitudes. Each handle-game-force combination was practiced for 2- to 3-minute intervals and repeated 2-3 times. Different handles required different modes of manipulation, that is, game movement responses produced by thumb, finger, wrist, forearm or elbow, and shoulder movements. Task demands were adjusted by changing mouse sensitivity, movement range, etc. Different games were also selected to adjust movement speed and precision. Progression was achieved by using a variety of commercial computer video games. Many readily available and inexpensive computer video games have therapeutic value. For example, the commercial internet website "Big Fish" games contains hundreds of arcade-style computer games in several genres, many of which are appropriate for the game-based RMD exercise program. In addition to speed, target, and accuracy movement requirements, these games include several cognitive elements, such as games with different types of distractor objects to avoid, matching activities, and those that require ordering objects. See Multimedia Appendix 2 for several examples of commercial computer games from the Big Fish website, which were used in this study. These computer video games offer sufficient diversity to appeal to a broad range of individual preferences. Progressing the difficulty levels regularly and introducing different computer video games to sustain the challenge and provide new experiences will facilitate the psychological feedback required to maintain interest and participation.

Control Group

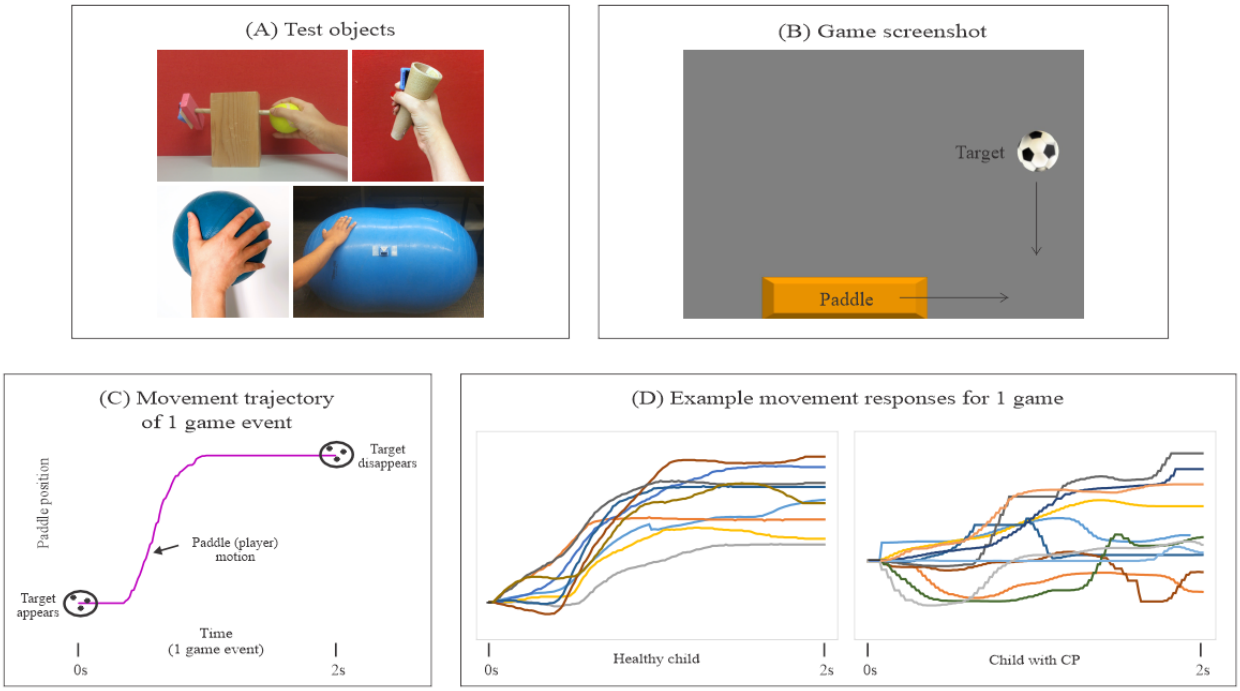
This included a goal-directed, physical therapy program. The protocols were based on RTP-based principles of modified constraint-induced movement therapy and hand-arm bimanual intensive therapy for fine and gross motor skills. Training tasks were individualized for every child according to their level of impairment and preset goals. Individualized exercises such as reaching for objects, removing rings and putting them back, ball throwing (under and overarm), turning a doorknob, clay activities, picking marbles from sand, putting pellets, rings, and pegs into sockets, opening bottle caps, manipulating objects such as a toy car, crumbling paper, hand-arm bimanual activities such as holding the ball with both hands and transferring, rolling bolster, writing, and self-feeding were chosen as part of the conventional protocol in a one-on-one therapy session.

Quantitative Analysis

The following outcome measures were obtained prior to and following the 8-week intervention.

Computer Game–Based Upper Extremity Assessment of Manual Dexterity

A miniature, wireless IB computer mouse (Therapy Mouse, Mobility Research) was secured to 4 test objects with different physical properties and functional demands. When the IB mouse is attached to a "test" object, the manipulation of the object is



XSL•FO
RenderX

used to control the motion of a game paddle of a purpose-built rehabilitation assessment application. For a full description of the computer game–based upper extremity (CUE) assessment, data recording, and analysis, see references [5,29,32].

Figure 2A presents the features of the four test objects:

1. Tennis ball rotation: It is a simple crafted object consisting of a wooden block and dowel. A hole was drilled in the wooden block and the wooden dowel was inserted. The IB mouse was attached to one end of the wooden dowel, and the other end was inserted into a tennis ball. Children grasped the tennis ball between their thumb and fingers and rotated the ball leftward and rightward to move the game paddle during gameplay.
2. Cone: The children grasped the cone and used pronation and supination to move the game paddle during gameplay.
3. Medicine ball (20 cm diameter): The children placed their hands on top of the medicine ball and used ulnar and radial deviation to rotate the ball and move the game paddle during gameplay.
4. Peanut ball: The children placed their hands on top of the peanut ball and moved it forward and backward using a combination of elbow flexion-extension and shoulder flexion-extension during gameplay.

Figure 2. Illustration of the computer game–based upper extremity assessment setup and data recording. Panel (A) displays 4 pictures of different test objects, each instrumented with an inertial mouse. Panel (B) shows a screenshot of the computer game–based upper extremity assessment game, featuring the target object (computer-controlled) and the game paddle (controlled by the rotation of the tennis ball). Panel (C) presents a single game movement trajectory (game paddle coordinates) for 1 game event, from target appearance (time 0) to target disappearance (time 2 seconds). Panel (D) depicts overlay plots of segmented and sorted game movement trajectories for a 60-second game trial. The plots illustrate the rightward rotation of the tennis ball, with the left plot showing data from a healthy child and the right plot representing data from a child participating in this study. CP: cerebral palsy.

A custom-designed rehabilitation assessment game, the RTP game software developed by the University of Manitoba, was used to evaluate the object manipulation tasks. The children were seated at a table with adjustable height. The test objects were placed on the table at a comfortable reaching distance. A standard computer monitor was used to display the RTP computer game tasks. The monitor was placed 1 meter in front of the children at eye level.

As illustrated in Figure 2B, a game target object (soccer ball) appears at the top edge of the display and moves to the bottom edge of the display. When the target object reaches the bottom, it disappears. The children were instructed to rotate the IB mouse on each of the 4 test objects to control the game paddle and catch the moving target object. Each game event from target appearance to its disappearance took 2 seconds. Each game trial was 60 seconds in duration; therefore, 30 game movement responses were obtained for analysis, with half of the game movement responses in each direction. The position of each successive target appearance was randomized. The RTP game software logs the coordinates of the game paddle (object rotation) and target game objects at 100 Hz for offline analysis.

Figure 2C presents the trajectory of a typical single game movement response. Figure 2D presents overlay plots of all game movement responses in 1 direction for 1 game trial. In this illustration, when using the cone as the game controller in the right hand, upward traces (rightward paddle movements) would represent supination.

The following outcome measures of structure and function were derived from the recorded game movement responses of each test object manipulation task:

- Success rate: It is the percentage of the total number of target objects that were caught in 1 game trial.

XSL•FO
RenderX

- Movement error: When a target is missed, the magnitude of the error (distance between paddle and target position) is calculated. The average value for all misses is then computed as the movement error. Units are the percentage of screen width.

The CUE assessment has shown moderate to high test-retest reliability [32].

Two Subtests of the Peabody Developmental Motor Scale-2

The two subsets of the Peabody Developmental Motor Scale-2 (PDMS-2) are as follows: (1) grasping subtest includes 26 items that measure a child's ability to use their hands and (2) visual-motor integration (VMI) subtest includes 72 items measuring a child's ability to use visual perceptual skills. Both the PDMS-2 grasping and VMI subtest scores have shown high test-retest reliability and good construct validity [46,47].

Qualitative Analysis

Upon completion of the 8-week exercise program, parents and children enrolled in the XG were invited to participate in an interview. The following open-ended questions were asked of all participants, and their responses were recorded: (1) When you agreed to participate, how did you hope your child would benefit from the therapy program? (2) What did you like about the therapy program? (3) What was challenging about implementing the therapy program for your child and you? (4) What did you think about the exercises or games or RMD your child was asked to perform? (5) How did your child respond to the exercises or games? Was there any exercise that your child did not seem to enjoy? (6) Would you want your child to continue with the same type of therapy program? Why or why not?

Parents and children who participated in the interviews were requested to share their ideas, thoughts, opinions, and personal experiences. The inductive analytical framework of interpretive description was used for qualitative analysis [17,48].

A staff physiotherapist who was blinded to the intervention conducted all the interviews. Interviews were conducted in the local preferred language (Kannada or English), and audio recordings were later transcribed into a written format. Transcripts were translated professionally, and then one researcher developed the thematic system by coding and categorizing the written transcripts of each interview. A second researcher reviewed the categorized data, identified any additional unique responses, and finalized the codes organized into final themes and subthemes.

Statistical Analysis

Descriptive statistics, including means, 95% CIs, and percentages, were used to summarize demographic variables and outcome measures. The Shapiro-Wilk test was used to assess the normality of the data [49]. Comparisons between groups were evaluated using the independent samples 2-tailed *t* test for continuous variables and the chi-square test for categorical variables. To analyze the effects of time (pre- to postintervention), group (XG and CG), and the time×group interaction on the CUE assessment, PDMS-2 grasping, and VMI, a mixed model ANOVA with repeated measures was used. Effect sizes for the ANOVA were computed using η^2, with the thresholds for small, moderate, and large effects defined as 0.01, 0.06, and ≥0.14, respectively, following Cohen guidelines [50]. All statistical analyses were conducted using SPSS (version 24; IBM Corp).

Results

Overview

The recruitment target of 34 children was achieved within 8 months. All enrolled children completed both pre- and postassessments and attended all exercise sessions, resulting in a compliance rate of 100%. There were no adverse events or technological issues reported during the exercise programs. These findings demonstrate excellent feasibility. Figure 3 presents the CONSORT (Consolidated Standards of Reporting Trials) diagram, illustrating the participant flow throughout the study.

XSL•FO
RenderX

Figure 3. CONSORT (Consolidated Standards of Reporting Trials) diagram for the randomized clinical trial.

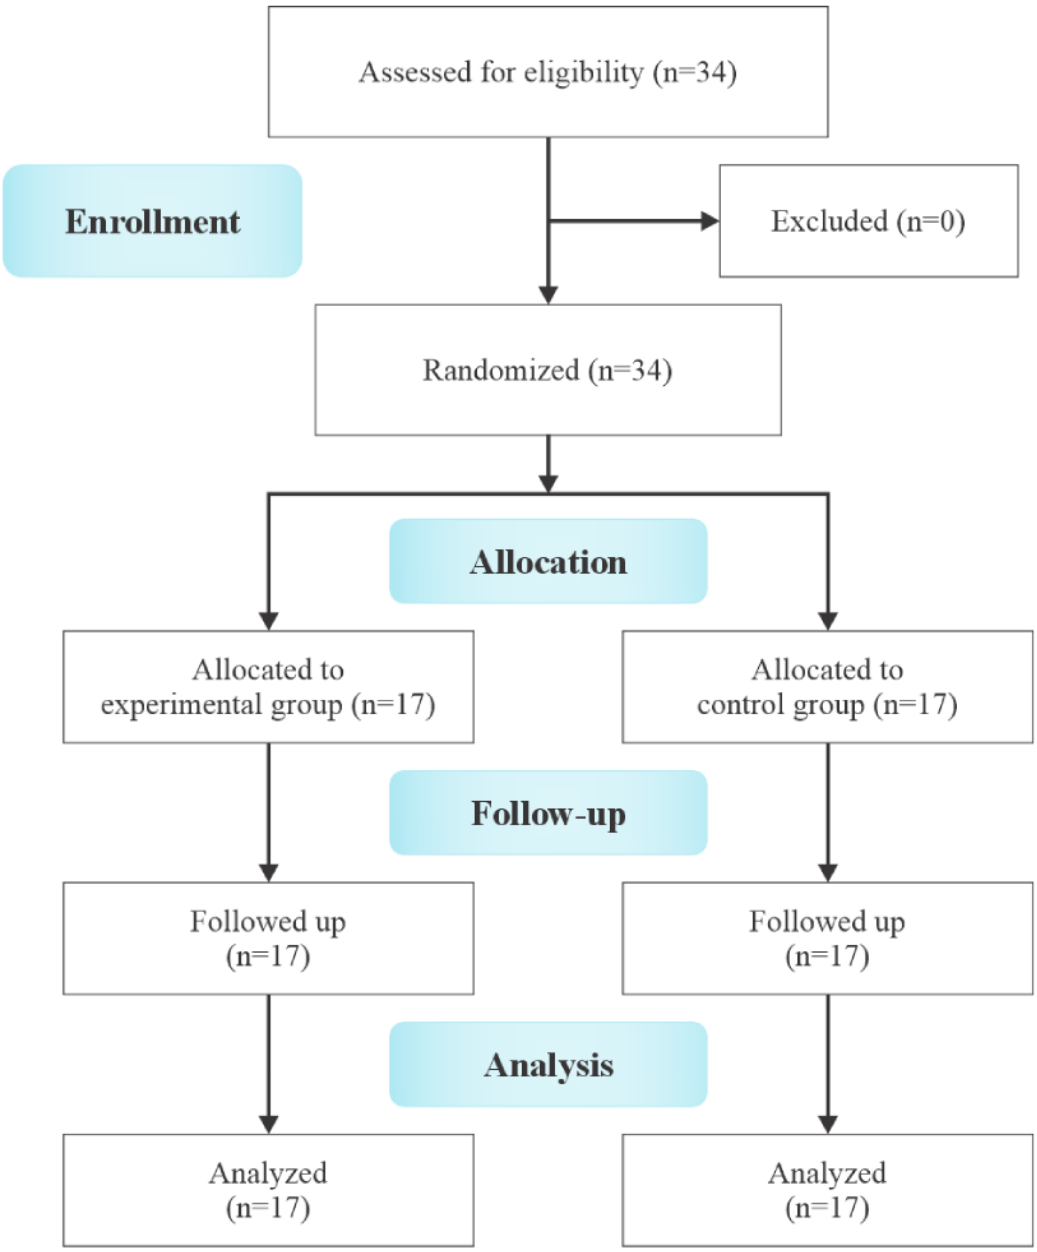


Table 1 presents demographic and clinical data categorized by group. The data were normally distributed, and there were no significant differences between groups at baseline in terms of age, sex, height, weight, GMFCS or MACS level, or treated hand. The majority of children were classified as GMFCS level II and MACS level II. The XG exhibited significantly higher scores in PDMS-2 grasping and VMI compared to the CG.

[a]XG: experimental group.

[b]CG: control group.

[c]Statistical significance was assessed using the independent samples 2-tailed *t* test for continuous variables (age, height, weight, PDMS-2 grasping, and PDMS-2 VMI) and the chi-square test for categorical variables (sex, treated hand, GMFCS, and MACS) to compare differences between the XG and the CG.

[d]GMFCS: Gross Motor Function Classification System.

[e]MACS: Manual Ability Classification System.

[f]PDMS-2: Peabody Developmental Motor Scale-2.

[g]VMI: visual-motor integration.

Tables 2 and 3 present the ANOVA results for success rate and movement error, respectively, analyzing the effects of time, group, and the time×group interaction. Figure 4 illustrates line plots of group means and 95% CIs before and after the intervention for success rate and movement error. Significant time and group effects were observed with moderate to large effect sizes across all 4 object manipulation tasks. Figure 4 highlights greater improvements in success rate and movement error for the XG compared to the CG, particularly evidenced by significant interaction terms in 3 of 4 object manipulation tasks for success rate and 2 of 4 tasks for movement error.

Qualitative Analysis

Overview

In total, 10 parents and children from the XG agreed to participate in interviews following the 8-week intervention. The following 5 themes captured the range of parents' and children's experiences and opinions about their child's exercise program. Textboxes 1-5 present parents' direct quotes for each theme.

XSL•FO
RenderX

Textbox 1. Parent quotes on issues encountered.

"We didn't face any type of problem during the therapy, although my child had faced little challenging at first while playing the games, he didn't understand the idea of gaming, but later he got to know how to play properly" [Parent 1].

"Some games involved one more person to assist the game as in to release the ball or bird to start the game, if even simpler games were included in treatment where child can only start the game and play easily would be really helpful" [Parent 5].

"Can improvise games, can add other interesting games specially cartoon ones which they watch regularly on TV, this will help them in playing the games even more interesting" [Parent 6].

"There were no serious problems faced, but my child had little issues with holding the handles properly, he had no idea about how exactly to hold the handles to move them to play. The main device keeps sliding a little while playing, so one person had to always hold the main device so that child can play without any problem, if the device can be fixed in one place or with better grip below it would be nice" [Parent 7].

"My child had difficulty in understanding what movement she should perform to play the games, such as catching the fish, she had little confusion with moving the handles left and right" [Parent 8].

"My child had difficulty in understanding the rules of the game" [Parent 9].

Textbox 2. Parent quotes on expectations for therapy outcomes.

"I thought that my child will be able to do hand movements better and she will get better" [Parent 3].

"I hope that his concentration, eye hand co-ordination may improve with this therapy" [Parent 4].

"I thought that my child's hand movements will improve also concentration will improve which will help him to use laptop" [Parent 5].

"I thought that my child's mind will get sharp, she can see properly with her eyes while playing" [Parent 6].

"I thought that my child's hand will get stronger with the help of this therapy" [Parent 7].

"Initially I have not predicted that this kind of therapy could help the child as I have no idea about this computer based therapy but later on I realized its very nice as it is based on game as well as work on multiple approaches in improvement by hand movement with eye co-ordination" [Parent 9].

"I thought because of this game therapy my child's concentration would improve" [Parent 10].

Textbox 3. Parent quotes on motivation and engagement with the computer game–based protocol.

"My child cries a lot while doing exercises, she would come to therapy after saying that she will be allowed to play computer games, because of this her therapy also used to happen. This I liked very much" [Parent 3].

"It's more interesting for children, my child is doing very interestingly and happily, it helps to improve concentration and eye- hand co-ordination. My child was playing happily, he likes the fish game most" [Parent 4].

"My child used to do other exercises fast while thinking that he is playing games which I liked and, he was playing games very enthusiastically" [Parent 5].

"If she plays computer games, her mind will get sharp. She got to know that what fish, ball birds look like, and she used to play well with happiness" [Parent 6].

"I liked that because of this computer game therapy my child's hand improved, she started using her hands for doing activities like to draw lines, coloring etc., which I liked about this therapy so much. She played well, she started to learn to play better later, and my child played all the games well" [Parent 7].

Textbox 4. Parent quotes on improvements in hand function and eye-hand coordination.

"I feel technology is useful. It will help to improve my son's hand problems and I liked it" [Parent 1].

"My child was not watching TV much, so I thought because of this computer games she might develop interest in watching TV and that her hand will gain strength and get better" [Parent 3].

"I liked that because of this computer game therapy my child's hand improved, she started using her hands for doing activities like to draw lines, coloring etc., which I liked about this therapy so much" [Parent 7].

"At first my child was feeling very difficult to play the games, later he improved better, hence I was satisfied. Now he is using his hand better than before" [Parent 8].

"This therapy program basically improves the eye co-ordination with hand movement. It is nice therapy as it is done in game manner" [Parent 9].

"I thought because this game my child's hand movement will improve this I liked very much. we can implement this technology based treatment for children, now my child is making his hand straight while playing games" [Parent 10].

XSL•FO
RenderX

Textbox 5. Parent quotes on suggestions for future implementation of computer game–based therapy.

"If we could make them play for more time it would benefit them even more, this treatment should be added to regular exercise regimen" [Parent 1].

"My child had difficulty in understanding the speed and technique of the game at first and was not playing that well at first, which was the difficulty" [Parent 2].

"Some games involved one more person to assist the game as in to release the ball or bird to start the game, if even simpler games were included in treatment where child can only start the game and play easily would be really helpful" [Parent 3].

"Can improvise games, can add other interesting games specially cartoon ones which they watch regularly on TV, this will help them in playing the games even more interesting" [Parent 4].

"Kids who need this kind of treatment will be benefitted well, hence this treatment should be available to as many children as possible" [Parent 5].

"My child enjoyed playing games, but when my child was not well or due to some other issues when we were not able to go to therapy problem, my child would really miss this treatment, so if this game device was available for purchase it would really help" [Parent 6].

"If it could play for a greater number of times it would be even more helpful" [Parent 7].

"My child had difficulty in understanding the rules of the game" [Parent 8].

Issues

Parents found the computer game–based platform promising; however, they noticed that children initially found it hard to understand how the RMD device works and how to play games while using it. The RMD allows only 1 degree of freedom in any movement being practiced. The protocols for children were planned to repetitively practice challenging movements while performing a goal-directed task.

Parents' Expectations

All parents participated in the study with the expectation of improvement in hand function for their child. Most parents also expected improvements in eye-hand coordination and better concentration. Due to socioeconomic barriers, 2 parents also hoped that their child would get better exposure to computers. A few parents hoped that the computer game–based protocol would motivate their child to stay focused during therapy sessions.

Motivation

All 10 parents and children found the computer game–based protocol engaging, challenging, and extremely motivating. All 10 parents would like the computer game–based protocol to continue as regular therapy and suggested that the games should be incorporated in more ways during therapy. Children responded well to the types of games chosen for their individualized protocols; however, it was necessary to use a wide variety of games to maintain their interest in the protocol.

Improvements in Hand Function and Eye-Hand Coordination

All 10 parents observed improvements in their child's hand function and eye-hand coordination, consistent with the quantitative data. Many parents also noticed positive changes in their child's overall level of participation in daily activities and their ability to concentrate on tasks.

Plans for Future

Parents observed that there was difficulty in the initial stages of their child's participation and understanding in the computer game–based therapy program. However, after crossing the learning curve, children found the protocol engaging and fun. They suggested that this protocol should be available more frequently in clinical settings or at home to facilitate continuous improvement.

Discussion

Principal Findings

This study demonstrated the feasibility and therapeutic benefits of a game-based RMD for improving manual dexterity in children with CP. Both the XG and the CG showed significant improvements in the PDMS-2 subtests and the CUE assessment of manual dexterity. In addition, the XG outperformed the CG, with greater improvements in PDMS-2 grasping and VMI as well as higher success rates and fewer movement errors in the CUE assessment. Additionally, parents reported an increase in their children's independence in daily tasks, reflecting the positive impact of the game-based exercise program on functional hand use.

The RMD's design and functionality are crucial to achieving the observed therapeutic benefits. Various handles of different sizes and shapes were used, which could be handled with a 2-finger grip, 3-finger grip, or whole-hand grasp, and manipulated during gameplay using thumb-finger motion, wrist motion, or a combination of elbow and shoulder motions. Both the types of handle motions and the choice of computer games have specific therapeutic value. Many inexpensive commercial computer games that can be played with the RMD require different levels of movement amplitude and precision, that is, speed and accuracy. Regular introduction of new games and progression through difficulty levels are crucial to maintain the interest and participation of the children.

Several researchers and clinicians emphasize the importance of high repetition and task-specific training in facilitating the recovery of hand function [12,51,52]. One main feature of the RMD game–assisted exercise program was to increase the number of repetitions of goal-directed movements, that is, graded speed and accuracy. Each game was played for 2-3 minutes, with each game event lasting approximately 2 seconds, resulting in 60-90 goal-directed game movement responses per game. Typically, each child played several computer games for 30 minutes. Thus, during each exercise session, the children

XSL•FO
RenderX

made several hundred game movement responses. This high number of repetitions involved goal-directed, precision movements with random directions, variable amplitudes, and speeds. Additionally, visual feedback of the game paddle relative to various moving game objects was always available. Continuous visual feedback guided the position and motion of the game paddle or sprite rather than the object being manipulated. This type of practice promotes implicit learning of eye-hand coordination [53,54].

Initially, children with severe impairments succeeded in games that involved slow movements and low precision, such as large paddle sizes, large game target objects, few distractor objects, and limited cognitive demands. Children with moderate to mild impairment could engage in a larger variety of games that had faster movement speeds, greater movement precision, and added cognitive demands.

There are no published reports that have calculated the minimal clinically important difference (MCID) for either grasping or VMI subtests. However, the MCID for the total motor quotient has been reported to be 8.3% [55]. In this study, the percentage improvement in grasping and VMI subtests for the XG was 12% and 9.3%, respectively, exceeding the MCID reported for the total motor quotient. The improvements observed for the XG were significantly greater than those observed for the CG, that is, 4% for grasping and 2% for VMI. In the previous study [3], a randomized clinical trial evaluated the effects of a game-based exercise program using an IB computer mouse on manual dexterity in young children with CP aged 4-10 years. The CG received task-specific training similar to that used in constraint-induced movement therapy. Each group received 16 weeks of therapy, 3 times per week. They observed an 18% improvement in PDMS-2 grasping and a 12% improvement in PDMS-2 VMI for the group that received the game-based exercise program. Improvement in the CG was 12% for PDMS-2 grasping and 9% for PDMS-2 VMI. In the previous study [3], the intervention lasted 16 weeks, twice as long as the duration of this study. This discrepancy likely explains the variation in percentage improvement observed in grasping and VMI between the 2 studies: 18% versus 12% for PDMS-2 grasping and 12% versus 9.3% for PDMS-2 VMI.

The PDMS-2 grasping measures daily activities involving the fingers of both hands, such as picking up small objects, buttoning and unbuttoning, stringing beads, and using hand tools. Significant improvements in PDMS-2 grasping were observed despite these tasks not being practiced during the game-based manipulation exercise program. The PDMS-2 VMI assesses an individual's ability to use visual perceptual skills for various eye-hand coordination tasks, including stacking blocks and drawing figures. In this study, the RMD game tasks required precise movements based on visual feedback from the moving game objects. This requirement is reflected in the substantial improvements seen in both the PDMS-2 tasks and the CUE object manipulation tasks.

Most parents expressed their willingness to join the trial because therapy focused on manual dexterity and addressed the lack of eye-hand coordination in their children. Both the XG and CG showed significant improvements in success rate and a decrease in movement error in all 4 object manipulation tasks, with moderate to large effect sizes. There was a significant time×group interaction, demonstrating that improvements in success rate were significantly greater for XG compared to CG.

The improvements observed in the CUE assessment of function, as well as in both the PDMS-2 grasping and VMI, were consistent with the quantitative data. Parents reported positive changes in their child's hand function, eye-hand coordination, overall level of participation in daily activities, and concentration levels. They agreed that the addition of computer games was motivating and encouraged their children to actively participate and have fun during exercise sessions. Most parents from the XG commented that the game-based exercises were challenging yet engaging and that their children enjoyed playing them. During the initial stages of the protocol, some parents observed reluctance due to a lack of understanding of the computer games and difficulty with producing precision movements. However, after 2-3 sessions, most parents felt that the computer game–based platform provided a promising way to improve children's compliance with the therapy program. Other studies incorporating computer games in therapy have also reported that children enjoyed the games used in their exercise programs [13,15,34,35].

Future Enhancements

The unidirectional force mode, while assisting movement in 1 direction, does not ensure that the handle movements will successfully interact with the target game objects. Additionally, 1 movement direction may receive resistive force, which may not be desirable. A real-time intelligent control scheme is under development, involving communication between the manipulandum and the RTP game. The controller will receive the coordinates of both the game targets and the game paddle. This knowledge about movement directions and amplitudes will be used to determine the direction and magnitude of the force required to rotate the handle and assist the subject in moving the game paddle as needed to interact effectively with the game target objects. This closed-loop assistance can be provided in both movement directions during gameplay, amplifying limited and small voluntary movements of those severely affected while allowing opportunities for progression with increased movement demands.

It is also common for children with paralysis to experience sudden, uncontrolled movements and difficulty managing their strength. To address this, a design change was made after the study to allow the device to be securely attached to a table, preventing unwanted movement during use. The modified device can now be easily attached to a table, providing greater stability and control during gameplay.

Conclusions

The results of this feasibility study demonstrate the feasibility, acceptability, and positive outcomes of the RMD game–based exercise program for the rehabilitation of hand function in children with CP. The findings indicate that computer game–assisted exercise programs can improve manual dexterity in children with CP. The results support further research and development related to the effects of computer game–assisted

XSL•FO
RenderX

rehabilitation technology. The long-term effects of computer game–based training on hand function will need to be confirmed in future RCTs.

Abstract

Background: People with Parkinson disease (PD) often report low volume and reduced intelligibility of speech. Common household devices that use voice-assisted technology (VAT) require users to speak slowly, clearly, and loudly for the technology to function. For people with PD, this can be challenging, but this also suggests that VAT may have potential as a therapeutic tool. While VAT is an emerging health care technology, it is important to better understand the thoughts and experiences of people with PD who are already using it despite having speech and voice difficulties.

Objective: This study aimed to explore experiences of using VAT to address hypokinetic dysarthria secondary to PD, based on the perspectives of people with PD and family carers.

Methods: People with PD experiencing mild to moderate speech changes who were smart speaker users, and their carers, were invited to participate in 1 of 4 in-person focus groups. Between September and December 2024, focus groups were audiovisually recorded. A semistructured topic guide informed by published evidence was used to guide discussions. Results were transcribed and analyzed through a framework analysis approach (managed using NVivo software).

Results: A total of 15 participants, including 8 (53%) people with PD and 7 (47%) carers, participated in 4 in-person focus groups. Findings revealed shared experiences with VAT that were marked by its therapeutic potential and practical challenges. Five main themes were identified: (1) therapeutic potential for speech and voice, with subthemes of changes in volume, intelligibility, and clarity of speech; the role of VAT feedback; and VAT as an everyday device; (2) distrust of technology, with concerns surrounding data privacy, the listening nature of devices, and measures users take to protect themselves; (3) frustrations with devices, including devices not understanding, devices timing out, and the lack of conversation; (4) support needs, including the impact of a lack of knowledge and the need for education and guidance; and (5) design considerations for a future VAT tool in speech and language therapy (SLT).

Conclusions: This study extends on previous research findings, demonstrating that VAT may be acceptable to people with PD to create changes in volume, clarity, and intelligibility. However, attention must be given to users' privacy concerns and frustrations with devices before VAT can used as a tool in SLT. Future research should design solutions to address current usability challenges with people with PD and professionals in three ways: (1) co-designing education and guidelines for people with PD, describing the use of VAT for speech and voice difficulties; (2) refining commercial VAT for use in SLT; and (3) establishing the feasibility of a therapeutic VAT intervention for people with PD with speech and voice difficulties.

KEYWORDS

Parkinson disease; voice-assisted technology; smart speakers; speech and voice; dysarthria; speech and language therapy

Introduction

Background

Parkinson disease (PD) is a progressive neurodegenerative condition that presents with rigidity, slowness of movement, and tremor [1]. In the United Kingdom, approximately 145,000 people are living with PD, including more than 4200 in Northern Ireland [2]. One of the most prevalent effects of PD is a change in speech and voice, affecting up to 90% of people with PD [3]. Also known as hypokinetic dysarthria [4], reduced volume and unclear speech worsen over time, impacting intelligibility and clarity of speech. These changes impact activity, social participation, and well-being [5].

Despite these figures, 48% of people with PD in the United Kingdom do not access speech and language therapy (SLT) [6], which may be due to long waiting lists, regional clinician shortages, and barriers related to the resource-intensive nature of therapy programs such as Lee Silverman Voice Treatment. Therefore, there is a need to explore therapy alternatives to make SLT accessible to more people with PD [7].

Voice-assisted technology (VAT) is defined as a device that uses natural language processing or automatic speech recognition (ASR) to interpret words and convert them into actionable requests. The most common commercially available VAT devices are Amazon Alexa and Google Home. Amazon Alexa is manufactured by Amazon. People with PD have been identified as a population likely to benefit from using VAT therapeutically [8]. However, VAT systems currently demonstrate poor recognition of dysarthric speech, with error rates increasing alongside speech severity [9,10]. This results in the device giving auditory or visual feedback using the recognition light, which prompts some participants with speech difficulties to change their speech to enable interaction with VAT [11-13]. Duffy et al [13] highlighted the potential of VAT to improve speech of people with PD. This study used an online survey to explore the knowledge and experiences of people with PD with VAT, in addition to reporting effects of using VAT on speech and language. In total, 290 participants reported making a deliberate effort to improve their speech clarity when interacting with VAT by specifically speaking “slower, clearer, and louder.” Similar speech changes have been reported across literature in other conditions [14,15], and this is strikingly similar to the goal of traditional SLT for people with PD. However, this survey did not solely investigate the impacts of using VAT on speech and voice in an SLT context and any reported impacts were limited by the constraints of survey methodology. Therefore, this study builds on the study by Duffy et al [13], using focus groups to provide a more in-depth and nuanced understanding of what factors contribute to this effect of increased volume and intelligibility, specifically with people with PD who use VAT regularly and report speech and voice difficulties. Focus groups may provide richer insights into experience of speech and voice difficulties, including facilitators and barriers to using VAT. Therefore, an exploration of how VAT is being used by people with PD with speech and voice difficulties and their carers is required to provide an understanding of how to use VAT to improve speech and voice outcomes as part of SLT. This ensures new technologies, such as VAT, can be used in a way that meets end user needs and may lead to a higher chance of uptake in the future [16]. An additional paper describes the perspectives of speech and language therapists regarding VAT as a tool for speech and voice difficulties in PD.

This study explores the experiences of using VAT to address hypokinetic dysarthria, secondary to PD, from the perspectives of people with PD and carers.

Objectives

This study had the following objectives: (1) to understand the type, extent, and nature of VAT use while experiencing hypokinetic dysarthria secondary to PD; and (2) to understand experiences of those who are facilitating people with PD to use VAT with hypokinetic dysarthria.

Methods

Qualitative research methods such as focus groups allow individuals to reflect on their own experiences in a supportive environment while also developing novel contributions though group discussions [17]. In-person focus groups were used for data collection to encourage conversations among participants and create richer data.

Ethical Considerations

This study was reported in accordance with the Consolidated Criteria for Reporting Qualitative Research checklist [18] and is part of a larger PhD study that received ethical approval from the Ulster University Research Ethics Committee in July 2024 (approval number FCNUR-24-016-A). All participants provided informed consent. Privacy and confidentiality were ensured—only the research team were able to see personal demographic data, and data will only be held as long as the university guidelines and General Data Protection Regulation require. Following transcription, all participants’ data were anonymized. Participants were reminded that if they knew another participant at the focus group they were to respect their right to confidentiality in their participation. No participants in the research were given payment.

Patient and Public Involvement

Before study development, a partnership was created between third-sector organization Parkinson’s UK Northern Ireland and the research team to provide a voice for people with PD and their carers throughout the research. A person with PD and a caregiver were recruited through Parkinson’s UK Northern Ireland and a speech and language therapist was recruited through research connections as “experts by experience” to co-design the research. These 3 patient and public involvement representatives influenced and informed various aspects of the study design, including participant information sheets, interview

XSL•FO
RenderX

guides, and consent forms. They also contributed to the study's conduct and dissemination through input during online meetings, advising on recruitment strategies, focus group location, and duration. Experts by experience were asked to provide feedback on information sheets via email, indicating that complex language should be avoided. Consequently, the information sheets were revised to include more patient-friendly language. Furthermore, feedback on the interview schedule was also provided, with experts by experience suggesting that focus groups should be conducted in-person rather than online, as they felt it could limit technological barriers to participation. They also suggested that introductions from researchers should include an informal preamble about smart speakers, emphasizing the technology's relevance for people with PD and for the speech and language therapists working with this population. As a result, focus groups began with personal stories about PD and the professional journeys and provided background on what smart speakers are, why they might work to improve speech and voice, and included the lead author's personal experience using her own Alexa device. The experts by experience offered valuable lived experience insights to the academic team during data collection and charting, including suggestions to offer the option of individual interviews to speech and language therapists who were unable to attend focus groups, to maximize data collection.

Study Recruitment

Recruitment advertisements were posted on the research portal, featured in the Research Support Network monthly emails, and distributed as flyers to Parkinson's Support groups local to Northern Ireland. Some of the participants had established a relationship with the lead researcher (JM) due to work with Parkinson's UK in Northern Ireland and knew about her reasons for conducting research.

The population size could not be determined due to a lack of up-to-date data on the number of people with PD experiencing speech and voice difficulties in Northern Ireland. Therefore, 2 focus groups per each population, each comprising 3 to 4 participants, were chosen to better support people with communication disorders and provide variations in opinion while allowing data saturation. This is a smaller number than the 6 to 8 participants typically recommended in the literature, and was purposefully planned to allow discussion of ideas without discouraging quieter voices, as can happen in large groups. Participants were asked to contact the research team to express their interest in the study and were screened via telephone by the primary researcher according to predefined inclusion and exclusion criteria (Textbox 1). Potential participants were sent study information and consent forms by email or post, depending on their preference, and were asked to indicate their suitability for participation in a focus group. Once consent was gained a demographic survey, the Voice Handicap Index (VHI) [19] and a Digital Health Readiness Questionnaire was sent to participants. The VHI was included as it is a standardized tool used by speech and language therapists to measure clients' self-reported changes in voice and is commonly used with the PD population to ensure a person-centered approach to treatment, rather than focusing solely on the disease or impairment [20]. Carers did not receive the VHI.

Textbox 1. Study inclusion and exclusion criteria for people with Parkinson disease (PD) and carers.

Inclusion Criteria for People with PD

- Adult aged >18 years
- Mild to moderate dysarthria or voice difficulties (to include users of augmentative and alternative communication
- Diagnosis of PD
- Current or previous use of voice-assisted technology (VAT)
- Able to participate in a focus group up to 90 min

Exclusion Criteria for People with PD

- Moderate or severe cognitive impairment
- History of other neurological disorders

Inclusion Criteria for Carers

- Adult aged >18 years
- Live with or care for a person with PD
- Experience of facilitating use of VAT with a person with PD

Procedure

Each focus group or interview was facilitated by a female speech and language therapist (JM), with a researcher present (qualified speech and language therapist or health care professional with a PhD), and lasted between 1 hour, 9 minutes, and 1 hour, 21 minutes. Focus groups were conducted in person at the Ulster University Belfast campus. A semistructured topic guide informed by literature was prepared in advance to ensure methodological consistency across focus groups, and the lead author attended focus group training before conducting the research. The topic guides were differentiated to reflect the slight differences in lived experience between people with PD and their carers when using or facilitating VAT. Prompting

XSL•FO
RenderX

questions encouraged equal participant contributions and topic guides were differentiated to reflect the perspectives of each stakeholder group. This was reviewed by patient and public involvement representatives, including a person with PD, a carer, and a speech and language therapist, and refinements were made to the phrasing of questions. A summary of the questions posed to people with PD and carers is provided in Multimedia Appendices 1 and 2. Participants were invited to discuss their experiences of using VAT to address the main research question: to explore the experiences of people with PD and their carers in using VAT to address hypokinetic dysarthria. Field notes of key ideas were taken during the focus groups.

Data Analysis

Focus groups were audiovisually recorded and transcribed using Microsoft Teams. To ensure methodological rigor and ensure contextual accuracy, transcriptions of videos were completed within 24 hours of the focus groups. All transcriptions were manually checked, and any errors were corrected before analysis. All personal and identifiable information was anonymized before analysis.

Framework analysis was used to structure the work as it enables an in-depth analysis of themes across a dataset and allowed researchers to collaborate [21]. In addition, given the lead researcher's involvement with the Parkinson community, it allowed awareness of any biases and improved transparency [22]. The five stages of framework analysis were followed [23,24]: (1) familiarization and data immersion, (2) develop theoretical framework, (3) indexing and data charting, (4) data summary in analytical framework, and (5) data mapping and interpreting. The group discussion further refined the initial theoretical framework. The initial draft framework was developed using published evidence [8,25].

Data recordings were transcribed before being imported into qualitative data management software NVivo (version 14; Lumivero) for analysis. Following data familiarization, initial ideas were documented on a mind map with a reflexive journal by the primary researcher (JM) and shared for discussion with coauthors (GK, OD, and KP). The reflexive journal noted authors' initial thoughts during transcription of each dataset and allowed the lead author to consider connections, similarities, and differences between data. Upon first reading, the lead author created a mind map to group these ideas together and create initial codes for analysis. Further discussion and data immersion allowed creation of draft themes, where the lead author created a second mind map considering connections between the codes, and how they could be grouped into overarching categories. Using a mind map allowed the researchers to reflect upon biases and assumptions and explore alternatives in data interpretation to ensure results accurately represented participants' lived experiences. The framework was refined to reach consensus at further meetings with coauthors. Data indexing was completed by the primary researcher (JM). Summarization of indexed data into codes and thematic charting was completed by JM and discussed with coauthors (GK, OD, and KP) and used to formulate the final theoretical framework [21]. Original data extracts from transcriptions are included, alongside the participant number, to enhance trustworthiness and credibility of findings. Furthermore, the results were sent to all participants for member checking to ensure that the written findings reflected their lived experiences and to enhance rigor of the research. Most participants responded that they were satisfied with the reporting of research. One participant reported that they appreciated that the researchers stayed true to the "Northern Irishisms" and sentence structure used during focus groups, as this accurately represented how ideas were expressed. Changes made included checking the anonymization of quotes and incorporating headings for subthemes, as some participants felt that these changes made it easier to follow for lay readers.

Results

Participants

People with PD and their carers (n=16) were recruited via Parkinson's UK in Northern Ireland, a third-sector organization. A total of 16 participants were recruited, of whom 15 (n=8, 53% people with PD and n=7, 47% carers) participated in focus groups. One carer dropped out after recruitment due to scheduling conflicts. Each group consisted of 3 to 4 participants per focus group across the 4 focus groups (Table 1). Our experience of holding separate focus groups for people with PD and their carers and not involving professionals was positive. People with PD provided open and honest reflections [21], with each contributing to the conversation, which likely would have been constrained in a mixed group. However, this resulted in a distribution of participants by sex, with mostly male people with PD and female carers. People with PD and their carers who were familiar with each other from the wider Parkinson community encouraged each other in conversations providing the richest insights and the longest focus groups. One participant in a group whose members did not know each other reported the following: "I think discussing then with each other...you learn from each other. I've learnt things from this group tonight." [P5].

A total of 16 participants were recruited to the study; however, only 15 participated. People with PD (n=8) and partners or carers (n=7) attended in-person focus groups at Ulster University Belfast (Tables 2 and 3). Most of the people with PD were male (7/8, 87%) and ranged in age from 57 to 77 years. Most of them (7/8, 87%) had been diagnosed for over a year, while one had been diagnosed more recently.

Table 1. Format of qualitative data collection focus groups and number of participants in each group.

Population and format	Number of participants	Length of time
People with Parkinson disease		
In-person focus group 1	4	1 h 21 min
In-person focus group 2	4	1 h 12 min
Ca rers or partners		
In-person focus group 1	3	1 h 9 min
In-person focus group 2	4	1 h 12 min

Table 2. Demographic characteristics of people with Parkinson disease (PD) in in-person focus groups.

Person with PD ID	Gender	Age (y)	Year of diagnosis	Voice Handicap Index severity
P1	Male	59	2012	Moderate
P2	Male	61	2013	Normal
P3	Male	57	2023	Severe
P4	Male	73	2020	Moderate
P5	Male	77	2022	Moderate
P6	Female	70	2019	Normal
P7	Male	77	2014	Moderate
P8	Male	68	2017	Mild

Table 3. Demographic characteristics of carers in in-person focus groups.

Carer ID	Gender	Age (y)
P9	Female	55
P10	Female	65
P11	Female	67
P12	Male	72
P13	Female	74
P14	Female	66
P15	Female	57

The VHI is a subjective self-rating questionnaire for people with voice problems, where people with PD self-rated the impact of their voice disorder on their quality of life. The VHI uses statements about voice problems, which are ranked from 0 to 4 on frequency: 0=never, 1=almost never, 2=sometimes, 3=almost always, and 4=always. There are 10 questions across 3 sections, with 30 questions in total [19]. This covers the functional, emotional, and physical impacts of voice disorders, with a total score of 120. Scores between 0 and 30 show mild impairment, 31 to 60 moderate impairment and 60 to 120 severe impairment. On average, the participants reported a moderate impairment on the VHI [19] between 42 and 52, with 2 reporting very mild impairment (5 and 21) and one within the severe range (87).

The Digital Health Readiness Questionnaire required participants to rank 20 statements about technology use and ability using a 5-point Likert scale: 1 represented never or strongly disagree; 2 represented rarely or disagree; 3 represented sometimes or neither agree nor disagree; 4 represented often or agree; and 5 represented daily or strongly agree. Statements covered digital access, use of digital technology, digital literacy, digital health literacy, and learnability. Although 6 people with PD had good digital access, that is, they used the internet, a laptop, and a smartphone or tablet daily, only 3 used health-related applications, and the majority lacked digital health literacy. Participants had mixed digital skills. While 5 could complete basic tasks such as sending emails, sharing pictures, and video-calling, 3 indicated experiencing more difficulties. Moreover, 7 were motivated to learn about technology, and 5 agreed that digital skills could positively impact their health. Complete results from the Digital Health Readiness Questionnaire can be found in Multimedia Appendix 3.

Of the 7 carers or partners, 6 (86%) were female and 1 (14%) was male and ranged in age between 55 and 74 years. All carers had good digital access and 5 used health-related applications. Overall, carers had strong digital skills and almost all could complete basic tasks such as sending emails, sharing pictures, and video-calling confidently. All 7 carers were motivated to

XSL•FO
RenderX

learn about technology and 6 agreed that digital skills could positively impact their health.

There were five main themes identified across the groups and datasets: (1) therapeutic potential for speech and voice, (2) distrust of technology, (3) frustrations with devices, (4) support needs, and (5) design considerations for a future VAT tool in SLT. Table 4 presents on overview of the themes and subthemes. The main and subthemes identified by each group are outlined with appropriate quotes in the subsequent sections to enhance credibility of results, without identifying the speaker.

Table 4. Results from research with themes and subthemes listed.

Themes	Subthemes
Therapeutic potential for speech and voice	• Changes in volume, intelligibility, and clarity, as well as role of feedback • Can act as a communication partner • A useful or everyday device
Distrust of technology	• Data privacy • Listening nature • Measures to protect themselves • A more pragmatic approach
Frustrations with devices	• Repetition, timing out, or error scaffolding • No conversation or generalization • No therapeutic relationship
Support needs	• Impact of lack of knowledge • Need for education
Design considerations for a future voice-assisted technology tool in speech and language therapy	• Develop a speech and language therapy program • Monitoring speech and voice changes • Additional feedback

Theme 1: Therapeutic Potential of VAT

Participants reported several facilitators of VAT that indicate its potential use as a clinical tool for the management of speech and voice difficulties.

Changes in Volume, Intelligibility, and Clarity and the Role of VAT Feedback

VAT promoted positive changes in volume, clarity, and intelligibility of speech. Positive implications for activity, participation, and well-being were also reported. Interacting with VAT caused people with PD to use adaptive strategies to change their speech.

For example, participants reported increased volume when talking to VAT:

> *She raises her volume and very deliberately, and says "Alexa television on."* [P12, carer]
>
> *I'm a bit like you; I would shout at it. Raise my voice.* [P5, person with PD]

Others described increased clarity of speech and a slowing down their pace:

> *I would say "Alexa play me Mozart the marriage overture," and it comes out with some pop tune, and then I'll shout back, and then I catch myself on, and speak slowwwwly and then it would work.* [P8, person with PD]
>
> *I have to step back and compose myself, I suppose mentally, and speak out slower and clearer because I realised it's my voice that's not really getting to her.* [P5, person with PD]

One participant summarized their interactions with VAT as follows:

> *I find myself speaking much louder, slower and clearer, and then it finally pumps out the record!* [P8, person with PD]

The feedback provided by VAT created awareness and prompted people with PD to adapt their speech using strategies. This feedback was seen to be key to changes in volume, clarity, and intelligibility as participants indicated the following:

> *It doesn't respond, maybe the first time. OK, you know that she hasn't either heard you or you need to speak slower and louder.* [P6, person with PD]
>
> *You should learn if Alexa doesn't hear you, Alexa won't respond. You learn to repeat yourself a bit more clearly.* [P12, carer]

VAT as a Communication Partner

Carers reported that VAT could also act as a communication partner for people with PD with speech and voice difficulties, providing opportunities to rebuild confidence in using their voice:

> *There aren't a huge amount of opportunities during the day for him to have a really good conversation until I come home. So... its another avenue for him to use his voice.* [P9, carer]
>
> *There's a benefit, because if it's given him more confidence to use his voice then, that's important.* [P9, carer]

XSL•FO
RenderX

A Useful Everyday Device

In addition, people with PD and their carers reported everyday functional uses of VAT, ranging from basic requests, such as asking for the date and time, weather updates, setting reminders and timers, and playing music, to more complex requests such as finding recipes and cooking, searching for facts, checking sports scores, singing, participating in quizzes, and controlling smart home appliances.

Most participants reported using an Amazon Alexa Echo Dot device, (third or fifth generation), or a Echo Dot Kids. Only a few participants reported using a Google Home or Google Nest device. Participants owned between 1 and 3 devices in their homes, and their frequency of use varied widely from once or twice a day to more than 10 times daily. They reported having a VAT device in their kitchen, living room, or bedrooms. Playing music and listening to the radio or news were popular requests among participants in addition to medication reminders and controlling smart home appliances:

> *I want to get a news programme, I want music, whatever. Sit back and listen to the news or just to music and updates.* [P5, person with PD]

> *I think it's great for the alarm because we're both forgetting. I say ', Did you take your tablet?' It's the always forgetting.* [P10, carer]

> *It controls everything else in the house. We have to have one upstairs at night so we can get into bed at night and turn off the landing lights because the switch for the landing lights is under a picture, a big, big heavy pictures so we can't get at it.* [P14, carer]

In addition, participants used their VAT devices for entertainment, for example, games and singing:

> *Games! You ever played games on the Alexa Party game? They all have to be speaking ones.* [P2, person with PD]

In addition, people with PD suggested that VAT was easy to use because of voice interaction and carers explained how this overcame the physical limitations associated with PD:

> *Well, I'm so used to the convenience of Alexa and not physically going and turning the radio on...You use the voice, you've got it.*" [P8, person with PD]

> *You can set that up where she can phone your contacts, and that'll probably be good for my husband because he can't use his phone. Tremor.* [P10, carer]

Theme 2: Distrust of Technology

A distrust of VAT devices, with concerns surrounding data privacy, General Data Protection Regulation compliance, and governance, was reported frequently by participants. The inhuman nature of VAT, perceptions of the device as an outsider, and sometimes fear of the technology contributed to distrust. Other participants were less concerned about these risks.

Data Privacy

People with PD and their carers expressed caution about VAT devices eavesdropping on their conversations, as the devices are always listening. These concerns resulted from media reports and a lack of transparent communication from VAT companies regarding data privacy:

> *I just worry about it being a listening ear in the room. Too many people know too much about you sometimes I think.* [P13, carer]

> *Adverts start popping up and you're going that's spooky, because that's what we were talking about.... They are there and they are listening, you know that.* [P15, carer]

The Listening Nature of Devices

This listening nature of devices contributed to participants' suspicions and distrust of VAT, particularly regarding hacking:

> *I suppose I'm one of these people that will sit back and say how does this work. Is it all OK? Is there anything about this that's sinister?* [P11, carer]

Protection Measures

Furthermore, privacy concerns with VAT devices meant that participants did not openly welcome devices and were distrusting, with some taking measures to protect themselves:

> *I still regard it as an intruder. Handle with care.* [P5, person with PD]

> *You know the way you can programme your sat NAV to have a voice from Northern Ireland? I would really like her to be one of us. I think that would just, maybe it wouldn't feel as if it was so much of an intruder in the house.* [P9, carer]

> *I would switch it off, whenever it's not being used. Because of this—we got a warning, we got a message from the police, Watch smart phones, watch Amazon Alexa's because they monitor everything.* [P5, person with PD]

Pragmatic Attitudes

Despite this, some participants took a more pragmatic approach to VAT and their privacy. For example, one participant felt that VAT devices did not pick up sensitive information:

> *You've got to be sceptical to some extent of the conspiracy theorists who say that Alexa is listening to you...what are they going to do? What benefit do they get out of it?... They're welcome to listen to our conversation! Very exciting. "You want a cup of tea?" "Yeah." That's it!* [P12, carer]

Theme 3: Frustrations With Devices

Participants described frustrations with VAT devices, including not being understood, having to repeat themselves, devices timing out, and difficulties with error scaffolding. However, these issues did not necessarily prevent them from using the technology. Challenges with having a conversation or developing therapeutic relationship with VAT were also highlighted.

XSL•FO
RenderX

Frustration

Frustration when interacting with VAT was widely reported by people with PD. This was often linked to VAT not understanding people with speech and voice difficulties and them having to repeat their requests:

> *Hm, yeah I curse at it every time.* [P4, person with PD]

> *He'll say something and his voice is so low, that it doesn't catch it. And then he says it again and then he gets frustrated and he just says to me "tell that thing to do it."* [P14, carer]

VAT devices often timed out before participants finished speaking, which further contributed to frustration. One person with PD reported the following:

> *If I do, longer sentences usually the gap in between it starts going and answering half the questions, and I go hadn't finished yet!* [P2, person with PD]

Another partner described that VAT "just runs out of listening time" [P14, carer].

Feedback in this paper refers to both the blue light on the VAT devices that turns on when the device is listening, and the verbal feedback the devices may give when trying to action a request. Participants reported some difficulties taking action following VAT feedback:

> *And also Alexa, because I don't know what it's heard, it's really hard.* [P2, person with PD]

> *He will ask her to play a song or something and she'll play something completely different. And I say you have to speak louder or she didn't hear you, she didn't understand what you said.* [P10, carer]

Lack of Conversation

VAT's limited conversational ability in standard settings was considered as unreflective of real-life communication and posed a challenge for delivering therapy. One person with PD reported the following:

> *To me if I'm doing anything with Alexa its either a game or your perfunctory task, you're saying do this, do that or ring somebody. It's not something you're having a conversation—it's when you get into that conversation flow, it's trying to remember to keep your voice going sometimes.* [P2, person with PD]

> *If I'm at the kitchen sink and she's putting stuff away with my back turned to her, you know, and she wants to say something she doesn't want to say, "HUSBAND, I'm going to say something. Now, listen to me." Okay? That does not happen.* [P12, carer]

In addition, this partner expressed skepticism of regarding VAT's ability to help with therapy generalization:

> *Well, I mean if she has to raise her voice and enunciate clearly and speak slowly to Alexa, that doesn't feed through to speaking with me.* [P12, carer]

Lack of Therapeutic Relationships

The perception that VAT might replace real speech and language therapists may be considered as a potential barrier. The therapeutic relationship developed between speech and language therapists and clients was considered missing with VAT with participants considering human clinical decision-making as an integral part of therapy:

> *You know you can't be left to your machine and yes, with no humanity to it, you know? You need that person.* [P11, carer]

> *It's face to face, it's a person, it's somebody that's giving you visual feedback and giving you auditory feedback all the time and is setting the pace of the of the lesson OK. And that's got to be important.* [P12, carer]

Theme 4: Support Needs

Impact of a Lack of Knowledge

Participants explained that a lack of adequate knowledge about VAT capabilities and limited experimentation prevented them from fully using the potential of the devices and understanding how VAT could be a useful tool for PD:

> *I think there is a lot of potential in Alexa. The problem for us is, you don't know what you can and can't do with Alexa.* [P2, person with PD]

> *We don't really know what he can do with it.... We've never done anything else with it except control the things around the house.* [P14, carer]

Need for Education and Guidance

People with PD and their partners suggested education and guidance were priorities. Suggestions included practical and technical support and layman's explanations about how VAT use could impact speech and voice to help people with PD understand why they were using the devices during therapy:

> *Most importantly for us, we need to know why we're doing it as well. I think people have Parkinson's need to know.* [P2, person with PD]

> *I want to, I suppose, maybe to learn to use it for its available uses.* [P5, person with PD]

> *It just frightens me to go into it and start fiddling about with settings. So maybe some sort of training or help.* [P13, carer]

Participants discussed various methods for this education, including workshops with demonstrations, videos, reference manuals, and leaflets. Overall, it was clear that more than one delivery format of guidance would cater to varied abilities and should, "take Parkinson's into consideration. And everyone at different level, you know, different abilities and different changes" [P13, carer].

XSL•FO
RenderX

Theme 5: Design Considerations of a Future VAT Tool in SLT

Develop an SLT Program

Participants provided design considerations for the future therapeutic use of VAT for people with speech and voice difficulties in SLT, including developing an SLT "program" with interactive features, the ability to monitor speech and voice progress, and additional prompting and feedback.

Some participants embraced the idea of SLT delivered predominantly through VAT while others indicated they preferred a more hybrid approach of "speech therapist plus programme":

> *If there was a built-in programme, you could interact with Alexa.* [P3, person with PD]
>
> *So it could be some kind of speech exercises.... Like an app even that you could put on it.* [P14, carer]
>
> *If there was maybe an initial speech and language session for guidance, for training and then you're set off on your own to manage yourself.* [P9, carer]

Despite this, a minority of carers felt, "it is hard to see it work," or simply preferred in person speech therapy.

Prompts and reminders could be useful to help facilitate home practice of exercises with VAT and may help people integrate everyday practice:

> *So he gets into the habit of remembering to take a breath, remembering just. Y'know, here's a reminder for you, do this or do that, practice these breathing exercises in and out and projecting your voice.* [P14, carer]

Participants suggested numerous ideas for how an SLT Alexa skill might function or contain, including exercises, reminders to complete therapy tasks, conversation practice, feedback and prompting, and the ability to monitor progress or maintenance across tasks. For example, exercises could be delivered through an Alexa skill, which could target articulation, breath support, phonation, singing, and reading:

> *If your pronunciation is wrong, you look at your pronunciation before and after a game.* [P1, person with PD]

Maybe have Alexa read it first and then you read it. Or you read it and then have her read it back. [P9, carer]

Monitoring Speech and Voice Changes

The ability to track changes and measure progress in speech and voice was a common suggestion, aimed at supporting the maintenance of these skills over time:

> *The thing is that you're competing against your voice of yesterday. And if you can keep it the same as your voice of yesterday, we're ahead.* [P2, person with PD]
>
> *You could do, y'know your exercises at the start, and then some word work, and then go onto reading paragraphs in the second week.* [P1, person with PD]

Percentages and scores were suggested as feedback methods provide a measure of speech and voice when using VAT:

> *So if you did Alexa, and said to Alexa "Count to ten today" and it said "You counted to ten and six numbers were good, 4 numbers weren't."* [P2, person with PD]

Some people with PD described the positive impact this would have, while others felt differently, suggesting that feedback could be demotivating, counterintuitive, and negatively impact well-being:

> *What you would hopefully learn was, "I was better today than I was yesterday" and you'd realise where you put the emphasis or where you slowed down, and it'd guide you.* [P5, person with PD]
>
> *I don't want it to be a diagnosis to say your voice is getting weaker. I want it to be, "If you keep this going for Alexa, your voice will get stronger."* [P2, person with PD]

People with PD proposed using VAT's feedback light as an alternative to scores:

> *Alexa is going playing the music and you're singing along, and it goes "You're red because you're not high—we can't hear you." And then you sing high and it goes to yellow. And then you go to green. Green means your singing it properly.* [P2, person with PD]

A feedback feature to facilitate self-awareness of speech and voice difficulties may also be included. People with PD suggested that hearing how VAT interpreted their speech could help facilitate the use of adaptive speech strategies.

> *You say that, it records and sends it back, "Oh, that's not right." That's what she heard, you know. That's what it's hearing, and then you pronounce it right.* [P1, person with PD]
>
> *And the programme would go, "You're going too fast. You're going too slow. I don't understand." Yeah. So just give you feedback because see, once you've got feedback you can go, ok right it says slow down. So you go slooooower.* [P2, person with PD]

In addition, more specific feedback from VAT on speech and voice was suggested:

> *If it could interact with you and say you're not speaking clearly enough. I'm speaking at it and "You're not clear enough, you're better now."* [P5, person with PD]

Discussion

Principal Findings

The aim of this study was to explore the experiences of using VAT to address hypokinetic dysarthria, secondary to PD, from a range of stakeholder perspectives. People with PD and their carers discussed the therapeutic potential of VAT for speech and voice difficulties, with it being regarded as a novel technology that could promote louder speech with increased clarity and intelligibility. However, challenges such as

XSL•FO
RenderX

frustrations with devices and distrust of technology must be addressed. By meeting participants' support needs and integrating feasible design considerations, the use of VAT as a tool in SLT may be considered in future research.

Evaluating the Therapeutic Potential of VAT

People with PD reported that using VAT made them speak clearer and raise their volume. This indicates that VAT can facilitate unlimited practice attempts and prompt participants to adapt their speech [14,15,26], resulting in a therapeutic benefit. These findings build on existing research that highlights VAT's potential role in improving and maintaining speech volume, clarity, and intelligibility [8,11,13,25] and the role of VAT feedback in shaping improvements in self-awareness, which led to self-reported improvements. In addition, VAT could facilitate practice of articulation, clarity, and volume exercises—the speech subsystems commonly targeted by speech and language therapists during therapeutic management of PD [27]. Thus, VAT could maximize therapeutic outcomes, while reducing health care resource demands associated with intensive interventions such as Lee Silverman Voice Treatment.

While this research focused on people with PD, previous research has also emphasized a gap in knowledge regarding potential for VAT as a therapeutic support for people with motor neuron disease with speech and voice difficulties [12]. Given the aforementioned findings, this warrants further research into therapeutic potential of VAT for neurodegenerative conditions as a tool for speech and voice difficulties. This study builds upon the findings by Duffy et al [13] to inform the design of a feasibility trial that meets the needs of users and integrates use solutions current difficulties. To inform practice, future research should consider the studies by Quinn et al [28], who used interviews and device logs to evaluate the acceptability and feasibility of a smart speaker–delivered physical activity program, and Smith et al [10] and Makin et al [29] who used before and after measures to examine if a VAT intervention could improve speech clarity for adults with intellectual disability. Future research may seek to extend the work by Smith et al [10] with people with PD, focusing on volume, clarity, and intelligibility with before and after measures.

Although VAT has therapeutic potential, there are potential caveats that require further exploration. ASR models, which underpin VAT, can be variable in their understanding of speech for reasons other than speech clarity, volume, and intelligibility [30]. For example, device updates, user ethnicity, and regional accents can impact word error rates. Indeed, research indicates that black speakers had a higher word error rate than white speakers when using common commercial VAT systems such as Apple, Amazon, and Google [31]. In addition, VAT users may adapt nonstandard accents to facilitate interactions with VAT [32], which is likely to have implications for users from ethnic minority backgrounds or with regional accents. People who use VAT might change their accents, if they do not have a standard English accent, as well as increasing their volume and speaking more clearly. Therefore, users should be careful that they do not begin to use westernized accents in favor of regional or international accents when using VAT to help the device to understand them better.

The wider literature has also indicated that VATs' limited conversational abilities was a usability issue [33]. It may be suggested that the transactional nature of VAT requests means that using VAT to practice speech may not carry over into real-life conversations [30]. While VAT may be useful to isolate practice of impaired volume and intelligibility across word, phrase, and sentence level, it may be difficult to generalize practice into conversation and create meaningful change in activity or participation. Furthermore, research investigating the error rates of ASR, which underpins VAT, has shown that error rates are higher for conversational speech than for short phrases or read speech in people with speech disorders [34,35]. Therefore, it is difficult to know if VAT could facilitate meaningful conversation practice for people with PD that generates increased real-life conversational participation. Future research should seek to establish how features of commercial VAT could be used to promote more conversational engagement with VAT for people with PD. This would build on the current research, solving the reported barrier of a lack of conversational engagement with VAT, and may enable conversational practice with VAT in the context of SLT.

Turning Distrust of VAT Into Reassurance

Concerns for data privacy, security, and unwanted surveillance are well documented in relation to VAT use among older adults and in therapeutic interventions [8,28,36]. Previous research with people with PD indicated that between 9% and 33% of people expressed privacy concerns regarding VAT [8]. Similar concerns emerged in this study, potentially influenced by significant and rising media discourse about artificial intelligence in the media [37], and perceptions of VAT as an artificial intelligence device. However, other factors may contribute, such as varying levels of digital literacy, as reported among people with PD and their carers in this study, and less frequent use of VAT, which for some resulted in fear toward technology—a pattern observed with the older population [38]. Others were actively embracing VAT, potentially due to a high level of digital capabilities, personal innovation, habit, positive attitudes to technology, or less aversion to risk [39]. While privacy pragmatism and cynicism concur with wider literature [40], other people with PD have previously reported that they are actively embracing new technological advances [8] with high levels of ownership and use of VAT reported among older adults. This builds on previous research [8] by highlighting the role of digital skills and habit in shaping privacy concerns and trust in technology and emphasizing the need for digital literacy education. Future research may build on current findings by collaborating with people with PD and their carers to discuss the best delivery method for digital skill upskilling.

Despite these concerns, privacy concerns alone do not deter people with PD and their carers from using VAT. Efforts should be made to upskill the digital skills of people with PD, increase their knowledge of privacy protection, and promote active security measures to mitigate risks. This concurs with results from the Digital Health Readiness Questionnaire, where people with PD lacked digital literacy and had mixed digital skillsets, but were motivated to learn about technology. Although efforts may also upskill carers, participants in this research had strong digital skills and literacy. Future research should seek to reassure

XSL•FO
RenderX

people with PD and their partners about the integrity of VAT's privacy policies and surveillance concerns and develop tailored guidance to support users with diverse digital skill levels and age groups. This would build on the current research by using specific privacy concerns and providing solutions that directly address user needs and may positively impact use.

Navigating Frustrations With VAT

Technological limitations of VAT and resulting frustrations were discussed, including issues with VAT not understanding speech; devices timing out; and a lack of meaningful feedback, conversation, and relationship. Similar frustrations surrounding the inconsistency of VAT have been reported by people with dysfluent speech [41] and neurological disabilities in wider research, particularly where VAT did not understand them, or provide meaningful feedback on errors [42].

In addition, VAT should be used cautiously for feedback on speech and voice due to potential well-being implications and users should be careful not to assign responsibility for all VAT inaccuracies to speech and voice [30]. Speakers can blame themselves for ASR errors and link this to their sense of identity, including racial, regional, and location identity. Therefore, participants may modify their dialect and word choice to be understood by ASR [32], which may negatively impact their sense of self. Despite acknowledged limitations, subjective improvements in confidence, self-awareness, accessibility, and well-being have been reported when using VAT. Wider literature has also demonstrated increased independence, well-being, and quality of life for older adults following the use of VAT [43]. This paper provides the foundations for future research to cocreate solutions to the use barriers identified by people with PD and their carers. By using ideation methodology, such as design thinking, and participatory design methods, future research could integrate multistakeholder collaboration to create solutions that are rooted in user needs, as identified by this study.

Supporting Adoption and Use of VAT

Although people with PD and their carers were at varying stages on their journey with VAT adoption, increased use generally corresponded with greater integration into their daily routines. This pattern mirrors broader trends observed in the general population [44]. However, participants frequently reported a lack of awareness of VAT's full functionality and capabilities, which they identified as a barrier to wider adoption. Given that smart speakers ownership approximately doubled during the pandemic, from 22% of households in 2020% to 39% [44], this knowledge gap is somewhat unexpected.

The level of VAT use and integration by participants appeared to shape their attitudes toward its usefulness and ease of use. This aligns with established technology adoption models, such as the Unified Theory of Acceptance and Use of Technology 2 (UTAUT2) [45], which suggest that factors such as performance expectancy (perceived usefulness) and effort expectancy (ease of use) can impact technology acceptance. In this context, people with PD who perceived VAT as beneficial and easy to use were more likely to integrate it into their routines. This highlights that future refinement of a VAT tool should aim to show why VAT is easy to use and useful for speech and voice to increase adoption by people with PD. However, those unfamiliar with VATs' capabilities struggled to extrapolate their everyday uses of VAT to speech and voice therapy. Furthermore, the privacy-personalization paradox [46] offers insights into VAT adoption, as it suggests that while users appreciate that personalized technology can enhance their everyday lives, concerns about data privacy can create hesitation around its use. Indeed, some people with PD and their carers reported reluctance to use VAT due to uncertainty about data privacy and security. Addressing these concerns through education and structured guidance on VAT's therapeutic applications could facilitate greater adoption and integration into SLT practices and extend on this study's findings.

In addition, participants indicated that they would benefit from education and training. This reflects findings from previous research surrounding therapeutic use of VAT in SLT and with older adults [25,36], indicating that digital health interventions should include education in how to use technology effectively and provide technical support throughout. While Cave [30] recommended development of a clear and accessible guide to using ASR tools, no research to date has created or examined an educational intervention for VAT as a therapeutic tool for speech and voice difficulties [47]. Future research may use facilitators and barriers to VAT use, identified by this study, to cocreate training and educational resources for people with PD and their carers, by using solution focused idea generation workshops and integrating behavior change frameworks [48]. This may also include identification of best methods for delivering training effectively to encourage increased confidence, adoption, and use of VAT for speech and voice difficulties.

Design Considerations for a Future VAT Tool

Participants in the study made various suggestions about a future VAT tool for therapeutic management of speech and voice, including a specific skill for VAT, extended feedback on speech and voice, and the ability to measure progress. Esquivel et al [42] indicated similar suggestions for use of VAT for people with neurological disabilities, including a voice assistant hub with suggested skills, training, and a repository with personal stories. Duffy et al [13] and Kulkarni et al [25] also suggested that additional research may include user experience in a therapeutic VAT tool. Wider research advocates for including the lived experiences of people with PD using VAT for speech and voice in the potential design, development, and testing of VAT tools [13,42].

Therefore, future research should build upon these identified uses, facilitators, and barriers, using participatory co-design methods with speech and language therapists, people with PD, carers, and technology experts to brainstorm solutions to some of these perceived barriers with VAT. Co-design is an established way to develop health care technology and supports people with communication difficulties [49]. This ensures that VAT reflects the needs of people with PD and their carers, reducing abandonment of VAT and digital exclusion for people with PD [29].

RenderX

Limitations

This study was conducted exclusively with people with PD and their carers in Northern Ireland. While this may be identified as a limitation, it is likely that their views are representative of experiences of people with PD across the United Kingdom and beyond with some variation in technology adoption globally. Technology use and adoption varies across countries and the findings may not represent the global experiences of people with PD who are VAT users. Furthermore, the sample of people with PD recruited in this study were White. This poses a question of how results may vary with potential cultural and regional differences. Future studies should seek to replicate findings to understand the generalizability of results, recruiting a range of people with PD from diverse cultural and ethnic backgrounds.

Inclusion in the study required participants to be actively engaging with VAT. Therefore, this indicates that people with PD and their carers were self-selecting participants and may have already had the basic digital skills that facilitated the adoption of VAT. As such, they may have been biased toward the use of technology and have a positive outlook toward its use. This is a limitation in any qualitative work that explores a particular subject. Other people with PD and their carers who may not have adequate digital skills may have had a different outlook and a less favorable attitude toward VAT use.

Recommendations

Our study highlights several suggestions for future research, as outlined in the Discussion section. The following recommendations are suggested to develop the therapeutic use of VAT:

1. Refinement of commercial VAT, specifically for targeting volume, clarity, and intelligibility of speech as part of SLT, using user-led co-design: this may include feasible solutions to technological limitations, which do not redevelop the technology, and extended conversational abilities, which meet the needs of people with PD and their carers and improving their experience.
2. Co-design of clear and accessible education and guidelines to help meet the needs of people with PD and their carers: this may include realistic expectations of how VAT can benefit speech and voice, a summary of VAT's capabilities and information on privacy. Future work must also identify the optimal route for delivery of education and training, particularly for those who lack basic digital skills.
3. Establishing the feasibility of a therapeutic VAT intervention for people with PD with speech and voice difficulties, including pre- and postacoustic analysis of voice or self-reported impacts in volume, clarity, and intelligibility.

Conclusions

This study builds upon the findings of Duffy et al [13] by exploring the experiences of people with PD and their carers using VAT with speech and voice difficulties. Participants reported positive therapeutic changes in volume, clarity, and intelligibility; however, frustrations with technology and privacy concerns may need to be addressed before VAT can be integrated into SLT. The next step will explore the role of multistakeholder collaboration to co-design feasible solutions to VATs' usability challenges with people with PD, their carers, speech and language therapists, and technology experts. Furthermore, additional work is needed to trial commercially available VATs as a tool for improving speech and communication changes in people with PD, as well as to explore potential generalization and maintenance effects.

Acknowledgments

The authors would like to thank the 3 members of the patient and public involvement group who contributed to this research, as well as the people living with Parkinson disease and their carers who generously gave up their time to attend focus groups. The authors also wish to thank Parkinson's UK in Northern Ireland for their continued support with this project.

Abstract

Background: People living with Parkinson disease (PD) often experience low speech volume and reduced intelligibility. Research suggests that common voice-assisted technology (VAT) devices, like Amazon Alexa and Google Home, can encourage individuals to modify their speech, speaking more clearly, slowly, and loudly. This highlights the potential of VAT as a therapeutic clinical tool in speech and language therapy (SLT). However, while VAT is emerging as a novel health care technology, gaps exist regarding understanding speech and language therapists' (SaLTs) experiences using these devices in clinical practice for PD-related speech and voice difficulties.

Objective: This research set out to explore various experiences of using VAT to address hypokinetic dysarthria, secondary to PD, from a range of stakeholder perspectives. This paper specifically focuses on clinical insights from SaLTs.

Methods: SaLTs with prior experience of using smart speakers in clinical practice with people with speech or voice difficulties were invited to participate in focus groups or interviews. Between September and December 2024, seven SaLTs participated in semistructured focus groups or interviews using a topic guide. Discussions were informed by published evidence. Results were transcribed and analyzed using a framework analysis approach and were managed through NVivo software (Lumivero).

Results: Four main themes were identified across the groups: (1) potential for VAT in SLT, (2) managing therapeutic beige flags, (3) empowering SaLTs to become digitally enabled practitioners, and (4) envisioning the future of VAT in SLT.

Conclusions: This study recognizes VAT's potential as a therapeutic tool that may improve volume, clarity, intelligibility of speech, and facilitate at-home practice for people with PD. However, before VAT can be widely implemented, considerations around data privacy, device limitations, and practical integration into clinical care must be addressed. Future research is proposed to design solutions to address usability challenges for both clients and clinicians. Finally, this paper offers key clinical recommendations for the development of a therapeutic VAT tool for speech and voice difficulties in SLT.

Introduction

Up to 90% of people with Parkinson disease (PD) develop hypokinetic dysarthria [1], characterized by masked facial expression, reduced range of motion and volume, imprecise articulation, accelerated speech rate, prosodic insufficiency, reduced stress, rapidly repeated phonemes, and, in some cases, palilalia [2]. These speech impairments worsen over time due to the progressive nature of PD, resulting in low volume, which contributes to poor intelligibility and clarity of speech. This can lead to embarrassment, reduced well-being, social participation, and a loss of identity [3,4].

Early speech and language therapy (SLT) intervention is recommended during the management of PD [5], with guidance suggesting that therapists use compensatory strategies, external aids (eg, pacing boards, voice amplifiers, and augmentative alternative communication devices), or evidence-based treatments. The gold-standard therapy for hypokinetic dysarthria is Lee Silverman Voice Treatment (LSVT) LOUD [6,7], which targets vocal loudness and recalibrates internal monitoring mechanisms, using principles of motor learning and neuroplasticity. This focuses on the cue "BE LOUD," aiming to target volume, and often has subsequent positive implications for articulation. Therapy is comprised of four areas: (1) daily exercises including a sustained phonation, pitch glides and functional phrases, salient speech hierarchy tasks across words, phrases, sentences, and conversation; (2) recalibration using feedback tools and education around changes in speech in Parkinson; (3) daily homework exercises; and (4) carryover exercises to promote use of loud voice in everyday life. However, LSVT is resource-intensive, and four sessions each week, for a month, are recommended to promote lasting changes. Often, there is a shortfall between these evidence-based recommendations and the real dosage provided during face-to-face therapy. This limits the accessibility of LSVT in the United Kingdom. Furthermore, regional speech and language therapist (SaLT) shortages and postpandemic waiting lists exacerbate difficulties accessing SLT [8], leaving a large percentage of people with PD without therapy access. Given these barriers, alternative therapeutic approaches are required to facilitate increased access to SLT for people with PD.

Voice-assisted technology (VAT) uses natural language processing and automatic speech recognition (ASR) to interpret speech and translate it into actionable requests. These devices are consumer-facing apps of artificial intelligence, and help the devices to provide interactive, contextually aware responses. VAT is more commonly known by commercial names such as "Amazon Alexa" and "Google Home," or as a smart speaker. VAT has potential as a therapeutic tool in SLT for people with speech and voice difficulties [9-11]. However, dysarthric speech is often misinterpreted by VAT, with recognition accuracy decreasing as speech severity worsens or sentence length increases [12,13]. Despite this, error feedback can prompt some participants with speech difficulties to adapt their speech to enable interaction with VAT [14,15]. For example, people with PD have reported increasing their vocal effort, loudness, and clarity when interacting with VAT [10]. This is similar to the aims of LSVT, and findings are supported by wider literature [9,11]. Additionally, some SaLTs have integrated VAT into therapy for individuals with dysarthria, finding that it provides objective and impartial feedback on speech clarity and fosters improvements in volume and intelligibility [16]. However, it is important to note that the outcomes in this literature are self-reported, perceptual changes in speech and voice, rather than objective, quantifiable changes. This highlights a gap within the literature regarding the acoustic outcomes associated with VAT use for speech and voice.

While research has not yet established functional outcomes of VAT use in clinical practice, research indicates potential positive functional implications. VAT can create communication opportunities with others in the household [14,17] and contributes to increased speech confidence [10,16]. This is because VAT is perceived to provide objective, unjudgmental feedback on speech, which can reduce social barriers for users and the anxiety and embarrassment associated with repeating themselves [9,10]. Furthermore, the everyday nature of VAT avoids the stigma associated with bespoke SLT communication tools [10,16]. Notably, research also indicates potential functional risks when using VAT: communication avoidance due to increased awareness of difficulties [9] and frustration with speech not being recognized and subsequent error recovery [10]. VAT has also been recognized as a motivational tool for encouraging home-based SLT practice, addressing a recognized limitation of LSVT, where practice is described as repetitive and lacking real-world validity [18]. However, despite a growing evidence base for the use of VAT as an emerging therapeutic technology in SLT, to date, there is limited exploration of SaLTs' experiences of using VAT therapeutically with people with speech and voice difficulties. Understanding SaLTs' experiences of VAT ensures that future developments can meet their clinical needs and may reduce technology abandonment [19].

Therefore, this study aimed to explore the experiences of using VAT to address hypokinetic dysarthria, secondary to PD, from the perspectives of SaLTs.

The objectives of this study are as follows: (1) to understand how SaLTs are using VAT to support those with dysarthria; (2) to explore the therapeutic potential of using VAT for speech and voice outcomes, from SaLTs' perspectives; and (3) to establish how to support the implementation of VAT in SLT.

Methods

Study Design

A qualitative methodology using online focus groups and individual interviews was used to explore SaLTs' experience. Both SaLTs and researchers participated online via videoconferencing in their own respective homes, and no nonparticipants were present. Engaging in focus group discussions fosters dynamic conversations, often leading to fresh insights and idea generation [20], which is particularly valuable when evaluating the use of emerging technology. Notably, online focus groups have been found to produce a greater variety of novel ideas compared to traditional in-person discussions [21], as participants are described to be more

XSL•FO
RenderX

"professional," taking time to listen and consider their contributions before responding to questions or suggestions during online interviews and focus groups.

Individual interviews were used to supplement focus groups due to SaLTs' scheduling conflicts. Online videoconferencing software (Teams; Microsoft Corp) was used, enabling data collection across a wider geographical area [22]. The lead author is a SaLT who has current and ongoing experience with the Parkinson population. It is acknowledged that this position could lead to potential bias in the interpretation of findings. Several measures were taken to address this, including transcription of focus groups and interviews within 24 hours and the use of a reflexive diary, which are further discussed within the data analysis section.

Ethical Considerations

This study was reported in accordance with the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist [23] and is part of a larger PhD study that received ethical approval from the Ulster University Research Ethics Committee in July 2024 (FCNUR-24-016-A). All participants provided informed consent. Privacy and confidentiality were ensured: only the research team was able to see personal demographic data, and data will only be held as long as the university guidelines and General Data Protection Regulation (GDPR) require. Following transcription, all participants' data were anonymized. Participants were reminded that if they knew another participant at the focus groups, they were to respect their right to confidentiality in their participation. No participants in the research were given payment.

Patient and Public Involvement

A patient and public involvement steering group was established prior to study commencement to provide a voice for key stakeholders and ensure they played an active role in shaping the research. This group included a SaLT with firsthand experience using VAT in clinical settings, a person living with PD, and a caregiver. These three "experts by experience" helped to co-design the project, influencing and informing this work's aims, methodology, and dissemination. Experts by experience were asked to provide feedback on information sheets via email, indicating that complex language should be avoided. Consequently, information sheets were revised with more patient-facing language. Furthermore, feedback on the interview schedule was also provided, with experts by experience suggesting that focus groups should build in time for participants to discuss their personal or professional journeys. They also suggested that introductions from researchers should include an informal preamble about smart speakers, which emphasized the technology's relevance for people with Parkinson and the SaLTs working with this population. As a result, focus groups began with a summary of professional journeys, gave background to what smart speakers are, why they might work to improve speech and voice, and the lead author's experiences of using her own personal "Alexa" device. Experts by experience also offered valuable insights of lived experience to the academic team during data collection and charting, including suggestions to offer the option of individual interviews to SLTs who could not attend focus groups, to maximize data collection.

Recruitment

SaLTs were recruited purposively in the United Kingdom through the Royal College of Speech and Language Therapists, including the Parkinson's Clinical Excellence Network and Bulletin Magazine, to participate in online focus groups and interviews. The anticipated sample size was difficult to determine without concrete and up-to-date figures of SaLTs working with adults in the United Kingdom. This study had a smaller number of participants than the suggested six to eight in the literature [24] due to pragmatic considerations and challenges with recruitment and scheduling. To balance diverse perspectives with data saturation, a range of 2-4 focus groups was proposed. Ultimately, two focus groups and two individual interviews were conducted.

Participants were asked to express their interest in the study, and following initial contact, they were screened via email or phone, according to study inclusion criteria, by the lead researcher (JM). Participants were unknown to the research team before participating. Eligible SaLTs were required to be older than 21 years of age, as this is the earliest age at which clinicians can be qualified, and were required to have prior experience of using VAT in clinical practice, with individuals experiencing dysarthria. It should be noted that four of the seven SaLTs directly worked with people with PD, and the others with populations experiencing dysarthria. Additionally, participants required access to an internet-enabled device with a camera for videoconferencing. There was no minimum clinical practice experience or experience of using VAT in clinical practice required to participate. Given that VAT use in the United Kingdom is still deemed to be emerging, this is a small, niche population. Increased inclusion criteria may have further limited the sample size. SaLTs meeting the inclusion criteria received an information sheet and consent form via email. Once consent was obtained, participants completed a digital health readiness questionnaire (Multimedia Appendix 1) and a demographic survey (Table 1). They then provided their availability for scheduling focus groups. SaLTs unable to join a focus group were offered the option of an individual interview. No background information was gathered relating to the severity of dysarthria of clients the SaLTs worked with, due to the exploratory nature of the study. Additional research may seek to investigate this further.

Table 1. Demographic data for SaLT[a] participants.

SaLT ID	Gender	Age (years)	Clinical experience	Current clinical population	Location
P1	Female	46	23 years—specifically Parkinson	PD[b]	England
P2	Female	33	12 years	Adult disability or TBI[c]	England
P3	Female	41	11 years—specifically Parkinson	Adult community—Parkinson, MND[d], MS[e]	Scotland
P4	Female	24	6 months	Adult community, including Parkinson	England
P5	Female	36	2 years	Adult community, including Parkinson	England
P6	Female	38	17 years—5 years of acute experience with Parkinson	TBI	Northern Ireland
P7	Female	43	18 years—specifically Parkinson	TBI	England

[a]SaLT: speech and language therapist.

[b]PD: Parkinson disease.

[c]TBI: traumatic brain injury.

[d]MND: motor neuron disease.

[e]MS: multiple sclerosis.

Procedure

A total of 7 SaLTs were recruited and participated in either a focus group (n=2 groups) or an individual interview (n=2 interviews). No participants dropped out of the study. The sample size and duration of each focus group or interview are shown in Table 2.

This study was conducted as part of a larger study with people with PD, carers, and SaLTs, participating in six focus groups and two interviews. This paper only reports findings from seven SaLTs, and findings from focus groups with people with PD and carers are presented in another paper [25].

Data collection was facilitated online by the lead author (JM), a female SaLT, and a coresearcher (a qualified SaLT or health care professional with a PhD), and lasted between 38 minutes and 1 hour 30 minutes. The lead author participated in training on leading focus groups prior to conducting this research. To ensure methodological consistency, a semistructured topic guide (Multimedia Appendix 2), informed by literature, was used, and SaLTs had access to this in advance of their focus group or interview. This included prompting questions to encourage reflection and elaboration by clinicians and was reviewed by the experts with experience before use. Participants were invited to share their experiences of using VAT as a tool to address speech and voice difficulties with adults, and field notes were made during the focus groups or interviews.

Table 2. Format of qualitative data collection and number of participants for each.

Format	Number of participants	Length of time
Online focus group 1	3	1 hour 30 minutes
Online focus group 1	2	1 hour 7 minutes
Online interview 1	1	38 minutes
Online interview 2	1	1 hour

Data Analysis

Focus groups were recorded audio-visually using Teams and were transcribed by the lead author (JM). To ensure methodological rigor and to ensure the accuracy of contextual memory, transcriptions of videos were completed within 24 hours of the focus groups. Before analysis, transcripts were anonymized, removing personally identifiable details, to ensure confidentiality.

Framework analysis was used to synthesize the results, as it facilitated understanding of results across a wider dataset [26]. Given the lead researcher's background in SLT, framework analysis also supported reflexivity, encouraging critical reflection on biases and assumptions to promote analytical rigor [27]. The analysis followed the five-step process outlined by Ward et al [28]: (1) data familiarization, (2) framework development, (3) systematic coding, (4) synthesis within an analytical structure, and (5) interpretation.

XSL•FO
RenderX

The initial theoretical framework was created using published VAT evidence [13,16]. Once transcriptions were completed, data were imported into NVivo (version 14; Lumivero) for systematic organization and qualitative analysis. The researcher engaged in repeated readings of the transcripts, using mind mapping and a reflexive journal to document emerging themes. Preliminary themes were noted and discussed with coauthors (OD, KP, and GK). This led to further data immersion and refinement by the lead author (JM) before creation of draft themes. A consensus was reached by the team following further reflection on the data. The finalized framework was developed by systematically indexing data, summarizing this into codes, and charting findings into a structured analytical model [26]. Direct participant quotations are presented to provide context, to link data with interpretations, and to enhance the credibility of findings. Furthermore, results were sent to all participants for member checking to ensure written findings reflected their lived experiences and to enhance the rigor of the research.

Results

Overview

The Digital Health Readiness questionnaire required participants to rank 20 statements about technology use and ability, using a 5-point Likert scale. Statements covered digital access, use of digital technology, digital literacy, digital health literacy, and learnability.

Although seven SaLTs were recruited, 1 (P5) did not return the digital health readiness questionnaire. All 6 SaLTs who responded had good digital access: they all used the internet, a laptop, and a smartphone or tablet daily, 5 used health-related apps, and all indicated digital health literacy. All were motivated to learn about technology and strongly agreed that they would learn quickly when offered personal guidance about digital technology. Multimedia Appendix 2 provides further details.

There were four main themes identified across the groups and datasets: (1) VAT as a potential driver of positive speech therapy outcomes, (2) managing therapeutic beige flags, (3) empowering SaLTs to become digitally enabled practitioners, and (4) future design and features of a VAT tool (Textbox 1).

Textbox 1. Results from research with themes and subthemes.

Theme 1: Voice-assisted technology (VAT) as a potential driver of positive speech therapy outcomes

1.1 Enabling speech practice and self-management

1.2 VAT reduces practice stigma as an everyday device

Theme 2: Managing therapeutic beige flags when repurposing commercial technologies

2.1 Usability barriers to therapeutic benefit

2.2 Need for monitoring and human interaction

Theme 3: Empowering speech and language therapists to become digitally enabled practitioners

3.1 Limited device knowledge for therapy

3.2 Suggestions for education and guidance

3.3 Navigating governance, data storage, and confidentiality

3.4 Smart speaker implementation concerns

Theme 4: Future design and features of a VAT tool

4.1 Develop a program or skill

4.2 Lee Silverman Voice Treatment through VAT

4.3 Additional feedback for self-awareness

Theme 1: VAT as a Potential Driver of Positive Speech Therapy Outcomes

Uses of VAT for managing dysarthria were reported by SaLTs, including therapeutic uses for speech and voice, VAT-supported self-management, and perceptions of VAT as an everyday, nondisability device.

1.1 Enabling Speech Practice and Self-Management

SaLTs discussed the role of VAT in therapy and supporting home practice for carryover, with most considering VAT to be functional as part of their toolkit:

> *It's used as a tool, as an adjunct ... It comes part of a massive part of treatment.* [P7]
>
> *I would almost separate it into two different roles ... The input would come from the therapy and the practice would come from the Alexa.* [P5]
>
> *You have all these like little homework tasks to do with LSVT. Alexa is kind of being your homework buddy, like a virtual assistant homework buddy for voice work.* [P7]

VAT was also identified as a practice tool for integrating volume, articulation, rate, and general intelligibility strategies:

XSL•FO
RenderX

> *I just ask them to use [it] in conjunction with strategies. So, we've got strategies we call SLOP strategies so slow, loud, over pronounce pause and making sure you take that deep breath.* [P4]
>
> *It's like the whole needing to, remembering to breathe, activating it and then breathing again quickly and then really, really clear speech. So, it's been a really good tool for him to try and remember to articulate the words quite clearly.* [P2]

SaLTs also indicated that VAT provided feedback on volume, clarity, and intelligibility of speech, and helped to develop self-awareness. Feedback can be a light on the device, or simply the device not responding to speech. This could prompt clients with dysarthria to adapt their speech using strategies:

> *They could be using it ... and getting that feedback themselves and thinking why is Alexa not understanding me. You know, if I raise my voice, will that help? If I be clear, will that help?* [P6]
>
> *So, he would ask, quite detailed biology questions ... then he would receive feedback if Siri understood him first time or not. It was, primarily for intelligibility feedback.* [P6]
>
> *It's an alert for your kind of clear speech strategies: to speak louder, to go slower.* [P7]

SaLTs also explained that this feedback, including how well clients were understood by the VAT device or how well it completed their functional requests, was often central to their goals:

> *The other goal was for her to get feedback on her intelligibility ... So, when Alexa didn't understand her, she had to repeat it and try and reduce the amount of time she would have to repeat it.* [P6]
>
> *With the speakers, you know, just being understood ... That's quite a quick good way of monitoring their volume and their clarity I suppose if the speaker can understand them the first time.* [P3]
>
> *I'll probably kind of set clearer goals within that report and say that we had a goal to kind of use Alexa, to be able to wake Alexa and kind of ask Alexa various questions and for that to work 70% of the time.* [P7]

This objective and unjudgmental feedback from VAT devices was seen as a factor in encouraging the use of adaptive speech strategies and reportedly reduced the client's reluctance to speak out:

> *We call it high challenge, low threat. Those activities that people ... they really want to have a go at, but that fear of failure, that fear of social rejection, isolation is taken away. Because the Alexa's, you know, it's going to respond to neither it'll tell you "Oh sorry I didn't understand that" or it will give you what, what you want.* [P5]
>
> *She really liked the idea of practicing with the Alexa to build her confidence.* [P6]

SaLTs also reported that VAT could be used to integrate functional phrase practice in the context of everyday requests whilst also promoting an increase in practice intensity for working-age clients:

> *Speech sounds on cue, or something like that ... they're repeating random sentences that mean nothing to them. Whereas using Voice Assistant Technology they can ask whatever they want and get an actual outcome.* [P6]
>
> *We then developed kind of ten phrases that he could use for Alexa, to kind of say to Alexa and get Alexa to do various things ... So it'd be things like Alexa, what's the weather today, Alexa, what time it?* [P7]
>
> *If people are working ... I think the intensity and the dosage would be good as well if they had access to that on a smart speaker and it would kind of do the role that we wouldn't be able to offer.* [P4]

Furthermore, SaLTs reported that VAT could act as a communication partner for people with dysarthria:

> *I always go back to the means, reasons and opportunities model ... It's when they don't really have the opportunities to interact that often face-to-face with people, I tend to use that as their interaction opportunity.* [P1]

Although this research focused on VAT as a therapeutic tool for speech and voice rather than a tool for environmental control, SaLTs indicated that VAT devices were often used for accessibility and environmental control, including clients interacting with VAT via augmentative alternative communication devices. The following quotes see SaLTs draw on wider experiences of working with clients with dysarthria, who did not have Parkinson:

> *He now has that set up at home in terms of turning on his lights and TV and things.* [P2]
>
> *They can use their eye gaze or their touch and have the computer speak on their behalf, and then it can turn on the lights or it's connected to a smart plug so they can turn on their kettle to make a cup of tea.* [P7]

Furthermore, by facilitating self-management of speech and voice difficulties, VAT could reduce reliance on ongoing therapy input and transfer responsibilities onto patients themselves:

> *Our aim is to deliver the strategies to people to self-manage, which, again is something that an Alexa could really help with ... It's kind of moving patients away from that almost dependency on therapy and how can I self-manage.* [P5]

SaLTs also considered how VAT could be combined with SaLT-made resources to maintain speech and voice prior to SaLT, and following discharge:

> *We could always post it out to people as soon as they come on the waiting list and say, you know, if you've got a smart speaker. It's worth a try. Just to maintain your functionality.* [P5]
>
> *Post therapy yeah, definitely. You could use it as a kind of maintenance tool to keep your kind of dysarthria strategies up.* [P6]

XSL•FO
RenderX

1.2 VAT Reduces Practice Stigma, as an Everyday Device

SaLTs discussed the nature of VAT devices, which meant that they were widely integrated in households, and clients were motivated to practice with them. This also brought about a societal acceptance that VAT devices may reduce the stigma of using a speech-aiding device:

> *It is something that they're familiar with and it's in their home ... They are really excited to try and give that a go.* [P4]

It's *not like a specialist piece equipment.* [P2]

> *They're normal to integrate as part of your life, it's much more acceptable ... It's not like you're singling them out and giving them some specialist equipment that doesn't look or feel like the general population ... My clients often they hate to be reminded of their disability. They're desperately trying to kind of live the life they lived before.* [P7]

Theme 2: Managing Therapeutic Beige Flags

Overview

Participants reported several factors that must be considered before VAT can be implemented as a tool for managing dysarthria, including therapeutic and practical concerns and challenges posed by VAT devices. These considerations are termed beige flags, unlike red flags, as the barriers do not prevent the use of therapeutic VAT but can make it more difficult.

2.1 Usability Barriers to Therapeutic Benefit

VAT devices not understanding clients, frustration, difficulty with error scaffolding, and devices timing out were reported as challenges when using VAT, although they did not necessarily preclude use.

Clients becoming frustrated when interacting with VAT was a concern for all the SaLTs:

> *At home, when we ask it something and then what it gives us is something completely random, it's hilarious. But if you've got difficulty with speech intelligibility, I can imagine that's not funny at all. It's actually really frustrating and just another thing that confounds the fact that you're struggling with your speech.* [P1]

> *I'm just aware of frustration as well: if they can't access the Alexa and they are working so hard at it, depending on the severity of their dysarthria. It is important that it's accessible to them and that they are getting success.* [P3]

SaLTs also explained that VAT often did not understand people, even when the clinician perceived their speech to be intelligible, and they highlighted how frustration could impact confidence. Additionally, it was recognized that fatigue and self-awareness could impact how well participants were understood by VAT:

> *It doesn't matter how clear their speech is, sometimes the smart speakers just don't get it ... It's frustrating when my client sounds really clear to me but still isn't picked up by the smart speaker. And trying to reassure them that it's not them, it's the speaker.* [P7]

> *Fatigue would also be an issue because they're dysarthric. So, in the evenings, the girl who's using it functionally would always say it's harder to do it in the evenings.* [P6]

> *They're not very good at changing their strategy, so they'll just repeat the same sentence again and again.* [P7]

SaLTs also highlighted that additional factors, such as VAT timing out and difficulties with error scaffolding, hampered the therapeutic value of VAT. Error scaffolding related to feedback, both from the blue light on VAT devices that turns on when the device is listening, and the verbal feedback that devices may give when trying to action a request:

> *It didn't actually give that feedback of "I didn't understand that" the blue light just went off.* [P4]

> *When he is pausing, if it's for too long, the device is stopping ... We've kind of had to start from scratch even though pausing is a really good strategy that I think is helpful in conversation.* [P4]

2.2 Need for Monitoring and Human Interaction

SaLTs discussed their reflections on therapeutic and practical concerns about using VAT in practice. Most clinicians indicated that they were unable to monitor clients' use of VAT during therapy and following discharge:

> *I don't want them to be unsuccessful either, and I'm not there to monitor that. I can't see what happens at home.* [P3]

Another SaLT indicated that monitoring required extra support or additional staff:

> *I've been relying on either myself going in and monitoring that, a speech therapy support worker or, know a spouse or a carer of some sort.* [P1]

Furthermore, VAT's challenges in providing conversation, with standard settings, were considered as a barrier for the delivery of therapy. SaLTs indicated that VAT was not reflective of real-life communication challenges:

> *All we've been practicing is you ask a question; it gives a response. But we want to, you know, get back to conversations with people. And so, it's kind of bridging that gap between these one-word responses to that device and how are you going to get back to the conversation?* [P4]

> *That sort of flow, the spontaneity and the flow of conversation is what patients need. It's great for them to practice their speech with short questions and one-word answers, but actually that's not what happens in communication and in conversation. It's much more of a flow, and you do have to think on your feet.* [P5]

XSL•FO
RenderX

Theme 3: Empowering SaLTs to Become Digitally Enabled Practitioners

Overview

Participants explained how a lack of adequate knowledge about what VAT can do, privacy, and practical and technical concerns prevented them from fully using the potential of the devices. They also suggested they needed guidance and education to help them further integrate VAT into clinical practice.

3.1 Limited Device Knowledge for Therapy

SaLTs discussed their uncertainties about what VAT can do, and all described a need for education about what Alexa can do:

> *I think it would be really interesting to know all of the other different services that a smart speaker offers, apart from just playing your favorite, your music or setting a timer.* [P2]

> *It depends on the therapist's experience really with these smart speakers ... There's those gaps as well if you've not used it in a specific way in your own home life, then you won't know about it.* [P3]

SaLTs indicated that they required education and guidance about using VAT as a tool for dysarthria:

> *I think it would be really useful to have like a guidance booklet on kind of what a smart speaker is, how it's used, like how the general population uses it, why people like it.* [P7]

3.2 Suggestions for Education and Guidance

SaLTs also gave several suggestions about what they would like guidance and education to include. For example, resources, evidence-based practice, goal setting, and outcome measurement. Table 3 highlights and elaborates on these key ideas, using quotations.

XSL•FO
RenderX

Table 3. SaLT[a] suggestions for education and guidance surrounding the therapeutic use of VAT[b] for dysarthria therapy.

Suggestions for education and guidance	Supporting quotation
Resources and example therapy plans	• "Even just like kind of therapy ideas pack. You know, this is what you could use it for. This is how you can use it, would be really nice because it's hard when your kind of thinking about things to do sometimes." [P6] • "So, I think, I think so, just having those sorts of those ideas and even something that you know, you could, you could, you could print off for that that person as well. Anything that can just help generate ideas and then having the guidance is good." [P3] • "And then to have some ideas of things to try because I had to kind of look outside the speech therapy population for ideas on things to try with it ... I couldn't come up with those on my own. So, I think just kind of showing people the different applications that you can use with smart speakers." [P7] • "Maybe also just kind of having like a little crash course into what people have found the best questions to ask are or some interesting ones that can prompt." [P5]
Scripts	• "So, we're sort of saying the same sort of thing, to the patients. A wee script is always good." [P3]
Idea sharing network with other clinicians	• "Like a sharing of practice in terms of what works, what hasn't worked, why hasn't it worked? And is there, you know, is there something that we can do differently, better perhaps to, to get that?" [P5]
Goal setting	• "How can you aim it to people who are working on different levels and different things? ... I think because everyone will use it in such a different way as well, depending on the severity of your dysarthria. And you know what, what your goals are as well. It would be really quite difficult currently." [P4]
Outcome measurement	• "Yeah, to measure that. What does progress look like? Because it will look very different for different patients depending." [P5] • "We're always working on is strategies, it's harder to sort of capture it when someone's got a progressive condition, isn't it?" [P3] • "What about the sort of goal setting and evidencing, evidencing it in that sort of way? I think that's always super, super useful. Not necessarily percentages, but if there was some sort of guidance." [P3]
Evidence-based practice relating to dosage and maintenance	• "I think it'd be useful in terms of knowing a bit of how much maybe you'd have to use it to improve speech ... I think there would be benefit from research to know, if you did this five times a day then your speech would increasingly get more intelligible." [P2] • "Evidence in terms of can they actually meet the levels of practice that you might need for maintenance, that would be something that I would find quite important." [P4]
Evidence-based practice relating to therapeutic impacts	• "If you've got that research behind it then you've got an easier sell to the rest of the team, and particularly with budget cut that we've had and the financial constraints, I think we do need this this sort of thing." [P3] • "If you were to do it purely from a data perspective, I wouldn't be overly interested because we don't work with data, we work with people ... if the data is telling me, yes, but the person is telling me no, then I'm not going to." [P5] • "I wouldn't be overly worried about the evidence being like, really clear cut, I would be thinking instead, is this accessible to the patient? Is this something that they would find motivating? Do I think they would enjoy and benefit from it? Is it something that they would have to go out of their way to do?" [P5] • "Because we don't offer LSVT[c], I think compared to another service that maybe do offer LSVT, they may want the research to be you know more developed." [P4]

[a]SaLT: speech and language therapist.

[b]VAT: voice-assisted technology.

[c]LSVT: Lee Silverman Voice Treatment.

3.3 Navigating Governance, Data Storage, and Confidentiality

SaLTs discussed common client concerns about privacy and their clinical reflections on this:

> *I think that is a concern with a lot of people, isn't it? And it might be more of a concern with patients' kids than patients themselves. You know, it would be ... Who's listening?* [P3]
>
> *Maybe people being concerned about the device is always on and always listening to them ... How much information is it storing as well and what's happening with that information.* [P4]

XSL•FO
RenderX

One SaLT discussed how VAT's recording of clients' requests could be used in legal cases and described the measures she took to protect clients:

> *You can hear like domestic violence and things on the Alexa. People have kind of gone back and picked up arguments that have happened. You know, in police cases and thing ... I tried to make sure that when clients are kind of talking, their phrases are kind of pretty benign phrases and not giving away too much information.* [P7]

Furthermore, SaLTs indicated that GDPR and governance policies could act as barriers to VAT use. GDPR refers to guidance about how patients' personal information is collected and stored, and is considered part of clinical governance. In the United Kingdom, the National Health Service has strict governance policies about how technology used in clinics must align with GDPR guidance:

> *We've had a lot of barriers from IT, from information governance ... IT security is a really, really big thing ... It's all about GDPR.* [P3]

> *The huge amounts of red tape within the hospital trust just made it impossible.* [P1]

As a result of these concerns, SaLTs indicated that support was required:

> *I think [we need] all of the information that we just spoke about to do with risk information, governance, GDPR. All of those sort of guidelines around it.* [P1]

SaLTs also indicated that a clear, but realistic, view of risks and benefits from a clinical perspective would support the integration of VAT:

> *Information Governance is incredibly important, but I kind of feel like the risk benefit is skewed somehow? They need to be balancing it a lot better, whereas all they see is risk.* [P1]

> *We always chat to them about, you know, just about the information, keeping it safe and absolutely the benefit totally outweighs the risk. They're like, I don't care, like, I just want to communicate with people.* [P3]

3.4 Smart Speaker Implementation Concerns

Participants discussed technical and practical concerns about using VAT, as well as making suggestions for support.

VAT devices' requirement for an internet connection meant SaLTs were unable to set up their own VAT for therapy, and therefore, most were only able to use VAT therapeutically if clients in the community owned a VAT device personally:

> *You can't just take your smart speaker and plug it in in someone else's house onto their Wi-Fi network, because immediately it knows it's on a different Wi-Fi and it needs to set up an account and things.* [P5]

> *The barrier would be access, if the person has one or not ... I only use it when people have already got it set up.* [P1]

> *Neither myself or others are recommending they get smart speakers. We're just going on the back of the fact that they already have them in the house and already using them.* [P3]

Furthermore, SaLTs expressed skepticism regarding VAT's reliability for therapy and the unpredictability of responses. Variations in responses due to personalization and differences in plug-in features were also problematic:

> *I have no idea if this Alexa is going to answer me or not or what it's going to say ... I can't guarantee that it will continue to do that once I leave ... You know, it's Harry Potter, isn't it where they say, "Don't trust something that can think for itself, if you don't know where it keeps its brain."* [P5]

> *"I don't know what's coming and that's a difficulty for like therapy planning. It's like you ask it to play some music and it says "you are not linked up to Amazon Music." Well ... that's a barrier because I don't know what they have access to and what they don't.* [P4]

Most SaLTs expressed a lack of clarity around SaLT roles when using VAT as a therapy tool. However, independent SaLTs had more role flexibility:

> *Thinking about our remit, the tech setup is not a speech therapy job! So again, that raises its own challenges.* [P5]

> *A lot of what we do is troubleshooting. So, we turn up at our client's house, the Wi-Fi is down, and we've got time to call the Wi-Fi company or to switch the booster on or you know, that's the way that we work. We're really integrated into client's homes.* [P7]

Given this, SaLTs explained that technology-specific guidance may help to overcome gaps in knowledge that were beyond clinical skills and would also help them with using VAT straight out of the box:

> *We're speech therapists. We're not technicians, we're not clinical scientists. So, I think any support along those lines is, is always really useful.* [P3]

> *A set of instructions that you follow with your client in their house for the first set up, and then any other set up that they want to do, which might have to be done by someone else.* [P5]

> *Maybe also some tech support ... If it is just not responding to you, is there anything you can try?* [P4]

Furthermore, SaLTs also had practical worries about using VAT. A lack of consensus around how VAT is currently used therapeutically, dosage requirements, measurement of therapy outcomes, and maintenance or generalization was discussed:

> *I haven't really done any sort of, anything formal with smart speakers.* [P1]

> *I don't know ... I don't give a particular dosage.* [P1]

> *Everyone's doing something different in my team ... We've not been super specific in how we do it and actually in I suppose how we're measuring our success as well.* [P3]

XSL•FO
RenderX

SaLTs indicated that future support may improve evidence-based practice using VAT, including demonstrating therapeutic impacts and required dosage to improve and maintain speech. Additional supporting quotes are found in Table 3.

> *It would be so exciting to strip everything away and just see if there's parameters of speech and voice got better just on smart speaker treatment.* [P7]
>
> *I think I'd be really keen to hear about that more sort of qualitative ... the data that from that perspective, you know the stories of how is it helping, and is it helping, and to what extent is it helping, I think more so than the numbers.* [P5]

Theme 4: Future Design and Features of a VAT Tool

Overview

Participants provided considerations for the future therapeutic use of VAT for people with speech and voice difficulties in SLT. This included developing VAT skills, delivering LSVT through VAT, increasing the ability to monitor speech and voice changes, and increasing levels of feedback to promote increased self-awareness.

4.1 Develop a Program

Participants indicated that they would like VAT to have a program for speech and voice therapy. This was described in various terms:

> *I think it would be amazing if there was an Alexa skill that dealt with therapy.* [P1]
>
> *There are all sorts of apps that you can link to Alexa. So, there might be something where you could work on your pitch and Alexa would give you some feedback.* [P7]

4.2 LSVT Through VAT

SaLTs also made suggestions regarding how a SLT VAT skill might function or features to include. For example, increased feedback, LSVT style exercises, conversation practice, and reminders to complete therapy tasks.

Participants described how LSVT-style exercises could be delivered through an Alexa skill, which could target articulation, breath support, phonation, singing, and reading:

> *I can see the 10 functional phrases. I can see that being practiced with a smart speaker. If you could think of things that you would say to Alexa where you get a response back where you know whether you've been clear enough, I can see that really working.* [P7]

SaLTs also suggested how reading aloud tasks could be facilitated by VAT:

> *You could get the lyrics to come down the screen ... could you do that with a reading passage? Could you get it to scroll a poem through in front of you?* [P1]
>
> *You could ask Alexa to listen to you whilst you read a passage for the kind of extra practice at the end.* [P7]

Furthermore, conversation was also highlighted as a beneficial feature for a VAT tool to incorporate:

> *I think just having those modelled conversations and actually having it answer you back with something that might be unexpected and you having to then formulate your response kind of like a conversation would be really helpful at the moment.* [P4]

SaLTs felt these exercises could form part of home practice, and prompts and reminders could be useful to help clients integrate their everyday practice:

> *I'd use it for that, reminding them to do it as a routine. And then maybe you know a bit later ... "Have you done it yet?"* [P1]

4.3 Additional Feedback for Self-Awareness

An enhanced feedback feature to facilitate self-awareness and recalibration of internal monitoring was suggested. More specific feedback from VAT on speech and voice was suggested. For example:

> *That wasn't clear enough. Can you say it again? Louder.* [P1]
>
> *Oh, I didn't quite understand what you said ... Could you slow down your speech?* [P4]
>
> *[VAT] could ... repeat back what they did understand* [P3]

One SaLT indicated that this may help to overcome difficulties with communication partner prompting:

> *I find that quite a challenge to get communication partners to actually do that whole repeating back ... If a smart speaker could do that would be amazing!* [P1]

Furthermore, SaLTs also indicated that scored feedback on intelligibility may be useful:

> *Sort of 6 weeks ago, I had to repeat myself 50% of the time, whereas now I'm only repeating myself 5% of the time.* [P6]
>
> *I mean, even better would be kind of being able to ... kind of give some feedback on percentage intelligibility or something, but I can imagine that would actually be very, very hard to develop.* [P3]

Finally, one SaLT suggested that this auditory feedback from VAT could be supplemented with visual displays and biofeedback:

> *If they've got that decibel meter in front of them and they could see that they're hitting the red part of it. That's the thing that helps ... I think some sort of biofeedback through a smart speaker would be really useful.* [P7]

Discussion

Principal Findings

This study aimed to explore SaLTs' experiences of using VAT to address hypokinetic dysarthria. Focus groups and interviews indicated the potential of VAT for improving volume and

XSL•FO
RenderX

intelligibility and supporting home practice. However, concerns about privacy, practical use, and device errors were noted. Key themes include VAT's therapeutic use and potential, managing technical and practical challenges, supporting SaLTs to become digitally enabled using VAT, and the design and features of a future VAT tool.

Therapeutic Potential as a Self-Management Tool

SaLTs discussed using VAT to support practice of volume, articulation, rate, and general intelligibility strategies, and reported using VAT as a biofeedback tool to provide feedback on speech clarity. This suggests that clinicians have experience of using feedback from VAT as an objective measure of intelligibility and to prompt increased self-awareness surrounding speech and voice. Kulkarni et al [16] reported similar findings, where SaLTs indicated that VAT could improve the accuracy of word productions for people with speech and voice disorders and increase clients' motivation to practice at home. Indeed, several studies have indicated the potential for VAT as an SLT practice tool with participants, reporting a need for clear speech when interacting with the devices [12,14,29]. Furthermore, Smith et al [14] found improved speech intelligibility related to VAT use and device-related phrases and reported a smaller, but positive effect, for unrelated generalization phrases. This was echoed by Duffy et al [10], where people with PD reported speaking "slowly, loudly, and clearly" when using VAT. Findings from this study offer a foundation for collaboratively designing a VAT tool to support home practice and management of speech, voice, and self-awareness changes in neurodegenerative conditions.

Speech subsystems of articulation and phonation are commonly targeted by SaLTs during the therapeutic management of PD [30]. Although LSVT is the optimum, gold-standard therapy for people with PD [7], with clearly quantifiable improvements in volume [31], difficulties meeting intensity requirements, practice abandonment, and poor self-reported maintenance of therapy gains for people with PD can act as barriers [18,32]. VAT may have the potential to overcome these challenges by supporting the delivery of LSVT and facilitating home practice, shifting the focus from direct SLT input to self-management of longer-term conditions [33]. This is consistent with previous literature, which has suggested leveraging technology to facilitate practice of SaLT exercises and maintain therapy for people with PD or dysfluent speech [12,34]. Indeed, research has used technology at home following LSVT, known as LSVT Companion, and demonstrated gains in volume similar to in-person follow-up [35]. Literature reports that LSVT Companion can help to overcome constraints of treatment delivery, such as mobility and geographical constraints, while maintaining treatment efficacy, and may enable self-management of speech and voice difficulties for certain clients [35]. While Companion is specific to LSVT therapeutic tasks, it promotes digital use for therapeutic outcomes, particularly beneficial for providing biofeedback and outcome measures to reflect on the success of the tasks the clients have performed. Although Companion refers to laptop software, future research may consider how features of the LSVT Companion may be adapted and implemented by VAT.

However, SaLTs should be cautious that VAT is not used in isolation, but rather as a tool "to add to therapists' toolboxes," requiring SaLT-mediated support and check-ins. Current findings also overlap with wider literature regarding technology use in SLT (apps), where advantages such as increased practice frequency and intensity, alongside improved therapy motivation and engagement, are reported [36,37]. Given that improved vocal loudness, sensory recalibration, and intensive, high-effort practice are targets of traditional LSVT in SLT, future research may examine if and how VAT could host an alternative delivery of standard LSVT protocols or create "skills" for commercial VAT devices. Future research also may examine the quantitative impact of a VAT intervention to improve volume, clarity, and intelligibility for people with PD, using a combination of pre- and postmeasures and user self-reports.

Despite this, the technological caveats of VAT must be considered carefully by SaLTs. ASR errors are often higher than expected for dysarthric speech, and device inaccuracies may be attributed to ASR models and utterance complexities [38], as well as phonemic distortions associated with dysarthric speech. As discussed by SaLTs in this research, this creates concerns about a lack of consistency when using VAT for therapeutic tasks where there will be different devices, different rates of error, and even different environments. Furthermore, proper nouns, names, and locations may not be recognized by ASR [39]. Therefore, it may be difficult to use VAT to practice personalized, functional phrases, and it may limit use to basic interactional requests for some clients. Furthermore, the commercial technology exhibits an ethnocentric bias, with ethnicity and regional accents negatively influencing device recognition rates with commercial VAT systems like Apple, Amazon, and Google [40,41]. Additionally, high word error rates have also been found where individuals speak English as a second language [42]. SaLTs should therefore be mindful of attributing all device errors to clients, as other factors may be at play. Therapeutic use of VAT should ensure that users with speech and voice difficulties do not change nonstandard accents to more westernized accents to facilitate interactions with ASR [43], as this may perpetuate inequalities and racial bias at odds with person-centered practice in SLT.

Balancing Therapeutic Considerations With Technical Challenges

SaLTs indicated that the use of VAT in SLT required careful balancing of facilitators and barriers during implementation.

SaLTs reported that device timing out, not understanding disordered speech, and a lack of meaningful feedback contributed to clients' frustrations when using VAT. These difficulties were also reported in a recent scoping review examining the utilization of smart speakers by clients and staff in health care [33] and in wider literature [44-48]. Indeed, wider literature also indicates the impacts of using VAT on well-being. Decreased confidence, frustration with increased repetition, security anxieties, and avoidance of communication with smart speakers due to increased awareness of speech difficulties were noted [11-13]. Additionally, these error rates contributed to clinician perceptions that VAT was unpredictable, and SaLTs were hesitant to use VAT with participants who had more severe

XSL•FO
RenderX

speech and voice difficulties, as they did not feel it would be beneficial. Literature examining SaLTs' attitudes toward VAT reported the same clinical implementation concerns [15]. Similarly, SaLTs in Kulkarni et al [16] who had not used VAT, also perceived clients with severe speech impairment to be unable to use VAT effectively, with perceived negative implications for confidence and motivation.

Despite this, findings from this study also saw SaLTs report that VAT practice enabled clients to improve self-confidence and independence. Particularly, the everyday nature of VAT devices and acceptability had a motivational impact for clients. This suggests that VAT may be a socially acceptable tool for therapy, with the potential to reduce the stigma of practicing with an assistive device. This shows promise in reducing barriers to use and developing motivation to practice. VATs' inclusivity as a therapy tool has been reported in literature, with studies indicating that VATs' removal of social barriers and autonomous motivation may improve intelligibility [14] and contribute to feelings of inclusion for people with communication and cognitive differences [46]. This concurs with wider literature, which has also reported subjective improvements in confidence, self-awareness, accessibility, and well-being for clients when using VAT [45,48,49]. Increased independence, well-being, and quality of life for older adults and people with disabilities following VAT use were also shown [45,49,50].

Therefore, clinicians should exercise clinical judgment and balance risks against benefits on a case-by-case basis when implementing VAT with people with PD. While there is emerging evidence relating to VAT use with people with PD in SLT and general social benefits of VAT for older adults, much of the cited evidence is based on populations without neurodegenerative conditions. Subsequently, this represents a current gap in the literature, which this study begins to fill. VAT use is likely to impact people with PD differently due to the nature of the neurodegenerative disease, and prolonged unsupervised use of VAT could potentially have negative emotional consequences. Future research should explore VATs' impact on motivation and therapy dosage in comparison to traditional SLT interventions.

Support Needs

SaLTs indicated that they had gaps in their knowledge about VATs' capabilities, as well as organizational barriers and privacy concerns. Therefore, participants highlighted that they would benefit from education and training, which would include technical education and reference material, privacy and security information, and therapeutic implementation guidance and resources. This aligns with previous research regarding the adoption and implementation of novel health care technologies, which frequently touches on privacy, GDPR, and confidentiality [13,51,52] and previous research surrounding the therapeutic use of VAT by SaLTs [16]. Future research must develop VAT standards specific to a health care context, establishing robust privacy and data security features with governance requirements in mind [33]. In the UK-based context, this should ensure VAT meets National Health Service GDPR collection and storage requirements.

While a lack of experience and training can contribute to frustration with technology [51], increased experience and knowledge can positively impact attitudes [53]. SaLTs' opinions of information and communication technology in therapy were impacted by perceived performance outcomes, benefits to their work, and support in terms of education and training [54], and wider research indicates that promoting positive SaLT attitudes to technology and digital media is vital to supporting adoption [55]. It may be that increased knowledge of VAT's capabilities in an applied SLT context could positively impact clinicians' perceptions of VAT's usefulness in SLT and lead to increased adoption. This is supported by technology adoption models such as the unified theory of acceptance and use of technology [56] and the technology acceptance model [57].

Despite this, no literature has examined education and training or knowledge translation interventions for clinical use of VAT as a tool for speech and voice difficulties. Literature regarding clinical applications of virtual reality in occupational therapy and SLT indicates that several education methods have been implemented, including manuals, web-based courses, and workshops [58,59]. Support for SaLTs using VAT with people with PD may include basic training about the range of technologies available, education regarding VATs everyday uses, skills and abilities, potential benefits, and information about applying the tool in practice, such as providing specific application examples with practice-based learning, information around privacy and GDPR, and linking to alternative delivery of known therapies such as LSVT [16]. Education and training strategies should work in tandem with research knowledge to translate the theoretical into practical and seek to empower SaLTs to become digitally enabled practitioners [60]. Future research should seek to create an educational VAT resource for SaLTs, using co-design methodology and behavior change frameworks to support the use of VAT as a therapeutic tool for the management of speech and voice disorders.

Design and Features of a VAT Tool (A Vision for the Future)

SaLTs indicated that a future VAT tool for therapeutic management of dysarthria may take the form of an Alexa skill, with practice exercises for various speech subsystems, functional phrases, and conversation, as well as increased feedback on speech and intelligibility. Given that commercial VAT is a widely available technology, using available features to overcome the described limitations would facilitate increased accessibility and ease of use for SaLTs. Wider research has created physical activity and exercise interventions, based on recognized guidelines, and self-management instructions using Amazon Alexa Skills [17,61-63]. This indicates the potential for an Alexa Skill for SLT, which adapts standard LSVT protocols to facilitate alternative delivery and potential self-management as part of therapeutic management. Developer kits such as Alexa Blueprint and Alexa Skills Kits may be used. Research indicates that skills should be scalable, cost-effective, and customizable, with a focus on increasing motivation and engagement [33]. Alternatively, there may be skills available that can be repurposed for SLT purposes, and a voice assistant hub with suggested skills [24] may also be beneficial for SaLTs. Overall, to ensure VAT tools meet SaLTs' clinical needs, future

XSL•FO
RenderX

research should involve SLT end users in the cocreation of a VAT tool for the therapeutic management of dysarthria. This may use frameworks such as Design Thinking or ideas to focus on designing solutions to barriers suggested in this research, as well as ideating and refining suggested features.

Limitations

This research was conducted with SaLTs based in the United Kingdom. Whilst participants work in a range of geographical locations across the United Kingdom, their experiences may not reflect the more diverse attitudes and experiences with VAT globally. Future work should replicate findings to ascertain result generalizability.

Second, to be eligible for participation, SaLTs had to be actively engaging with VAT already. These participants are likely to have positive attitudes to VAT and may have self-selected for participation. Furthermore, these SaLTs may also have adequate digital skills to use technology that may not have been evident in SaLTs who were not users of the technology. Given that the aims of the review focused on users of VAT, this is an expected limitation with the target population required to fully answer the research question.

Finally, due to scheduling conflicts, additional interviews to focus groups had to be completed. Given that there is a more transactional interaction during interviews, richer data may have been generated by the inclusion of these SaLTs in focus groups. However, this reflects the pragmatic considerations of conducting research with working clinicians and is a point of consideration for future studies.

Additionally, given the novel nature of the VAT technology, a low number of clinicians are actively implementing the technology in clinical practice. Therefore, this study had a smaller number of participants than the suggested 6-8 in the literature [24] due to pragmatic considerations and challenges with recruitment and scheduling. Therefore, individual interviews were completed with two SaLTs. As artificial intelligence will undoubtedly play a larger role in health care in the coming years, replication of this research in the future may yield interesting results.

Recommendations

This study makes recommendations for future research to develop the therapeutic use of VAT:

- Co-design of a therapeutic VAT tool for hypokinetic dysarthria, which may include feasible solutions to technological limitations, to meet the clinical needs of SaLTs.
- Co-design of applied education and guidelines for therapeutic use of VAT, technology upskilling, and privacy and governance applications. Future work must also identify the optimal route for the delivery of education and training based on behavior change frameworks.
- A feasibility trial of a therapeutic VAT intervention for people with PD with dysarthria, including pre- and postacoustic analysis of voice or self-reported impacts.

Conclusions

This study builds upon Kulkarni et al [16] by exploring SaLTs' experiences of using VAT as a therapeutic tool for speech and voice difficulties. Positive therapeutic outcomes for intelligibility, volume, and clarity of speech are reported, with the potential for VAT to facilitate home practice and self-management of dysarthria. However, clinicians must balance this with well-being implications, device errors, practical implementation factors, and privacy concerns. These difficulties should be addressed in future research to enable the integration of VAT as a therapeutic tool.

Future research should use participatory research with clinicians using VAT to create achievable and practical solutions to VAT's usability challenges and consider the adaptation of the standard LSVT protocol to facilitate the development of an Alexa Skill. The feasibility of a VAT tool for SLT may be established by adapting Smith et al [14]. By examining quantitative outcomes relating to intelligibility and volume and self-reported changes, as well as potential generalization and maintenance effects, an initial evidence base may be established for the use of this novel technology in SLT.

Acknowledgments

The authors would like to thank Donna McGuckin, Emmet Leyden, and Dr Marc Parker for their contribution to this research as members of the patient and public involvement group. The authors would also like to thank the speech and language therapists from across the United Kingdom who generously gave up their time to attend focus groups and interviews.

Abstract

Background: Artificial intelligence (AI)–based gait analysis systems are increasingly applied in rehabilitation settings for objective and quantitative assessment of gait function. However, despite their potential, clinical adoption remains limited due to insufficient consideration of usability, user experience, and integration into actual clinical workflows.

Objective: This study aimed to conduct a formative evaluation of a prototype AI-based gait analysis system (MediStep M).

Methods: A mixed methods formative usability evaluation was conducted with 5 licensed physical therapists. Qualitative data were collected through focus group interviews, and quantitative usability was measured using the system usability scale (SUS). A scenario-based usability assessment was applied to identify user interface challenges, workflow issues, and potential design improvements.

Results: Participants identified major usability barriers, including limited accessibility of the power button, absence of battery status indicators, burdensome manual calibration, and insufficient clinical detail in the gait analysis reports. They also emphasized the need for wireless operation, improved portability, and integration with hospital electronic medical record systems. The mean SUS score was 57 (grade D), indicating suboptimal usability and the need for iterative design refinements.

Conclusions: Although AI-based gait analysis systems hold promise for enhancing rehabilitation outcomes, key usability challenges must be resolved before clinical implementation. Improvements in hardware portability, automated calibration, data management, and user interface design are essential to ensure safety, efficiency, and clinical applicability. These findings provide evidence-based insights to guide iterative development and promote user-centered innovation in AI-based rehabilitation technologies.

KEYWORDS

usability evaluation; AI-based gait analysis; focus group interview; system usability scale; rehabilitation

Introduction

Gait analysis plays a critical role in the rehabilitation of individuals with neurological or musculoskeletal impairments [1-4]. Quantitative assessment of gait function enables clinicians to objectively evaluate motor performance, establish evidence-based treatment plans, and monitor functional recovery over time [2,5]. However, conventional gait analysis systems such as treadmill-based or marker-dependent motion capture platforms require specialized laboratories, trained operators, and controlled environments [6,7]. These limitations restrict their feasibility for routine clinical application and hinder broader accessibility in diverse rehabilitation settings [6,8].

XSL•FO
RenderX

Recent advancements in artificial intelligence (AI), computer vision, and depth-sensing technologies have facilitated the development of markerless, AI-driven gait analysis systems capable of automatically estimating joint coordinates and computing spatiotemporal gait parameters [9-12]. Such systems have the potential to make gait analysis more portable, cost-effective, and clinically scalable [6,10,13]. Compared to conventional systems such as Zebris, which rely on treadmill-based assessments within constrained spatial setups, emerging overground AI-based systems are designed to enable natural walking conditions with minimal setup requirements [9,14].

Despite these technological advancements, many AI-based gait analysis systems continue to face significant usability challenges that limit their integration into real-world rehabilitation environments. Reported issues include labor-intensive calibration procedures, unclear user feedback interfaces, hardware nonportability, and poor alignment with clinical workflows. Previous research in human factors and digital rehabilitation has emphasized that usability—particularly intuitiveness of the user interface, workflow efficiency, and error prevention—is a primary determinant of successful clinical adoption and user satisfaction [15].

To address these challenges, we conducted a formative evaluation of a prototype AI-based gait analysis system, MediStep M. The evaluation was performed with physical therapists, who represent the primary end users of gait analysis technologies in clinical practice. A mixed methods approach was employed, combining qualitative focus group interviews (FGIs) with quantitative assessments using the system usability scale (SUS). This approach aimed to identify use-related problems, interface limitations, and potential design improvements to guide iterative enhancement of AI-based rehabilitation technologies and to ensure their alignment with clinical usability requirements.

Methods

Study Design

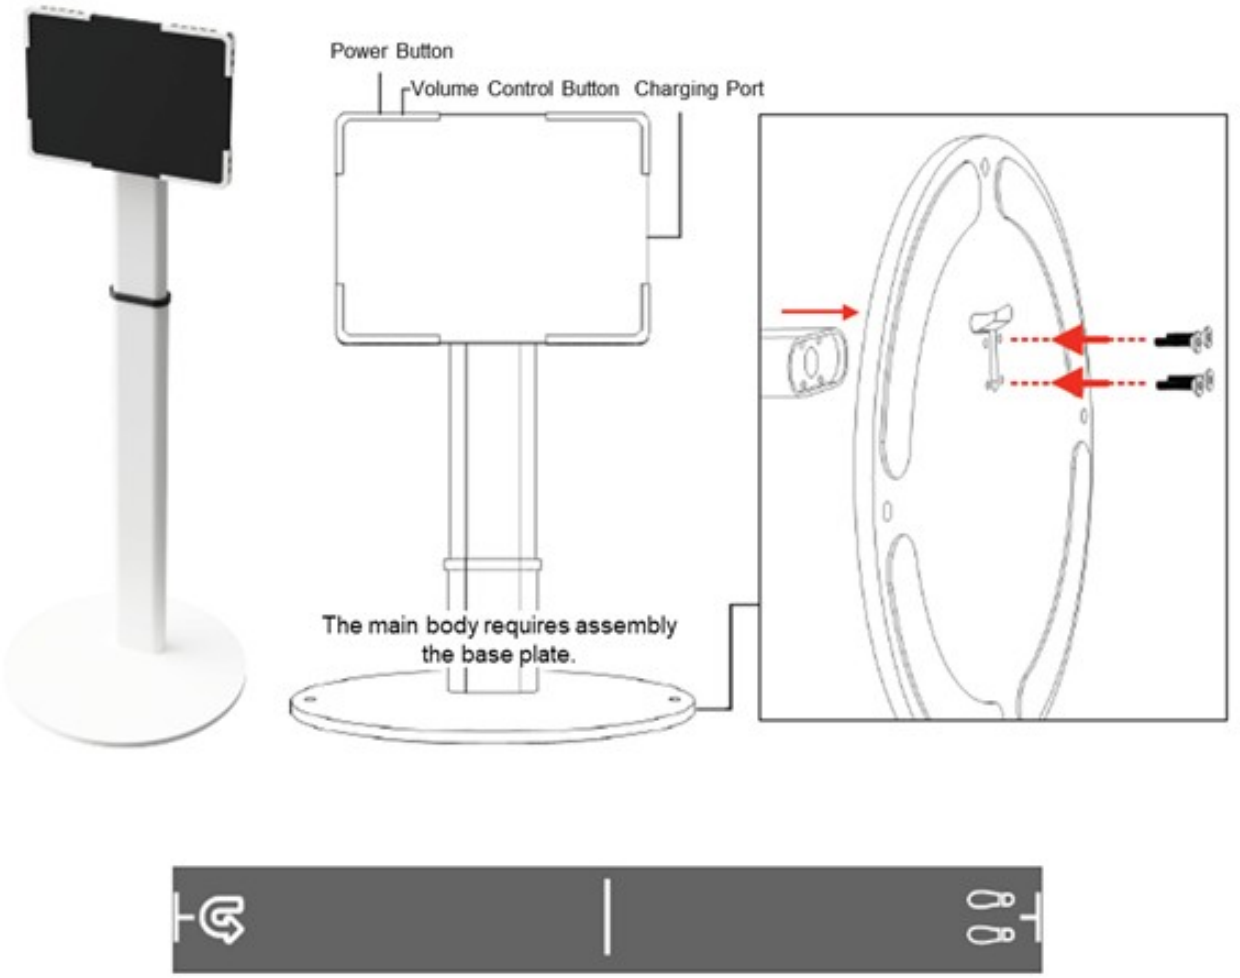
This study employed a formative evaluation design to identify use-related problems and interface improvement needs of a prototype AI-based gait analysis system (MediStep M). The evaluation followed the usability engineering framework described in IEC 62366-1:2020, focusing on user-system interaction and workflow alignment.

Materials

MediStep M is a prototype AI-based gait analysis system commissioned by the manufacturer for formative evaluation. The system was designed to enable objective assessment of gait deterioration in older adults and to monitor functional recovery following therapeutic interventions. Currently, in the prototype stage, the system consists of general-purpose hardware (a tablet device) running the MediStep M software (Figures 1-2).

XSL•FO
RenderX

Figure 1. Artificial intelligence–based gait analysis system hardware: tablet and gait mat.



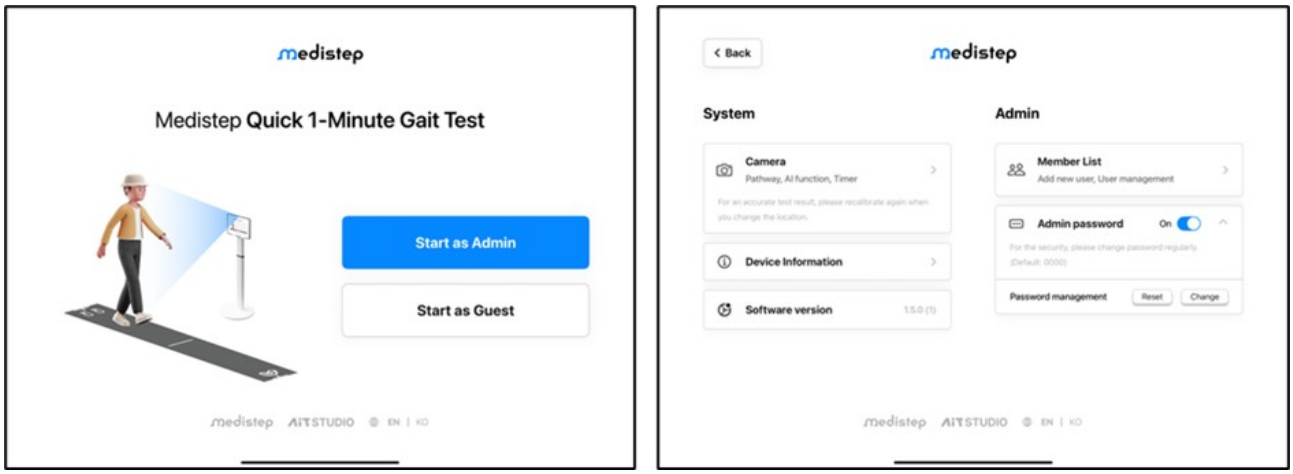


Figure 2. Artificial intelligence–based gait analysis system software interface (start user interface and settings user interface).

Using the tablet's built-in camera, the system captures side-view videos of participants performing back-and-forth walking tasks. Through markerless pose estimation technology, the software automatically extracts full-body joint coordinates and computes spatiotemporal gait parameters. These parameters are visualized and quantified to generate comprehensive gait reports, including stride length, walking speed, arm swing amplitude, upper-body inclination, and gait asymmetry. The generated reports are intended to assist clinicians in evaluating gait characteristics and identifying deviations from normative patterns.

Participant Recruitment

Five licensed physical therapists participated in the study. All participants had a minimum of 5 years of professional experience in gait assessment and rehabilitation. Recruitment

XSL•FO
RenderX

was conducted through the National Rehabilitation Center via an internal call for participation.

The inclusion criteria were as follows: (1) licensed physical therapists with clinical experience in gait analysis or rehabilitation, (2) current engagement in gait-related clinical practice, and (3) prior exposure to gait analysis systems or equivalent medical devices.

Participants who were not actively involved in patient treatment or who performed administrative duties only were excluded. The final sample consisted of 4 male therapists and 1 female therapist, reflecting diverse experience levels across inpatient and outpatient rehabilitation contexts.

Procedures

Formative Evaluation Procedures

The formative evaluation was conducted at the National Rehabilitation Center in Seoul, Republic of Korea. Each session was conducted in a controlled clinical environment and lasted approximately 90 minutes (Table 1).

Table 1. Formative evaluation procedures, involving practitioners and evaluators, conducted for 90 minutes under the guidance of a facilitator.

Composition	Details	Time (min)
Orientation	• The moderator introduced the focus group interview to the participants (physical therapists) and provided an explanation of the product to be discussed, including its purpose, an overview, and the methods involved.	10
Guidance on consent	• The moderator informed participants about the video and audio recording procedures. • After confirming that the physical therapists fully understood the details of the study, written informed consent was obtained voluntarily. • Prior to the interview, the moderator conducted a survey to collect general demographic information from the participants.	10
Perform focus group interview	• The moderator conducted user training, demonstrations, and interviews according to a predetermined script. • The participants (physical therapists) observed the demonstrations, responded to interview questions, and were allowed to operate the product if necessary. • An observer documented the entire interview process.	50
Perform SUS[a]	• Following the focus group interview, SUS was administered, followed by an additional interview to gather further feedback from the participants.	20

[a]SUS: system usability scale.

The evaluation consisted of 3 main stages:

1. Product demonstration: The facilitator conducted a live demonstration of MediStep M according to predefined clinical use scenarios. This included device setup, calibration, gait data acquisition, and report interpretation. The demonstration followed the manufacturer's standard workflow and was intended to simulate typical clinical usage conditions.
2. Participant interaction and observation: Participants observed the demonstration, and when appropriate, were given the opportunity to interact with the system interface (eg, initiating data capture, reviewing gait reports) to better understand its functionality. During this phase, the facilitator encouraged participants to verbalize their thoughts and perceptions regarding usability issues and potential improvements.
3. FGI and SUS assessment: After the demonstration, participants took part in a 60-minute FGI to provide detailed feedback on user interface intuitiveness, workflow integration, and areas for improvement. Subsequently, SUS was administered to quantify perceived usability. Reverse-scored items (2, 4, 6, and 8) were appropriately adjusted before calculating individual and mean SUS scores.

Task Scenarios

Table 2 shows the different scenarios in product demonstration, including device setup, calibration, gait data acquisition, and report interpretation.

XSL•FO
RenderX

Table 2. Task scenarios.

	Task	Subtask
1	Powering on the device	• Connect the charging port and check whether the indicator light turns on. • Press the power button located at the upper left on the front panel to turn on the device.
2	Camera calibration	• Open the calibration settings window and perform the camera calibration before starting. • While monitoring the screen, position the device so that the entire walking path is centered within the camera's field of view. • Adjust the device's position and orientation to ensure the vertical guideline aligns with the centerline of the walking mat. • Resize the guidelines so that both ends of the horizontal guideline align with the T-marks at either end of the walking path.
3	Using the MediStep application	• Click the "Start as Administrator" button. • Enter the user information into the designated fields on the software interface. • Review the displayed information, and then click the "Start AI[a] Gait Assessment" button.
4	Gait analysis	• Select the recording standby timer. • Touch the record button.
5	Interpretation of results	• The gait analysis results and corresponding gait videos can be reviewed through the report screen.
6	Member management	• Adding/deleting members • In the member list under the settings menu or on the examiner selection screen, tap the "Add New Member" button. • Enter the member's name, the first 6 digits and the first digit of the last 7 digits of their resident registration number, and their height. • Then tap the "Add" button. To delete a member, select the member from the list. A pop-up window will appear with options to edit or delete the information. Tap the "Delete" button. • Editing member information • This function is accessible only via the member list in the settings menu. • Select the desired member; a pop-up window will appear with options to edit or delete their information. After making the necessary changes, tap the "Complete Edit" button.

[a]AI: artificial intelligence.

FGI Method

An FGI is a qualitative research method that collects data through in-depth discussions with intentionally selected participants on a specific topic [16,17]. This approach encourages individuals to openly share their experiences and engage with others' insights, thereby providing diverse perspectives and rich, detailed information on the subject matter [18]. FGIs are considered an appropriate research method for analyzing and identifying areas for improvement in gait analysis software interfaces from the perspective of clinicians with experience in using similar medical devices (Figure 3). The FGI questionnaire (Table 3) was structured based on the type of questions, including introductory, transitional, key, and closing questions [17].

Figure 3. Conducting the focus group interview session.

XSL•FO
RenderX

Table 3. Focus group interview questionnaire.

Stage	Questions
Opening questions	• General characteristics: (eg, age, gender, clinical experience, experience with similar medical devices) • Interview question: Are you currently using gait analysis products or similar medical devices to assess or treat patients?
Transition questions	• Could you describe your experience using similar products or medical devices? • What types of assessments or treatments have you performed using gait analysis products or similar medical devices? Please include the purpose and methods of the assessments or treatments. • In your opinion, what are the advantages of using gait analysis products or similar medical devices for clinical assessments? • What key aspects should be considered in the development of gait analysis software?
Key questions	• Based on the user manual provided, do you have any comments on the product's composition (eg, contents, structure, or layout)? • Following the verbal explanation and demonstration, do you anticipate any user interface errors or potential hazards when using the MediStep M interface? • Are there any elements of the user interface that you believe should be improved? (demonstration provided according to the product scenario.) • Do you have any additional comments or suggestions regarding this product?
Ending questions	• If you have any further opinions on aspects to consider in the development of gait analysis software, please share them.

SUS Evaluation Tool

The SUS is a quantitative evaluation tool used to assess how users perceive system usability [19]. The SUS comprises 10 items rated on a Likert scale (1=strongly disagree to 5=strongly agree) (Table 4). The total score was converted to a range of 0-100 points to evaluate overall system usability. Moreover, the SUS scores were assigned a letter grade from "F" (0-60 points) to "A" (91-100 points) according to a standardized grading system [20,21].

Table 4. System usability scale questionnaire.

Items	Statement
Utility	I think that I would like to use this system frequently.
Complexity	I found the system unnecessarily complex.
Simplicity	I thought the system was easy to use.
Professionalism (technician support)	I think that I would need the support of a technical person to be able to use this system.
Integration	I found the various functions in the system were well integrated.
Unity	I thought there was too much inconsistency in this system.
Learnability	I would imagine that most people would learn to use this system very quickly.
Convenience	I found the system very cumbersome to use.
Satisfaction	I felt very confident using the system.
Professionalism (prior learning)	I needed to learn a lot of things before I could get going with this system.

Data Analysis

Qualitative data from FGIs were transcribed verbatim and analyzed using an inductive thematic analysis approach. Two independent researchers coded the transcripts to identify recurring patterns, usability barriers, and improvement suggestions. Themes were derived through iterative comparison and consensus discussions.

Quantitative data from SUS were analyzed descriptively to calculate mean scores, standard deviations, and percentile rankings based on established SUS benchmarks. Both qualitative and quantitative findings were triangulated to derive comprehensive insights into the system's usability and user needs.

Ethical Considerations

The study protocol was reviewed and approved by the institutional review board of the National Rehabilitation Center (government-affiliated national rehabilitation center in Seoul, Republic of Korea; NRC-2024-06-046). All participants provided written informed consent prior to participation and were informed that participation was voluntary and that they could withdraw from the study at any time without any penalty or disadvantage. Participants received a nonmonetary gift with a value of up to KRW 50,000 (US $34.05) as a token of appreciation for their participation. To ensure confidentiality,

XSL•FO

all identifiable personal data were removed, and all photographic materials were anonymized prior to analysis and publication.

Results

Participant Characteristics

Five licensed physical therapists participated in the evaluation, with clinical experience ranging from 7 to 23 years (Table 5). All participants had prior experience using similar gait analysis systems (eg, Zebris, Joynt, or Morning Walk) and reported a usage frequency of 1-3 times per week.

Table 5. General characteristics of the participants.

ID	Sex	Experience	Similar medical device			
			Used before	Model name	Experience of use	Frequency of use
P1	Female	8 y 8 mo	Yes	Zebris	1 y	1 time/wk
P2	Male	18 y 9 mo	Yes	Zebris	1 y	3 times/wk
P3	Male	23 y	Yes	Joynt	1 y	1 time/wk
P4	Male	7 y 8 mo	Yes	Morning Walk	2 y 2 mo	3 times/wk
P5	Male	15 y 7 mo	Yes	Zebris	1 y	2-3 times/mo

Qualitative Findings (FGI)

FGIs revealed several key themes regarding usability, functionality, and areas for improvement of the AI-based gait analysis system.

Theme 1: Importance of Real-Time, Quantitative, and Understandable Feedback

The participants (P1-P5; as indicated in Table 5) appreciated the ability of gait analysis devices to provide quantitative assessments, particularly for aspects that are difficult to measure visually, such as gait symmetry and alignment. They emphasized that real-time feedback not only enhances clinicians' evaluation capabilities but also motivates patients by enabling them to monitor their own gait patterns. However, some participants noted that complex setup procedures and spatial constraints could limit the practical utility of such devices in busy clinical environments.

> *…The advantage is that machines can accurately measure what we cannot visually quantify, such as distance and symmetry, without requiring large spaces.* [P1]
>
> *…Real-time visualization of movements could help patients self-correct during therapy sessions.* [P2]

Theme 2: Necessity for Simplified and Portable Hardware Design

Although the hardware components and instructions were generally understandable, several participants stressed the need for wireless operations to enhance portability and convenience. The participants recommended minimizing wired connections, incorporating a wireless printer, and adding basic features such as a built-in level gauge for easier setup on uneven surfaces.

> *…The product should be portable. Wireless operation would greatly improve usability.* [P2]
>
> *…Adding a leveling tool on the device would help ensure proper setup on uneven floors.* [P3]

Theme 3: Challenges Related to Power Button and Battery Display

Many participants expressed frustration with the placement of the power button, which was obscured by the device frame. They suggested relocating it for easier access and improving the visibility of the battery status, either through a larger indicator light or by displaying the battery percentage on the screen.

> *…The power button is hidden behind the frame, making it very inconvenient to press.* [P1]
>
> *…It would be helpful to see the battery level on the main screen.* [P2]

Theme 4: Calibration Process Needs Automation

The participants criticized the manual calibration process, noting that it could introduce human error depending on the user's expertise and environmental factors. They recommended an automated calibration to enhance the reliability and usability of the system.

> *…Manual calibration can vary the results based on a user's skill. AI-based automatic calibration would significantly increase reliability.* [P1]
>
> *…It should not rely on the inspector's height but rather on more objective standards like leg length.* [P2]

Theme 5: User Interface and Patient Management System Improvements

Participants generally found the software interface to be user-friendly but identified specific areas for improvement. They requested enhancements to the patient management system, such as the introduction of an auto-complete search, ID-based patient identification, and simplified patient registration procedures.

XSL•FO
RenderX

> *…When selecting patients, it's inconvenient to search by full name. An auto-complete or list view would help.* [P3]
>
> *…It would be better if patients were identified by number rather than name for privacy and speed.* [P5]

Theme 6: Enhancing the Gait Analysis Reporting and Interpretation

Participants appreciated the effort to make the results accessible but criticized the oversimplification of the analysis outputs. The authors called for more detailed and clinically meaningful metrics and stronger reference explanations, particularly for cases involving pathological gait patterns.

> *…Simple statements like slow walking speed aren't enough. Specific advice is required, such as suggesting an increase in stride length by 10 cm.* [P4]
>
> *…The report distinguishes between normal and pathological gait patterns.* [P1]

Theme 7: Additional Requirements for Clinical Usability

Finally, the participants highlighted the need for expanded language support for international use, improved data extraction features (eg, exporting to Excel), and improved integration with hospital electronic medical record (EMR) systems. Some participants suggested adding remote-start features to minimize device manipulation during testing and prevent device tilting.

> *…If the device is intended for hospital use, data should be easily exportable and integrated with the EMR.* [P3]
>
> *…Remote control start could prevent tilting issues during test initiation.* [P2]

Quantitative Findings (SUS)

The mean SUS score was 57, corresponding to a grade of "D" on the SUS grading scale (Figure 4, Table 6).

Figure 4. System usability scale (SUS) results.

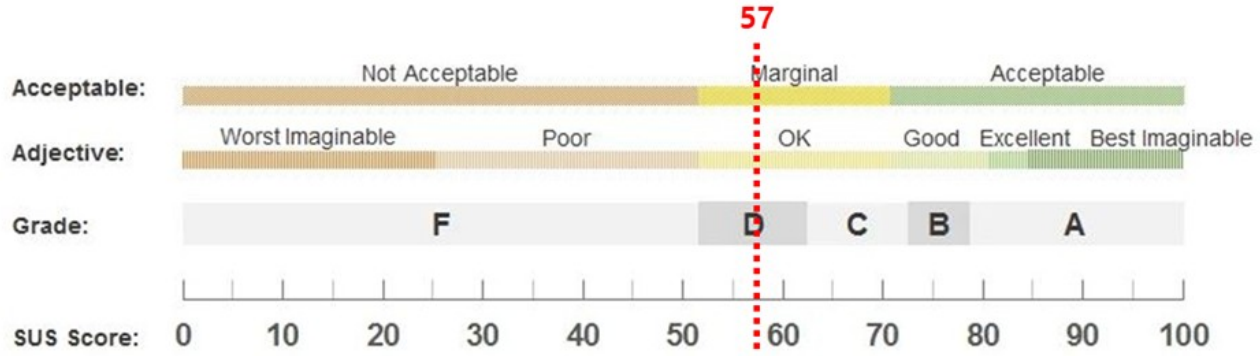

Table 6. System usability scale evaluation results (N=5).

Item	Min (point)	Max (point)	Mean (SD)	Scaled mean (SD)
Total	—[a]	—	2.88 (0.44)	57.00 (17.98)
Utility (Q1)	1.00	3.00	2.40 (0.89)	35.00 (20.00)
Complexity (Q2)	1.00	3.00	2.00 (0.71)	75.00 (15.81)
Simplicity (Q3)	4.00	5.00	4.20 (0.45)	80.00 (10.00)
Professionalism (technician support) (Q4)	2.00	4.00	3.40 (0.89)	40.00 (20.00)
Integration (Q5)	1.00	3.00	2.00 (0.71)	25.00 (15.81)
Unity (Q6)	1.00	4.00	3.20 (1.30)	45.00 (29.15)
Learnability (Q7)	3.00	5.00	4.00 (0.71)	75.00 (15.81)
Convenience (Q8)	1.00	4.00	2.20 (1.10)	70.00 (24.49)
Satisfaction (Q9)	3.00	4.00	3.20 (0.45)	55.00 (10.00)
Professionalism (prior learning) (Q10)	1.00	3.00	2.20 (0.84)	70.00 (18.71)

Discussion

Principal Findings

This formative usability evaluation identified key strengths and limitations of the prototype AI-based gait analysis system MediStep M from the perspective of clinical end users. Overall, the findings demonstrate that while the system shows strong potential to support objective gait assessment in rehabilitation, several usability issues must be addressed to enable efficient integration into clinical practice. The mean SUS score of 57 (grade D) indicates below-average usability, aligning with qualitative feedback obtained through FGIs.

Participants acknowledged the clinical value of quantitative gait analysis enabled by AI-based systems, particularly the ability to objectively visualize spatiotemporal gait parameters that are difficult to assess through observation alone. However, multiple usability barriers were identified across both hardware and software components. Hardware-related issues included limited portability, poor accessibility of the power button, and lack of a battery status indicator. Software-related challenges involved the need for automated calibration, improved patient management features, and more detailed gait reporting to support clinical decision-making. These findings highlight that usability and clinical applicability depend not only on algorithmic performance but also on the intuitiveness and efficiency of the overall user interface and workflow design.

The results of this study are consistent with prior usability research on AI-driven and markerless gait analysis systems, which similarly reported barriers such as setup complexity, calibration burden, and limited interoperability with EMR systems. Previous studies have also emphasized that successful implementation of AI technologies in rehabilitation requires a user-centered approach that reflects real-world clinical workflows [22-25]. Compared to treadmill-based systems such as Zebris, MediStep M offers an overground and portable configuration that allows a more natural gait pattern to be analyzed. Nonetheless, iterative refinement remains necessary to enhance user experience, workflow compatibility, and data management efficiency.

The findings from this study suggest several priorities for future development. First, hardware design should improve ergonomics and mobility through compact structure, wireless operation, and automated leveling mechanisms. Second, calibration procedures should be automated using AI-assisted alignment algorithms to reduce operator variability. Third, software feedback should evolve beyond raw numerical data to include graphical trends, interpretive summaries, and actionable recommendations for rehabilitation. Finally, interoperability features such as secure EMR integration and standardized data export formats are essential for broader clinical adoption.

Importantly, several of the usability issues identified in this formative evaluation were subsequently addressed by the manufacturer. As of March 2025, the finalized version of MediStep M incorporated significant hardware and software refinements, including a redesigned rear magnetic detachable cover, removal of the front frame obstructing the power button, and addition of a main-screen battery status indicator. Wireless printing capability using Apple AirPrint, an AI-based automated calibration algorithm achieving 97% accuracy compared to the manual process, and a CSV-based data export function were also implemented. This iterative process underscores how formative usability evaluations can directly inform product improvement and regulatory readiness.

Limitations

Several limitations should be acknowledged. The small sample size (N=5) limits the generalizability of our findings, and the predominance of male participants (4 out of 5) may introduce gender bias. As a formative study, the evaluation did not measure long-term usability or clinical efficacy outcomes. Future studies should include larger and more heterogeneous samples, repeated testing cycles, and longitudinal assessments to validate the system's usability and clinical performance after iterative refinement.

Conclusion

This study provides evidence on the usability of an AI-based gait analysis system from the perspective of clinical end users. Although the prototype demonstrated technical feasibility and clinical potential, several usability challenges were identified that require further optimization. The subsequent improvements implemented by the manufacturer exemplify how formative feedback can guide user-centered development of rehabilitation technologies, supporting safer and more effective integration of AI systems into clinical workflows.

Abstract

Background: An accurate tongue strength and endurance assessment is necessary for pediatric dysphagia. TongueFit is a new, portable orofacial manometer for measuring tongue strength and endurance and a game-based training app for children.

Objective: This study aimed to test the validity of TongueFit compared with a standard manometer as the current gold standard for measuring air pressure.

Methods: This laboratory study compared TongueFit and a standard manometer as the gold standard for measuring air pressure. This study was conducted in 3 different experimental conditions. The first experiment compared TongueFit and the standard manometer using a force tester (MCT-2150), with pressure controlled by MSatLite software. The second and third experiments involved 2-cm and 3-cm bulbs between the 2 devices. This study used Lin concordance correlation to measure the level of agreement.

Results: There was a mean absolute difference of 0.005 kilopascals (kPa) between the TongueFit and the standard manometer (n=35, ρC=1). Statistical analysis showed perfect agreement correlation (ρC=1). By using the 2-cm bulb, TongueFit's mean was 0.007 kPa lower, also showing perfect agreement (ρC=1). Furthermore, using the 3-cm bulb, results showed almost perfect agreement (ρC=0.999) with the TongueFit's mean, which was 0.044 kPa lower.

Conclusions: This study confirms the high validity of TongueFit as an orofacial manometer compared with a standard manometer, with negligible mean differences, as well as near-perfect and perfect agreement in the experiments. These results confirm that TongueFit is a valid and accurate tool for assessing tongue strength.

KEYWORDS

pediatric swallowing; tongue strength; tongue endurance; orofacial manometer; validity

Introduction

Eating and swallowing are dynamic processes essential for children's growth and development [1]. This complex mechanism involves the coordination of more than 30 nerves and muscles in the oral cavity, pharynx, larynx, and esophagus [2,3]. Typically, the swallowing process is divided into 3 distinct phases based on the passage of the bolus through different anatomical regions: the oral phase, the pharyngeal phase, and

XSL•FO
RenderX

the esophageal phase. Each phase is critical in facilitating food and fluids' safe and efficient passage from the mouth to the stomach, ensuring proper nutrition and hydration for optimal growth and function [3-5].

The tongue comprises bundles of highly flexible, vascularized, and innervated muscles that play a critical role in the oral phase of swallowing. Tongue movements, controlled by the intrinsic and extrinsic muscles, include protrusion, retraction, elevation, depression, rotation, lateralization, cupping, and twisting [6,7]. Tongue dysfunction can result in reduced tongue strength and endurance, potentially compromising swallowing function and leading to difficulty eating and swallowing, a condition commonly referred to as oral dysphagia [8]. Reduced tongue strength can significantly impact several aspects of tongue function, including chewing, bolus control, and bolus clearance. Previous research suggests that reduced tongue strength may contribute to oral and pharyngeal dysphagia [9]. Tongue muscle weakness could decrease intraoral pressure during swallowing, thereby increasing pharyngeal residue and risk of aspiration in the pharyngeal phase [6,10].

The early diagnosis of dysphagia is important for the prevention of malnutrition, dehydration, and aspiration pneumonia, in addition to allowing adequate treatment [11]. Previous studies evaluating neurological pathologies that affect swallowing disorders have observed a positive association between tongue strength and dysphagia. Dysphagic patients had significantly reduced tongue strength and endurance compared with patients with preserved swallowing [11-13]. Therefore, evaluation of tongue strength and endurance is critical, especially in populations of children who have feeding difficulties and are at increased risk for eating and swallowing disorders, such as children with cerebral palsy, Down syndrome, and other related conditions [14,15].

Assessment of tongue strength is essential because of its important role in eating and swallowing [16]. Various orofacial manometers have been developed to measure tongue force objectively and continue to evolve. One of the most widely used orofacial manometers is the Iowa Oral Performance Instrument (IOPI). The IOPI is a portable device designed to measure tongue strength and endurance, using an air-filled bulb as a sensor to measure the maximum isometric force of the tongue in kilopascals (kPa). The IOPI provides biofeedback in the form of a vertical light indicator that illuminates when the target pressure is reached. It also includes a training mode designed to improve tongue strength and endurance [17-19]. It has been used extensively in numerous studies and has shown reasonable validity and reliability. However, the IOPI has limitations. It is unavailable in the Indonesian market, and users reported problems slipping the air-filled bulb during measurements.

There was no tool specifically designed for children to measure and train their tongue strength and endurance. Therefore, we developed a device called "TongueFit" that is designed for both clinical and home use. It features a nonslip surface on the air-filled bulb sensor and incorporates a game-based biofeedback for exercise. The biofeedback was created as an Android-based app to complement the device. This app allows users to access measurement results, historical data, and game-based exercises. Integrating game-based biofeedback in TongueFit enhances dysphagia treatment by providing real-time feedback and rewarding good performance with scores. This approach transforms therapy into an engaging experience, fostering greater participation, particularly in pediatric patients.

Although TongueFit can also be used as an exercise tool to improve tongue strength and endurance, the focus of this study was solely on assessing the validity of TongueFit as a measurement tool. By focusing solely on the validity of TongueFit's measurement capabilities, we seek to provide empirical evidence to support its efficacy as a tool for assessing tongue strength and endurance. This study aimed to determine the accuracy of TongueFit in quantifying tongue muscle performance in kPa. In addition, by confirming the validity of TongueFit's measurements, we aimed to establish TongueFit as a valuable tool in clinical settings, facilitating more accurate diagnoses and tailored treatment plans for individuals with tongue-related impairments.

Methods

Overview of TongueFit

TongueFit consisted of 2 essential components: hardware and software, both of which were interdependent for operation. The hardware included a manometer device along with 2 variations of bulb sizes. The bulbs and tubes were made of biobased polyurethane and polylactic acid—food-grade materials that had undergone rigorous toxicity testing in the laboratory to ensure their safety (Figure 1). The tests were performed at the Stem Cells and Tissue Engineering Research Centre, Cluster Indonesian Medical Education and Research Institute Fakultas Kedokteran Universitas Indonesia, using human stem cells. A material was declared toxic if the percentage of stem cell death exceeded 30% of the total stem cells within the control group in the tests. Based on the toxicity tests conducted on the bulb and hose materials, which were repeated at 15, 30, and 60 minutes, the percentage of cell death was less than 16%. Therefore, it can be concluded that the bulbs and tubes are nontoxic.

The software component included a mobile app that allows users to measure tongue strength and endurance, access measurement results, review historical data, and participate in game-based exercises in Bahasa (Figure 2). Tongue strength is assessed by positioning the bulb anteromedial on the tongue and instructing the patient to elevate the tongue against the palate with maximum effort. This measurement is performed 3 times, and the highest recorded value is used as the reference target for endurance assessment and exercise therapy. Tongue endurance is evaluated by having the patient sustain tongue elevation against the palate at 40% - 60% of their maximum strength for as long as possible.

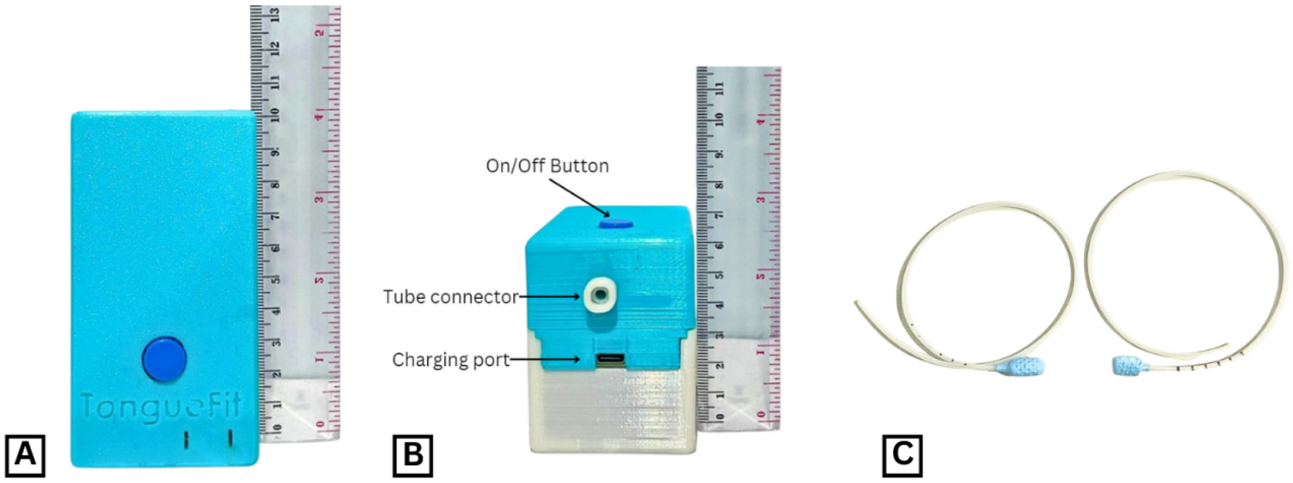
Figure 1. The hardware components of TongueFit. (A) The manometer; (B) the body of the TongueFit comprises the manometer hardware, an on/off button, a tube connector, and a charging port; and (C) the tongue bulb has two different sizes, consisting of the 2-cm bulb (right) and the 3-cm bulb (left).



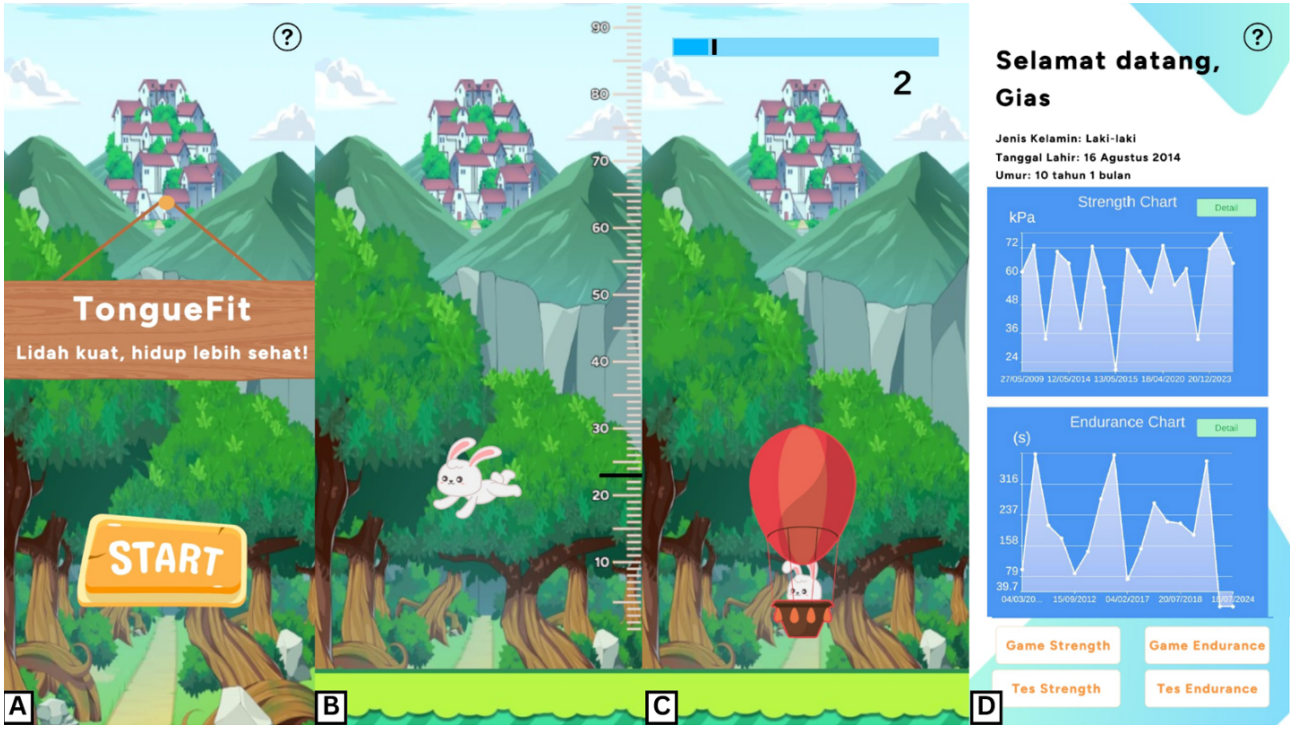


Figure 2. The TongueFit app. (A) Opening page; (B) tongue strength test; (C) tongue endurance test; and (D) tongue strength and endurance chart result.

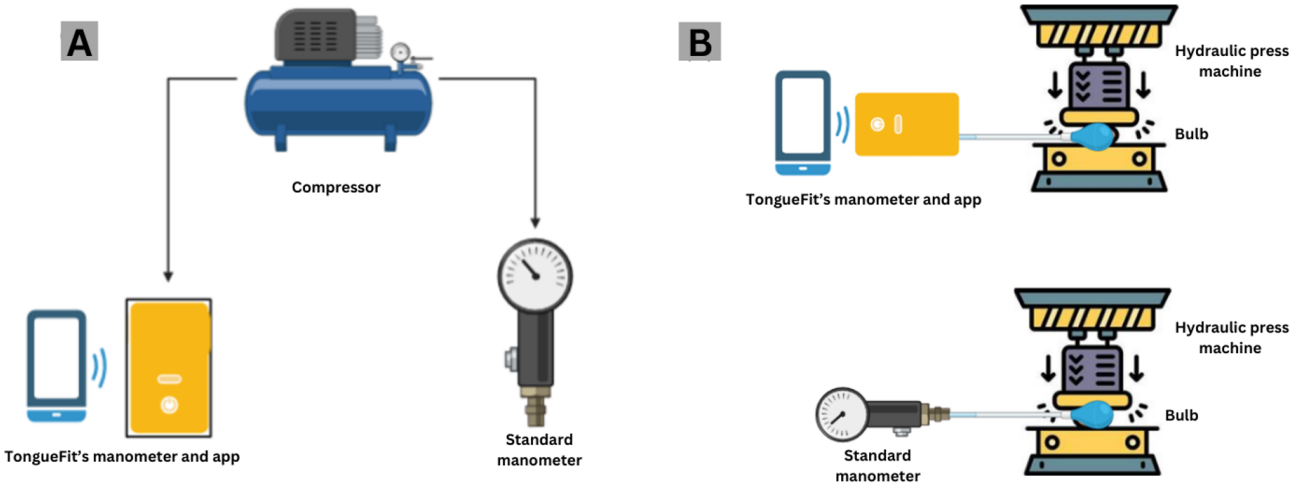
Tongue strength and endurance measurements were conducted before therapy to establish baseline values, which served as a reference for the exercise prescription using "TongueFit." The strengthening and endurance exercises targeted the anterior tongue, considering its muscle fiber composition, primarily type IIa fibers, which exhibit fast contraction properties while maintaining a degree of endurance [9,20]. As a result, the exercise protocol incorporated both strengthening and endurance components. The exercise prescription adhered to the FITT (frequency, intensity, time, and type) principle, with strengthening exercises performed at an intensity of 60% - 80% and endurance exercises at 40% - 60% of maximum tongue strength. Each session lasted for 15 minutes per exercise type, with 30 repetitions per session.



The development of TongueFit's device and app underwent user experience testing through the creation of a mock-up [21]. The mock-up of the tool was tested on a group of medical doctors experienced in pediatric rehabilitation representing potential users to ensure the quality and comfort of the final product. The testing process for the mock-up of TongueFit's device focused on evaluating comfort and ergonomics and identifying potential design improvements. In parallel, TongueFit's app mock-up trial assessed navigation, design consistency, and user interface comprehension. Based on the test results, the mock-up was improved and adjusted to better meet the needs of the target users.

In this study, we compared measurements obtained from TongueFit and a standard manometer (SNDWAY SW-512C, Dongguan Sndway Electronic), considered the gold standard

XSL•FO
RenderX

for measuring air pressure differences. TongueFit offered two different bulb sizes: a 2-cm bulb for children under 6 years of age and a 3-cm bulb for children over 6 years of age and adults. Our experiment included the evaluation of both bulb sizes and the TongueFit device itself. This study was conducted in 3 different experimental conditions (Figure 3). The first experiment compared TongueFit and the standard manometer using a compressor. The second and third experiments involved 2-cm and 3-cm bulbs between the 2 devices.

Figure 3. Validation test scheme. (A) TongueFit versus standard manometer with compressor, and (B) TongueFit versus standard manometer with bulb validation test.

TongueFit Versus Standard Manometer

This experiment was designed to validate the ability of the TongueFit to provide accurate pressure measurements compared with the standard manometer. Each device was connected to a universal high-performance force tester (MCT-2150, A&D), which acted as an air compressor and controlled air pressure source. This connection was made alternately through a polyurethane tube. The air pressure given to each device was controlled by MSatLite software (A&D). The pressure was gradually increased, starting at 2 kPa and increasing by 2 kPa for each measurement to a maximum of 70 kPa. Each measurement started from 0 kPa.

TongueFit With 2-cm Bulb Versus Standard Manometer With 2-cm Bulb

This experiment aimed to ensure the consistency of measurement results between the TongueFit and the standard manometer when each device was connected to a 2-cm air-filled bulb that we developed. To maintain a controlled pressure on the bulb, the previously used force-tester device (MCT-2150, A&D) was configured as a computer-controlled hydraulic press machine in the laboratory, using software called MSatLite (A&D) to apply pressure on the bulb.

To conduct this experiment, TongueFit was connected to the air-filled bulb via a tube, and the bulb was positioned under the hydraulic press machine with a fixture. The machine applied pressure to the entire surface of the bulb to ensure uniform pressure distribution. The compression of the bulb was carried out by using a hydraulic machine, starting from 0.6 mm and increasing by 0.2 mm for each measurement until 5 mm was reached, each measurement starting from 0 kPa. The same procedure was then performed with the 2-cm bulb connected to the standard manometer.

TongueFit With 3-cm Bulb Versus Standard Manometer With 3-cm Bulb

This experiment followed identical procedures to the 2-cm bulb experiment. Maintaining consistency in the experimental protocol ensured that the methodology, conditions, and variables studied remained consistent throughout the investigation. This approach allowed for a direct comparison between the results of the 2 experiments, facilitating a comprehensive evaluation of the effect of different bulb sizes.

Statistical Analysis

The obtained measurement data were recorded and processed using Microsoft Excel. Data analysis was performed using SPSS software (version 27; IBM Corp). The validity test used the Lin concordance correlation coefficient to assess the degree of agreement between the standard manometer and TongueFit. Lin concordance correlation coefficient (ρC) results of <0.9 indicate poor validity, the range of 0.9 - 0.949 indicates moderate validity, 0.95 - 0.99 indicates substantial validity, and values >0.99 indicate almost perfect validity.

Results

Overview

This study was a laboratory-based study that compared TongueFit and a standard manometer in 3 different experiments.

TongueFit Versus Standard Manometer

The sensor readings obtained by TongueFit (Table 1 and Figure 4) show a slightly higher mean value of 0.005 kPa compared with those recorded by the standard manometer when the compressor administered air pressure. Upon further statistical analysis, a perfect agreement value (ρC=1) indicates a precise agreement between TongueFit and the standard manometer readings.

Figure 4. Relationship between TongueFit device readings and standard manometer device readings. (A) The graph of the TongueFit device is a scatter plot with a black solid line representing the best line and a red dashed line representing the perfect line, and (B) the Bland-Altman plot of the difference between the 2 devices, with the black solid line representing the mean difference between the measurements and the red dotted line representing 1.96 SDs above and below the mean difference.

TongueFit With 2-cm Bulb Versus Standard Manometer With 2-cm Bulb

When tested with the 2-cm bulb (Table 2 and Figure 5), TongueFit showed a perfect agreement value (ρC=1), with its mean value being 0.007 kPa lower than that of the standard manometer. This indicated a consistent trend of TongueFit readings being slightly lower than the standard manometer across different bulb sizes.

Figure 5. Relationship between TongueFit and standard manometer pressure readings connected to the same 2-cm bulb. (A) The scatter plot with the black solid line representing the line of best fit and the red dashed line representing the line of perfect agreement. (B) The Bland-Altman plot of the differences between the 2 devices, with the black solid line representing the average differences between the measurements and the red dashed line representing 1.96 SDs above and below the average differences.

TongueFit With 3-cm Bulb Versus Standard Manometer With 3-cm Bulb

The test results using the 3-cm bulb (Table 3 and Figure 6) showed almost perfect agreement (ρC=0.999), with a 95% CI ranging from 0.998 to 0.999. In this scenario, the average TongueFit reading was significantly lower than the standard manometer by 0.044 kPa.

Overall, TongueFit showed strong validity across all experiments, as indicated by ρC values greater than 0.99. This means an almost perfect agreement between the TongueFit measurements and those obtained with the standard manometer.

Discussion

Principal Findings

Assessment of tongue strength is essential because of its important role in eating and swallowing [13]. Over time, several methods have been developed to measure tongue strength to evaluate tongue function. The orofacial manometer is a widely used tool for quantifying tongue strength, with the IOPI being one of the most commonly used devices. When lingual force is applied to the air-filled bulb, this measures the pressure difference against a predetermined air volume. It then digitally displays the pressure inside the bulb in kPa [10,11]. The TongueFit device, which we developed, works on the same principle. In addition, we integrated game-based biofeedback into the exercises to increase the children's engagement and participation in the process. This study provided evidence of

XSL•FO
RenderX

the satisfactory validity of TongueFit compared with the standard manometer. In the first experiment, the comparison between TongueFit and the standard manometer showed a negligible mean difference of 0.005 kPa, indicating a high level of agreement between the measurements obtained by both devices. In addition, the analysis showed a perfect agreement value (ρC=1), further emphasizing the accuracy of the TongueFit measurements. The analysis of the Bland-Altman plot also suggested a consistent, perfect agreement using the 2-cm bulb (ρC=1) and the 3-cm bulb (ρC=0.999). This study confirms the high validity of TongueFit as an orofacial manometer compared to the standard manometer, with near-perfect and perfect agreement in 3 experiments.

Previously developed tongue measurement devices, such as the Tongueometer and the Tongue Pressure Meter (TPM-01; JMS), had used the IOPI as a gold standard to validate or compare their measurement results [22,23]. Unlike previous studies, we refrained from this approach primarily due to its unavailability in Indonesia and the lack of published validation studies for the IOPI. Instead, we used the standard manometer, a standard device used for measuring pressure differentials, similar to the IOPI's air-filled bulb principle. Consequently, we considered the standard manometer an accurate and valid alternative for assessing air pressure differentials, similar to the IOPI's tongue force measurement method.

In contrast to this study, where the TongueFit was compared with a standard manometer, other studies have used the IOPI as a reference tool for comparison. Gibbons et al [24] compared the Tongueometer and the IOPI in measuring lingual pressure. Statistically significant, positive correlations were found between the mean values measured by the 2 devices for anterior isometric lingual pressure (concordance correlation coefficient=0.74, P<.001), demonstrating the concurrent validity of the Tongueometer with the IOPI. The independent samples t test revealed no statistically significant difference in the means for anterior isometric lingual pressure (t_{74}=−0.5, P=.65), suggesting similar performance between the Tongueometer and IOPI in this regard. However, a study by Curtis et al [22] found that Tongueometer pressure readings under controlled conditions (without using a bulb) were typically 7 kPa lower on average than IOPI pressure readings. Lin concordance correlation was used to assess the validity of Tongueometer readings compared with the IOPI and showed substantial validity (ρC=0.97, 95% CI 0.961 - 0.977). In addition, analysis using a Bland-Altman plot showed that only 16.8% of the data points were in agreement.

Yoshikawa et al [23] used the Pearson correlation coefficient to compare the measurement results of the TPM-01 and IOPI. Their results showed significant correlations between TPM-01 and IOPI measurements in both female participants (R^2=0.74, P<.01; IOPI PRO=TPM-01×1.21+11.2) and male participants (R^2=0.64, P<.01; IOPI PRO=TPM-01×1.07+15.4). Compared with the Tongueometer and the TPM-01, TongueFit showed better measurement validity than both devices. Thus, TongueFit can be considered a valid tool for assessing tongue strength, providing accurate measurements comparable with those obtained with the standard manometer under different experimental conditions. However, it was important to note that TongueFit was validated using the standard manometer, not the IOPI.

Most studies on tongue measurement devices focus on adult populations, while only a few target pediatric populations. Potter and Short [25] used the IOPI device to measure tongue strength in typically developing children aged 3 - 16 years old using a standard IOPI bulb. One concern in Potter and Short's study was whether younger children could tolerate the IOPI bulb since it contacts more than 50% of the tongue surface in a 3-year-old child compared with only 30% in adults. While they found that most younger children tolerated the bulb well, there were still a few who did not. Given the small sample size of the age group in the study (n=28), it was possible that with a larger sample size, more children would not be able to tolerate the light bulb. To the best of our knowledge, no device has been specifically designed for children. Previous studies used commonly available tools, whereas the TongueFit used in this study was specifically designed for children and incorporated a specialized app tailored to their needs. Therefore, this study is essential for advancing future clinical applications. Furthermore, assessing the validity of the orofacial manometer and the bulb is important.

Curtis et al [22] evaluated the tongue bulb of the Tongueometer against that of the IOPI, using both the IOPI and Tongueometer devices for separate measurements. In both sets of measurements, the Tongueometer consistently registered higher pressure readings. Specifically, when measured with the IOPI, the bulb of the Tongueometer had a median pressure of 1 kPa higher than that of the IOPI, increasing to 4 kPa higher when pressures exceeded 40 kPa. Analysis using Lin concordance correlation underscored substantial validity between the bulb of the tongueometer and the bulb of the IOPI (ρC=0.987, 95% CI 0.982 - 0.991). Conversely, the pressure readings of his bulb exceeded those of the IOPI's bulb by 2.7 kPa when measured with the tongueometer, with the discrepancy increasing with increasing pressure. Lin concordance correlation between the bulb of the tongueometer and the bulb of the IOPI (ρC=0.992, 95% CI 0.988 - 0.9914) indicated substantial to excellent agreement. Although the exact cause of this variance remains unclear, it is speculated to be due to differences in the size and shape of the tongue bulbs. In this study, the TongueFit showed better results according to Lin concordance correlation, showing a perfect agreement value for the 2-cm bulb (ρC=1) and an almost perfect agreement value for the 3-cm bulb (ρC=0.999).

To our knowledge, no other studies have evaluated the validity of tongue bulb measurements. A previous study compared the performance of the Tongueometer bulbs and the IOPI bulbs [22]. In contrast, our investigation sought to elucidate the differences in pressure determinations between a standard manometer and the TongueFit when using the TongueFit bulb. This thorough investigation was conducted to verify the consistency of pressure readings between the TongueFit and the standard manometer, with both devices connected to the 2-cm and 3-cm air-filled bulbs developed in our study.

Since the TongueFit bulb would directly contact oral cavity structures, ensuring its safety is paramount. Therefore, we conducted a toxicity assessment using human stem cells to

XSL•FO
RenderX

evaluate the raw materials comprising the bulb, tongue bulb, and tube. Our results indicate that the raw material, bulb, and tube have nontoxic properties, confirming their safety for intraoral use. This tool and app also passed preliminary testing and evaluation of the mock-up to identify potential improvements and enhancements to increase the functionality of both the device and the app. Therefore, the final tool and app are well-aligned with user needs, incorporating the findings from the mock-up evaluation. As we mentioned earlier, this study focused solely on the validity of TongueFit's measurement capabilities. The effect of TongueFit as a tool for tongue strength and endurance exercises will be investigated in future studies.

Conclusion

In conclusion, this study underlined the satisfactory validity of TongueFit compared with the standard manometer. The first experiment showed a negligible mean difference between TongueFit and the standard manometer, with a perfect agreement value, indicating high accuracy in TongueFit measurements. In addition, in the 2-cm and 3-cm bulb experiments, TongueFit showed a perfect agreement value compared with the standard manometer. This consistent trend suggests that TongueFit measurements are slightly lower across different bulb sizes. In addition, the test results using the 3-cm bulb showed an almost perfect agreement value. Furthermore, TongueFit has passed preliminary testing and toxicity assessments, ensuring it is safe, comfortable, and suitable for users. These results established TongueFit as an accurate and valid tool for assessing tongue strength and endurance, providing results that closely match those obtained with the standard manometer.

Acknowledgments

The authors thank Andi Aditya Ahmad Fauzi Hasan for supporting the development of TongueFit. This study was funded by the Directorate of Research Funding and Ecosystem, Universitas Indonesia, under Hibah Publikasi Terindeks Internasional 2024. We confirm that this financial support did not influence the study's results.

Abstract

Background: Knee osteoarthritis (KOA) requires long-term treatment that faces significant barriers, including inadequate physiotherapy services, especially in Slovenia and comparable European countries. Mobile health apps offer a promising solution to improve accessibility and adherence to KOA treatment.

Objectives: This study aimed to identify expectations of patients with KOA for app-based therapy, determine the functional requirements, and assess the main barriers and benefits of using mobile apps for KOA management. It also examined these factors about demographic data (gender, age, and education level) and motivation to perform knee exercises.

Methods: A mixed methods approach was used, integrating quantitative data from a structured questionnaire and qualitative data from in-depth interviews. The purposive sample comprised 82 patients with symptomatic KOA graded 1‐3 on the Kellgren-Lawrence scale, excluding those with cognitive impairments, wheelchair dependency, significant comorbidities, or language barriers.

Results: The analysis revealed that 53.7% (44/82) of patients preferred smartphones, while 40.2% (33/82) favored PCs for remote KOA management, citing accessibility and convenience. Exercise videos received the highest rating (μ=9.45), followed by goal setting and tracking (μ=8.95) and regular e-messages (μ=8.83). Telephone consultations with physiotherapists were also highly valued (μ=8.41). Significant differences were observed in the perceived importance of key disease information (F_9=2.077; P=.04) and exercise videos (F_9=2.788; P=.05) based on motivation levels but not by gender, age, or education. Perceptions of the appropriate duration of physical activity varied with motivation levels (F_9=2.490; P=.02) but not with demographic factors. Men rated ease of use (4.93 vs 4.71; F_1=3.961; P=.05) and the clarity of the exercise flow display higher than women. The most significant barrier was inaccurate disease information (μ=3.96), with notable differences across age groups. Younger participants (younger than 40 years) and those aged 51‐60 years expressed concerns about time management and information accuracy. Patients highlighted the ability to rewatch exercises as a key app feature, while time efficiency and improved access to physiotherapists were highly valued for convenience. Enhanced communication and accurate information were essential for building trust and ensuring effective treatment.

Conclusions: Mobile health apps for KOA management should be designed with a user-centered approach, prioritizing accessibility, motivation, and effective communication. Key functionalities include high-quality exercise videos, goal setting, symptom tracking, and regular electronic reminders. Mitigating user-reported barriers and integrating age-specific adaptations can enhance adherence and therapeutic outcomes. The findings highlight the potential of mobile health technologies to optimize KOA self-management and improve patient quality of life, particularly in health care systems with limited physiotherapy accessibility, such as those in Slovenia.

Introduction

Knee osteoarthritis (KOA) is a prevalent degenerative joint disease affecting 16% of individuals aged 15+ years and 22.9% of those aged 40+ years [1]. As a leading musculoskeletal disorder [2], it poses a growing economic and health burden [3-5], necessitating effective management strategies to mitigate symptoms and improve patient outcomes.

Exercise, self-management, and patient education are essential for KOA management, as recommended by the Osteoarthritis Research Society International and the American College of Rheumatology [6-9]. However, barriers such as misinformation, low self-efficacy, limited physiotherapy access, and restrictive care pathways hinder their effectiveness [10-16]. In Slovenia, the shortage of physiotherapists (50‐70 per 100,000 inhabitants) leads to prolonged waiting times, a challenge also reported in Eastern and Southern Europe, as well as in the United Kingdom, Canada, and Australia, where delayed access to physiotherapy negatively impacts treatment outcomes [17,18]. Given KOA's significant health care, economic, and social challenges, efforts are focused on developing effective, accessible treatments. As defined by the World Health Organization, mobile health technology includes medical practices supported by mobile devices [19]. Mobile health apps offer scalable solutions by delivering behavioral interventions, facilitating remote monitoring, and providing access to educational resources and clinical guidelines. Health apps support patients in adhering to exercise regimens, managing symptoms, and making informed health decisions, effectively bridging the gap between patients and health care providers, thus improving KOA management and outcomes [10‐14].

The use of digital health technologies for managing KOA is gaining attention due to its cost-effectiveness and accessibility. Systematic reviews and meta-analyses have found that digital self-management interventions for managing KOA—delivered through mobile apps, internet platforms, telephone, audio, and video—lead to small to moderate improvements in pain and function, with effects lasting up to 1 year [20]. McHugh et al [21] found that remote exercise programs are more effective when they include study-initiated follow-up and behavior change counseling. Choi et al [22] emphasized the need for mobile health technologies to support self-management and collaborative decision-making. Shah et al [23] confirmed that digital interventions, including cognitive behavioral therapy and tools that facilitate patient-clinician communication, are as effective as traditional methods for managing KOA and highlighted the importance of integrating patient preferences and contextual factors, such as education level, into the design of digital health interventions, which are often overlooked in current research.

Previous qualitative studies have demonstrated that gender and age influence user engagement and preferences. Women often value comprehensive health information and interactive support features, while men prioritize ease of use and efficiency [24]. Younger users prefer advanced features and detailed tracking, whereas older users may face challenges with digital literacy, favoring simpler interfaces with larger text and intuitive navigation [25,26]. Past studies have also indicated that patients with higher levels of education are more willing to engage with advanced app features and provide detailed feedback, favoring functionalities such as data tracking and interactive educational resources [24,27]. Existing qualitative research has established motivation as a critical factor influencing app-based therapy adoption and sustained use. McHugh et al [21] demonstrated that follow-up and behavior change counseling interventions are more effective, emphasizing motivation's role in app engagement.

Although mobile apps hold promise for KOA management, their adoption remains low. Most users discontinue use within 90 days due to suboptimal development methods that fail to support regular communication and patient motivation [28]. Existing mobile apps for KOA management face limitations, including suboptimal user engagement, insufficient personalization, inadequate integration with health care providers, and poor long-term adherence. This highlights the need for personalized goal setting, real-time feedback, automated phone call reminders, and regular clinician-patient communication to enhance engagement, adherence, and clinical effectiveness. In this context, high-quality exercise videos play a crucial role by adhering to evidence-based physiotherapy principles, providing clear demonstrations, precise instructions, appropriate pacing, and modifications for different skill levels, and ensuring safety, accuracy, and effectiveness in guided exercises [28-31]. Studies advocate a co-design approach involving end users in developing, testing, and refining interventions to improve patient satisfaction and app effectiveness [28-31]. This study investigated the user-centered app design process with patients with KOA to develop a more effective app-based therapy.

This study addresses a critical gap in the co-design process for developing a KOA mobile app by using a mixed methods approach within the context of an underresourced health care system, such as Slovenia. While mixed methods research has been used in evaluating digital health interventions, previous studies have primarily focused on other rehabilitation and assistive technologies domains [32-34], with limited application to KOA management. This study aimed to examine the expectations of app-based therapy of patients with KOA, identify key functional requirements (eg, personalized goal setting, real-time feedback, and automated reminders), and assess barriers and benefits of mobile app use for KOA management. Furthermore, it analyzed these factors concerning demographic characteristics (gender, age, and education) and motivation levels. The study tested the hypothesis that perceptions of functional requirements, app usefulness, barriers, and benefits vary significantly based on demographic characteristics (age, gender, and education) and motivation levels.

Methods

Study Design

The study used a structured co-design approach based on participatory design principles [35], ensuring active stakeholder involvement. Using the Double Diamond framework, we conducted qualitative data collection to identify user needs

XSL•FO
RenderX

(Discover), synthesized insights to define core functionalities (Define), iteratively developed prototypes with patients' feedback (Develop), and assessed usability and feasibility (Deliver) [35].

This study adopted a sequential explanatory mixed methods design, integrating quantitative and qualitative data to understand the research problem comprehensively. Integration occurred at multiple stages, including planning (study design), sampling (purposive selection based on survey results), data collection (qualitative interviews following quantitative analysis), data analysis (triangulation of qualitative themes with quantitative findings), and interpretation (integrated reporting for contextual depth). The quantitative analysis identified key trends and patterns, which then informed the development of qualitative interviews, allowing for an in-depth exploration of the emerging themes. A triangulation approach was applied to ensure systematic integration, mapping qualitative themes onto quantitative results to assess convergence, complementarity, and divergence. This method enabled a deeper contextualization of statistical findings, strengthening the study's validity, interpretability, and overall rigor [32-34].

Ethical Considerations

The National Committee on Medical Ethics of the Republic of Slovenia (no. 0120-471/2023-2711-4) granted ethical approval for this study. Informed consent was obtained from all participants before their inclusion in the study. Participants were thoroughly briefed on the research aims, their right to discontinue participation at any stage without penalty, and the voluntary nature of their involvement. To safeguard privacy and confidentiality, all data were anonymized before analysis, with no personally identifiable information being stored or disclosed. Data were securely stored on password-protected devices, accessible exclusively to research team members. No financial or material incentives were provided, as the study was designed to impose a minimal burden and relied solely on voluntary participation.

Quantitative Survey

A quantitative survey was conducted between March and June 2024 among patients with KOA recruited through purposive sampling to ensure a representative distribution of demographic characteristics and disease experiences. The sample size (n=82) was determined using power calculations, ensuring adequate statistical precision and validity. Participants were recruited after specialist examinations at Artros, Slovenia's leading orthopedic clinic. They met the inclusion criteria of having symptomatic KOA graded 1‐3 on the Kellgren-Lawrence Scale. Patients with cognitive impairment, wheelchair dependency, comorbidities, or limited language or digital skills were excluded. All participants provided informed consent and completed a 10-minute questionnaire, resulting in 82 completed surveys.

The instrument was developed based on measures or findings from previous studies [22-27] and refined for the Slovenian context through interviews with 5 experts, including academics and health professionals. It was piloted with 25 professionals (physiotherapists, rehabilitation specialists, and orthopedic experts) and patients to ensure clarity and relevance, incorporating various question types and scales for comprehensive data collection.

The survey tool was a structured questionnaire comprising 38 items designed to assess demographic characteristics, motivation, expectations, usability, barriers, and benefits related to a web-based application for KOA rehabilitation. It included multiple-choice questions, Likert scale ratings (1-10), and binary response options. The questionnaire consisted of 6 main sections: demographic data covering gender, age, education, and occupation; motivation to perform knee exercises, assessed using a 10-point Likert scale ranging from 1 (not motivated at all) to 10 (extremely motivated) and categorized as low (1-6) and high (7-10) based on established thresholds; expectations from the digital app (9 items), evaluating the importance of various app features such as educational content, goal setting, video demonstrations, reminders, and communication with physiotherapists; usability perception (6 items), measuring ease of use, navigation, and information clarity; potential barriers (10 items), identifying challenges such as technical difficulties, lack of web access, and low motivation; and perceived benefits (6 items), assessing factors such as time savings, improved motivation, and enhanced physiotherapist interaction (Multimedia Appendix 1). The questionnaire was self-administered in paper format within a health care setting, ensuring consistency in data collection while allowing respondents to complete it independently in a confidential environment. The questionnaire demonstrated high internal consistency, with a Cronbach alpha value of 0.85, indicating robust reliability.

Qualitative Study

In-depth interviews were conducted to understand the patient's needs, functional requirements, and esthetic preferences for a mobile KOA management app and identify barriers and facilitators to its use. After completing the quantitative survey administered by questionnaire (n=82 patients; Table 1), qualitative interviews were conducted with all selected participants, ensuring a comprehensive exploration of their experiences and perspectives.

Secondary school or less	54 (65.9)
Bachelor's degree	24 (29.3)
Master's degree/specialization	3 (4.9)
Doctoral degree	N/A[a]

[a]N/A: not applicable.

A semistructured interview guide, developed by reviewing existing literature [24-31] and expert consultation, provided a structured yet flexible framework for in-depth discussions. Following the initial interviews, the guide was carefully reviewed and refined, with minor adjustments made to improve clarity and relevance in response to emerging themes. Patients were asked to provide detailed insights into their expectations, needs, functional requirements, and esthetic preferences for a mobile KOA management app. In addition, they shared their views on barriers to app usage and potential facilitators. Trained researchers with expertise in qualitative health research conducted interviews. These interviews took place face-to-face in confidential and comfortable settings, such as quiet rooms in health care facilities or other mutually agreed locations, ensuring participant comfort and open communication. Each interview lasts between 45 and 90 minutes. All interviews were audio-recorded with the participant's informed consent and transcribed verbatim.

Data Management and Analysis

The quantitative analysis was conducted using descriptive statistics to analyze mean (μ) values and the normality of data distribution was assessed using the Shapiro-Wilk test, which confirmed a normal distribution (P>.05). Consequently, parametric tests were used for further analysis. Differences between groups were evaluated using the independent samples t test and ANOVA, with statistical significance set at P<.05. All data analyses were performed using SPSS (version 25.0; IBM Corp).

For the qualitative component, we conducted the thematic analysis using NVivo (version 12; QSR International) software to facilitate systematic coding and organization of data. Two researchers (KE and PK) independently coded the transcripts, ensuring intercoder reliability and reducing potential bias. We applied an inductive coding approach, where codes were derived directly from the data and categorized into broader themes. We used an iterative coding process to address overrepresentation and potential errors, cross-checked themes against the dataset, and resolved discrepancies through researcher discussions and consensus-building. Themes were identified through pattern recognition, with recurrent concepts reviewed for coherence and alignment with the research objectives. Differences in interpretation were resolved through researcher consensus, with a third researcher consulted when necessary to ensure analytical rigor and objectivity.

Results

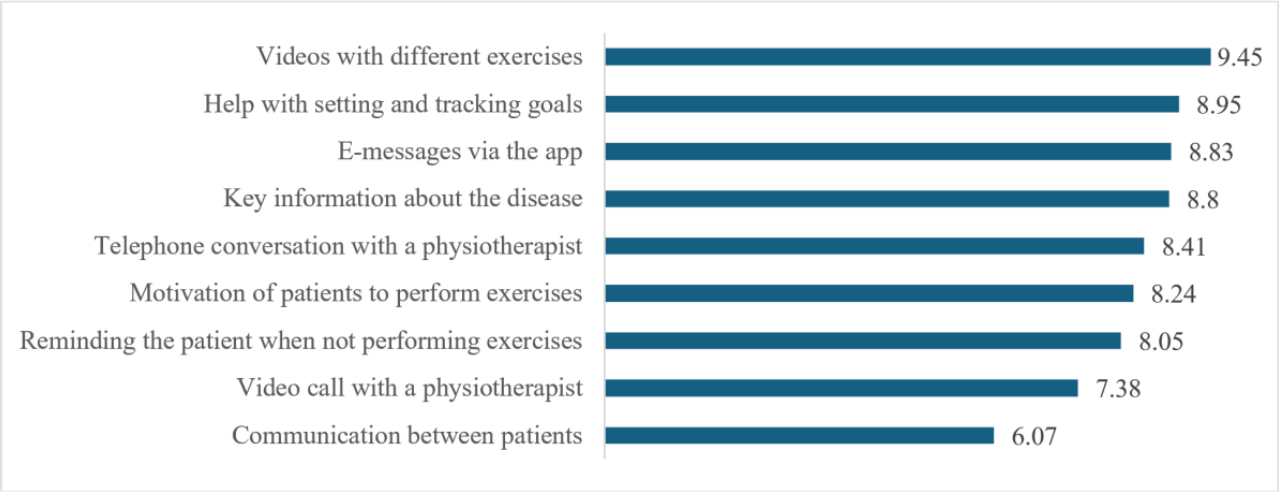
Overview

The results will be presented in thematic sections, explaining the quantitative findings with qualitative data. The study included 82 participants, with 67.1% (55) female and 32.9% (27) male respondents. The majority were aged 51 - 70 years (70, 58.5%), while smaller proportions were aged 31 - 40 years (2, 2.4%) and 71 - 80 years (17, 20.7%). Regarding education, 65.9% (54) had secondary school or less, 29.3% (24) held a bachelor's degree, and 4.9% (4) had a master's degree or specialization, with no participants holding a doctoral degree (Table 1).

Preferred Device for Remote KOA Management

Most respondents preferred performing KOA management via smartphone (44, 53.7%) or PC (33, 40.2%) due to their accessibility, convenience, and technical possibilities, as the in-depth interviews revealed. Smartphones offer quick and easy access to apps anywhere and anytime, increasing the likelihood of regular exercise. With their larger screens, PCs offer a better overview of exercise videos and instructions. Both devices support high-quality video content and easy web connectivity, which is essential for monitoring progress and communicating

XSL•FO
RenderX



with physiotherapists. According to patient 1, "With the phone, I could exercise anywhere, while with the computer, I could have a better overview of the instructions and exercises.… So, I could combine them depending on the situation."

Importance of the Functional Requirements of Mobile Apps for KOA Management

The results showed that the importance of functional requirements for mobile apps managing KOA did not significantly vary between genders, age groups, or educational levels. Table 2 demonstrates that differences in the importance of functional requirements for KOA management mobile apps are significant among various motivation levels for only 2 features: "key information about the disease" and "videos with different exercises." Patients with higher motivation levels expressed a greater desire for comprehensive information about their condition, including disease details, treatment strategies, and healthy lifestyle tips. Specifically, those who reported higher motivation also placed greater value on having key information about the disease included in the app, as indicated by the significant differences in mean motivation levels (F_9=2.077; P=.04). Qualitative analysis also confirmed that highly motivated patients seek detailed information to support their KOA management. A typical statement was from patient 3: "Having detailed information about my condition and access to exercise videos could motivate me to stay on track with my therapy." Similarly, the data indicated that highly motivated patients emphasized the availability of videos with different exercises for knee strengthening. These patients rated the importance of exercise videos significantly higher than those with lower motivation levels (F_9=2.788; P=.01). This suggests that motivated patients are more likely to engage with an app that provides clear, visual guidance through exercise videos, enhancing their ability to perform exercises correctly and consistently. Patient 4 stated: "The exercise videos in the app will help me to understand how to do the exercises correctly and motivate me to keep going."

Figure 1 illustrates the importance ratings of various functional requirements of mobile apps for KOA management, measured on a Likert scale from 1 (not important) to 10 (extremely important), reflecting participant preferences. Analysis of the in-depth interviews showed that patients rated the importance of these features based on their practical needs and preferences in managing their condition. The highest-rated function, videos with different exercises (μ=9.45), reflected the patients' need for clear, visual guidance to ensure that the exercises were performed correctly, as the analysis of patient statements revealed. Setting and tracking goals (μ=8.95) was also rated highly, as patients considered it essential for monitoring their progress and staying motivated. Regular e-messages via the app (mean rating: 8.83) and essential information about the disease (μ=8.80) were identified as crucial for keeping patients informed and involved in their treatment plans. Direct communication with health care providers was deemed important, as evidenced by the high rating of phone calls with a physiotherapist (μ=8.41), which suggests that patients value personalized advice and reassurance from professionals. Features that support treatment adherence, such as motivation to perform exercises (μ=8.24) and reminders when exercises are not performed (μ=8.05), were considered critical for maintaining a consistent exercise program. Although video calls with a physiotherapist (μ=7.38) and communication between patients (μ=6.07) were rated lower, they were still important for some patients, especially those seeking more direct interaction or peer support.

Figure 1. Importance of the functional requirements of mobile apps for knee osteoarthritis management.

Table . Differences in the importance of the functional requirements of mobile apps for knee osteoarthritis management regarding the level of motivation (ANOVA)[a].

Level of motivation	Sample size, n	μ[b]	σ[c]	*F* test (*df*)[d]	*P* value
Key information about the disease				2.07 (9)	.04
1	1	5.00	0.000		
2	2	6.50	4.950		
3	4	10.00	0.000		
4	2	8.00	2.828		
5	9	8.67	2.646		
6	8	8.00	3.071		
7	9	9.33	1.414		
8	22	8.05	2.420		
9	9	9.67	0.500		
10	16	9.88	0.500		
Videos with different exercises				2.788 (9)	.007
1	1	7.00	0.000		
2	2	6.50	4.950		
3	4	10.00	0.000		
4	2	9.00	1.414		
5	9	9.00	2.000		
6	8	9.63	1.061		
7	9	9.67	0.707		
8	22	9.32	1.041		
9	9	9.67	0.500		
10	16	10.00	0.000		

[a]All motivation measures in this and subsequent tables use a scale from 1 (lowest) to 10 (highest).

[b]Mean score of importance ratings for each functional requirement.

[c]SD values.

[d]ANOVA test statistic.

Appropriate Amount of Time to Exercise

Table 3 shows participants' preferences regarding the reasonable duration for app-based exercises, with response options of up to 15 minutes, 16 - 30 minutes, and 31 - 45 minutes. The results indicate that opinions on the appropriate exercise duration did not significantly differ based on gender, age, or educational level. This suggests a consensus among participants on the time they are willing to dedicate to physical activity within the mobile app. The analysis of the in-depth interviews revealed that a consensus between different demographic groups regarding the recommended duration of physical activity can be attributed to shared experience. Patients with KOA often experience similar symptoms, such as pain and stiffness, leading to a shared understanding of the benefits of exercise. Patient 5 said, "I know many people with this condition and can say that we all feel the same relief from exercise, regardless of our positions, so the recommended duration works for everyone."

As shown in Table 3, there was a statistically significant difference in opinion regarding the level of motivation based on the appropriate amount of time to exercise (F_9=2.490; P=.0.15). Patients with higher motivation levels (ratings of 7 - 10) favored longer exercise durations (mean ratings from 2.18 to 2.31) than those with lower motivation levels (ratings of 1 - 6, mean ratings from 1.00 to 2.00). A typical patient statement in this regard was from patient 6: "I find that longer exercise sessions could help me feel more accomplished and keep me motivated to stay consistent with my routine."

Usefulness of Mobile Exercise Apps for KOA Management

Table 4 indicates statistically significant differences in the assessment of the usefulness of mobile apps based on gender, measured on a 1 - 5 Likert scale (1=I do not agree at all, 5=I totally agree). According to the data, men generally rated KOA apps better than women in terms of overall ease of use, clarity of system information, and general friendliness. They also had significantly higher ratings than women for ease of use (μ=4.93 vs μ=4.71; F_1=3.961; *P*=.05), clarity of the exercise process display higher (μ=4.93 vs μ=4.71; F_1=3.961; *P*=.05), and ease of navigation on the tab (μ=4.89 vs μ=4.64; F_1=3.961; *P*=.04). In addition, men rated instructions on performing exercises higher (μ=4.93, σ=0.267) than women (μ=4.69; F_1=4.318; *P*=.04). Their ratings were also higher than women's ratings regarding providing help on how to perform exercises correctly (μ=4.93 vs μ=4.67; F_1=4.653; *P*=.03) and ease of communication with the physiotherapist (μ=4.78 vs μ=4.49; F_1=4.196; *P*=.04). These results show that, on average, men have higher expectations of user-friendliness, clarity of system information, and ease of app use than women.

Table . Differences in opinions of the usefulness of mobile exercise apps based on gender (*t* test).

	Sample size, n	μ[a]	Σ[b]	*F* test (*df*)[c]	*P* value
Ease of use				3.961 (1)	.05
Male	27	4.93	0.267		
Female	55	4.71	0.533		
A clear display of the training process				3.961 (1)	.05
Male	27	4.93	0.267		
Female	55	4.71	0.533		
Easy tab navigation				3.961 (1)	.04
Male	27	4.89	0.320		
Female	55	4.64	0.589		
Instructions for carrying out the exercises				4.318 (1)	.04
Male	27	4.93	0.267		
Female	55	4.69	0.540		
Help with the correct execution of exercises				4.653 (1)	.03
Male	27	4.93	0.267		
Female	55	4.67	0.579		
Facilitated communication with the physiotherapist				4.196 (1)	.04
Male	27	4.78	0.424		
Female	55	4.49	0.663		

[a]Mean score of importance ratings for each functional requirement..

[b]SD values.

[c]ANOVA test statistic.

The analysis of in-depth interviews revealed that gender differences in the perceived usefulness of mobile apps were attributable to distinct priorities and user experiences between men and women. Men rated ease of use, clarity of system information, and overall usability higher than women, indicating a preference for simple, efficient interfaces and clear, structured data. For example, patient 9, a male, stated, “I find it very important that the app is easy to use so that I can get to my exercises quickly and without problems,” making it clear that he valued functionality and efficiency. Similarly, the qualitative analysis showed that men placed more value on a clear display of exercise progress and easy navigation of the tabs, as indicated by the feedback: “A clear display of my progress will help me stay motivated and keep track of my workouts” (Patient 11). This suggests that men prefer features that improve their ability to independently track and manage their workout routines. Furthermore, the importance placed on detailed instructions and help in performing exercises correctly, with statements such as “Exact instructions and assist could help with exercises ensure that I perform them correctly and safely” (Patient 12), indicates a preference for precision and correctness in their exercise plans. Finally, the higher rating of facilitated communication with physiotherapists, supported by statements such as “Being able to communicate with the physiotherapist via the app is very helpful to get quick feedback and advice” (Patient 13), underscores the importance of direct and immediate support.

Table 5 shows an ANOVA analysis examining differences in perceptions of mobile app usefulness based on motivation levels (ranging from 1 to 10). The analysis revealed statistically significant differences for only 2 specific functionalities, with “Ease of Use” being the only factor reaching statistical significance: ease of use (F_9=2.397; P=.02) and good organization of information (F_9=2.358; P=.02). Highly motivated patients (rating 10) rated user-friendliness the highest (μ=5.00), while those with lower motivation (rating 1) rated it lower (μ=4.00). Good organization of information was particularly important for those with very high or low motivation, with ratings of 3, 4, and 10 yielding a mean score of 5.00, while those with medium motivation (rated 7) assigned a lower score of 4.11. The in-depth interviews revealed that the differences in opinions about the ease of use and organization of the information in the mobile app were due to users’ different needs and expectations based on their motivation levels. Highly motivated individuals desired efficient and straightforward tools to maintain their exercise routine, as in patient 14’s statement: “The app needs to be very user-friendly because, as it now says, it should make me engage with my exercises and stay

XSL•FO
RenderX

consistent." They would like an intuitive user interface to maximize their productivity and stick to their programs. Conversely, both less motivated and highly motivated users placed a high value on well-organized information, as clarity would help them focus and reduce cognitive load, improving comprehension and engagement. Patient 8 illustrated this statement: "When all the information is clear, I can focus better and know what I need to do next."

Table . Differences in opinions of the usefulness of mobile apps based on the level of motivation (ANOVA).

Level of motivation	Sample size, n	μ[a]	Σ[b]	*F* test (*df*)[c]	*P* value

Barriers to Using a Mobile App for KOA Management

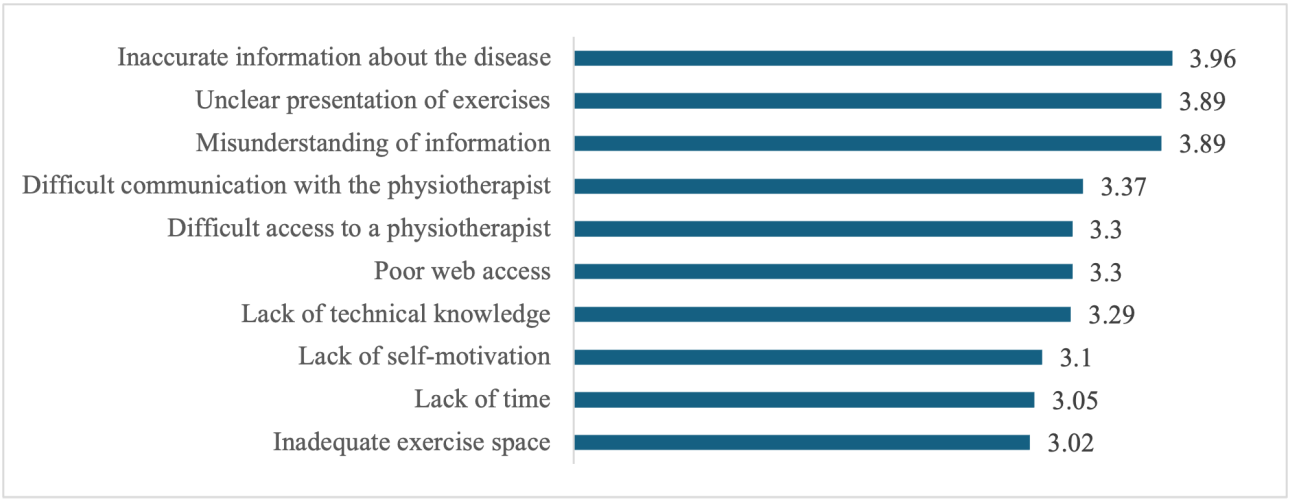

Figure 2 illustrates the barriers to using a mobile app to manage KOA, measured on a 1 - 5 Likert scale (1=I do not agree at all, 5=I totally agree). The highest-rated barrier was inaccurate information about the disease (3.96), closely followed by unclear presentation of exercises (3.89) and misunderstanding of information (3.89). Difficult communication with the physiotherapist (3.37) and access to a physiotherapist (3.3) were also important barriers. Poor web access (3.3) and lack of technical knowledge (3.29) reflected technology-related challenges. In addition, lack of self-motivation (3.1), lack of time (3.05), and inadequate training space (3.02) were moderate barriers.

Table 6 shows the results of an ANOVA analysis examining differences in the perceived barriers to using a mobile app for KOA management across different age groups. Participants aged 51 - 60 years reported the highest barrier scores for inaccurate information about the disease (μ=4.40), with younger participants younger than 40 years also expressing significant concern (μ=4.00). Similarly, lack of time was identified as an important barrier by participants younger than 40 years (μ=4.50) and those aged 51 - 60 years (μ=3.72). Motivation-related challenges were most pronounced among the youngest age group (μ=4.50, σ=0.707), while the unclear presentation of exercises was a key barrier for those younger than 40 years (μ=4.50, σ=0.707) and those aged 51 - 60 years (μ=4.36, σ=0.810). Participants aged 51 - 60 years exhibited a relatively low SD, suggesting greater consensus in their perceptions. In contrast, younger participants demonstrated higher SD values, indicating greater response variability, particularly regarding motivation and clarity of exercise instructions.

XSL•FO
RenderX

The in-depth interviews revealed that the barriers to KOA management via mobile apps stem from individual needs, lifestyle restrictions, and expectations of the app. Patients emphasized the need for reliable information: “You know, accurate information is the most important thing for me to trust the app” (Patient 4). Time constraints were important, especially for younger patients, as patient 22 explained: “I find it difficult to fit exercise into my busy schedule.” Motivation was also an important issue, requiring clear goals and support, as noted by patient 23: “Without clear goals and support, it’s difficult to stay motivated. And without motivation, you can’t do it, so it’s a big problem.” In addition, the need for clear exercise instructions was crucial, as patient 24 emphasized: “I need clear instructions to make sure I’m doing the exercises correctly.”

Benefits of Using a Mobile App for KOA Management to Manage KOA

Figure 3 illustrates the benefits of using a mobile app to manage KOA, measured on a 1 - 5 Likert scale (1=I do not agree at all, 5=I totally agree). The highest-rated benefit was the ability to view exercises multiple times (μ=4.65), which indicates how important clear, repeatable instructions are to users. Saving time (μ=4.50) and easier access to a physiotherapist (μ=4.48) were also rated highly, reflecting the importance of convenience and accessibility. Improved communication with the physiotherapist (μ=4.45) and the accuracy of information provided (μ=4.45) were critical to building trust and ensuring effective treatment. Greater autonomy (μ=4.43) and convenience (μ=4.39) underline that users appreciate being able to treat their condition independently and from home. Motivation to exercise (μ=4.38), cost savings (μ=4.38), and training efficiency (μ=4.37) highlight the comprehensive support offered by the app.

The analysis revealed no statistically significant differences between the perceived benefits of the app and demographic factors or motivation levels. Most respondents stated that they knew the potential benefits of using a mobile app for KOA management. For example, patient 26 said, “The benefits of the app are clear to me, and I think they’re also clear to the others waiting here, regardless of our age or situation. We all know that it can help us manage our condition effectively. That’s why it’s so important. I look forward to using it.”

Discussion

Principal Results

This study highlights the importance of motivation, usability, and content quality in adopting app-based therapy for KOA management. The findings indicate that exercise videos, goal setting, and clinician-patient communication are among the most valued app features, emphasizing the need for personalized digital interventions. While motivation levels significantly influenced the perceived usefulness of specific app functionalities, demographic factors such as age, gender, and education played a less prominent role in shaping user preferences.

Barriers to app adoption were primarily related to unclear exercise instructions, inaccurate health information, and limited communication with physiotherapists, suggesting that enhanced instructional clarity and interactive support are essential for improving user engagement. In addition, age-related differences in digital literacy and time constraints highlight the necessity of adaptable app designs that accommodate varying levels of technological proficiency.

The study also reinforces the value of on-demand access to exercise demonstrations, time efficiency, and improved clinician connectivity as key benefits of mobile health interventions. These insights emphasize the need for high-quality exercise content, real-time feedback, and user-friendly interfaces to optimize adherence and clinical effectiveness in digital rehabilitation for patients with KOA.

A correlation analysis between the 2 predominant patient-centric barriers (self-motivation and time) and the motivation measures revealed no significant associations, suggesting that, within our sample's limitations, these perceived barriers did not directly correspond to participants' self-reported motivation.

Comparison With Prior Work

The study revealed several significant findings about using mobile apps for KOA management, aligning with prior research that underscores the accessibility and convenience of app-based therapy for chronic disease management [27,36]. Consistent with previous studies on digital health interventions, our results confirmed that exercise videos were the most highly rated feature, supporting findings that visual demonstrations enhance patient comprehension and adherence to prescribed exercises [21,22,37]. Furthermore, goal setting, tracking, and regular electronic messages were rated highly, reinforcing evidence that structured feedback mechanisms contribute to sustained engagement in mobile health programs [21,27]. The high rating of telephone calls with physiotherapists further highlights the demand for personalized expert guidance, previously identified as a key factor in patient adherence and treatment satisfaction [22,36]. Features that enhance adherence, such as motivational support and automated reminders, were considered essential, echoing findings that digital health interventions incorporating behavioral reinforcement strategies are more effective in promoting long-term compliance [37]. While video calls with physiotherapists and peer communication were rated lower in this study than in some prior research [21,22,37], they remained valuable for individuals seeking real-time interaction or social support, consistent with the findings of Shewchuk et al [36]. This suggests that while many users prefer self-guided app-based therapy, integrating optional interactive elements may enhance engagement for specific subgroups. These results contribute to the growing literature on personalized mobile health interventions, emphasizing the need for flexible, user-centered digital therapy solutions tailored to patient preferences and engagement styles.

Significant differences in the perceived importance of functional requirements were observed based on motivation levels, with highly motivated patients placing greater value on detailed information and practical tools. This finding underscores the need for educational content and visual aids in mobile health apps, consistent with prior research indicating that higher motivation levels correlate with increased engagement in digital health interventions [21,37]. Studies have shown that interactive and visually enriched content enhances patient comprehension and promotes long-term adherence, particularly among those with high intrinsic motivation [22,38]. In addition, opinions on the appropriate duration of physical activity for KOA management also varied significantly by motivation level, reinforcing that individual motivation plays a critical role in adherence to prescribed exercise regimens [21,37]. Research

XSL•FO
RenderX

on behavioral interventions for chronic disease management has demonstrated that customizing exercise programs based on motivation levels leads to better adherence and long-term health outcomes [27,39]. Our findings align with this evidence, suggesting that mobile health interventions for KOA should incorporate adaptive exercise planning and motivational support mechanisms to maximize patient engagement and compliance.

Statistically significant gender differences were observed in evaluating the mobile app's usefulness, with men rating ease of use, clarity of system information, and overall usability higher than women. These findings align with prior research indicating that men prioritize efficiency, simplicity, and functionality in digital health apps. In contrast, women may emphasize engagement, support features, and detail instructional content [24-27,37]. Similar patterns have been reported in health technology adoption studies, where men preferred streamlined, goal-oriented interfaces. At the same time, women were more likely to value interactive elements and comprehensive health-related information [24,25]. These findings underscore the need for gender-sensitive design considerations in mobile health apps, ensuring that user interfaces are adaptable to different preferences and digital literacy levels. Prior studies have emphasized that incorporating customizable settings, adaptive content presentation, and user-driven navigation options can enhance usability and satisfaction across diverse populations [26,27]. Our results contribute to this body of research by reinforcing the importance of personalized digital health solutions that accommodate gender-specific interaction styles, ultimately improving engagement and adherence in app-based therapy for KOA management.

The main barriers to using a mobile app for KOA management identified in this study—inaccurate disease information, unclear exercise presentations, and misunderstanding of information—are consistent with previous research highlighting the critical role of information clarity and accuracy in digital health interventions [25,26,37]. Similar concerns have been reported in telehealth and app-based rehabilitation studies, where patients expressed difficulties in interpreting digital exercise instructions without professional guidance, emphasizing the need for well-structured, evidence-based educational content [36,37]. In addition, difficulties with communication and access to physiotherapists were cited as major challenges, which aligns with prior findings that limited real-time professional interaction can hinder user confidence and adherence to app-based therapy [25,26]. Studies on chronic disease self-management apps have also pointed out that patients often require a balance between self-guided digital tools and clinician oversight. This suggests that incorporating structured communication channels, such as scheduled check-ins or chat-based physiotherapy support, could improve user experience [36]. Significant age-related differences in perceived barriers were observed, reflecting variations in lifestyle demands, digital literacy, and health priorities across different patient groups. Previous research has found that younger individuals prioritize flexibility and convenience, whereas older adults may face more difficulties with app navigation and digital engagement [37]. This underscores the importance of age-sensitive customization, particularly in enhancing information accuracy, integrating time management features, providing motivational support, and ensuring the clarity of exercise instructions. Such adaptations have improved adherence and overall user satisfaction in mobile health interventions for chronic musculoskeletal conditions [25,26,36,37].

Both statistical and qualitative analyses showed that most respondents recognized the potential benefits of using a mobile app for KOA management, regardless of demographic characteristics or motivation levels. This aligns with previous studies highlighting digital health tools' universal appeal and effectiveness across diverse patient populations [27,37]. Research has shown that mobile health interventions can enhance patient engagement and self-management in chronic conditions, including musculoskeletal disorders, by providing accessible, structured, and adaptable therapy solutions [21,22,36]. Furthermore, studies on app-based therapy for osteoarthritis indicate that perceived usefulness and usability are key determinants of patient adherence, often outweighing differences in age, gender, or baseline motivation [21,37]. Our findings reinforce this notion, suggesting that while individual preferences vary, well-designed digital interventions can effectively support self-management in a broad patient population. This is further supported by evidence indicating that even patients with lower baseline motivation can benefit from mobile health solutions when features such as reminders, structured guidance, and personalized feedback are incorporated into the design [22,27].

Implications

This study offers several unique contributions to the understanding and developing app-based therapy for KOA management, addressing the gaps not covered in previous research. First, it identifies motivation-specific functional requirements, revealing significant differences in the perceived importance of app features based on motivation levels. Highly motivated patients prioritized features such as detailed symptom tracking and exercise planning, highlighting the need for apps to cater to varying motivation levels to enhance engagement and adherence. Second, the study uncovers gender differences in usability, with men rating ease of use, clarity of system information, and overall usability higher than women, emphasizing the necessity of considering gender-specific preferences in app design. Third, it identifies age-related barriers, noting that younger participants reported time management issues, while older participants were concerned with the accuracy of health information and technical challenges. Tailoring app features to address these age-specific concerns can significantly improve user satisfaction and retention. Fourth, the study finds a universal consensus on exercise duration, with no significant differences in opinions about the appropriate duration of physical activity across gender, age, or education levels, suggesting that general exercise guidelines are broadly applicable. Fifth, it highlights the importance of repeatable instructions, with patients' highest-rated benefit being the ability to view exercises multiple times, providing a clear direction for developing user-friendly educational materials within the app. Finally, using a mixed methods co-design approach, integrating quantitative and qualitative data, provides a comprehensive understanding of patient needs and preferences, offering a

XSL•FO
RenderX

nuanced view of the factors influencing app adherence and satisfaction that single-method studies may miss.

Limitations

Several limitations of this study should be acknowledged. First, the sample size of 82 patients, while sufficient for preliminary insights, may not represent the broader patient population with KOA. Recruitment from a single orthopedic clinic in Slovenia may limit the generalizability of the findings. Second, the mixed methods approach simultaneously captures patient preferences and barriers, which may not reflect changes over time. Third, reliance on self-reported data introduces potential biases, such as social desirability and recall bias. Although the mixed methods approach enriched the findings, future research could benefit from a longitudinal design to assess the long-term impact of mobile app usage on KOA management outcomes. Fourth, future research should investigate long-term adherence mechanisms and their effects on treatment outcomes to enhance the effectiveness and sustainability of mobile health interventions for KOA management. Fifth, because only 2 participants younger than 40 years were included, the SD in this subgroup was large, limiting the generalizability of our findings for this demographic. Finally, as observed in Slovenia, limited access to physiotherapy and rehabilitation services is a prevalent issue across Eastern and Southern Europe [38,39]. These health care constraints influence the expectations and priorities of patients with KOA for app-based management, highlighting the need for digital solutions tailored to regions with restricted physiotherapy availability. Therefore, addressing these limitations through innovative mobile health interventions is crucial for improving patient outcomes. Future research should validate these findings in diverse health care settings to assess the broader applicability of mobile health interventions.

Conclusions

This study demonstrates the usefulness of a mixed methods co-design approach for developing mobile apps for KOA management. The findings suggest that app-based therapy for KOA management should prioritize user-centered features such as accessibility, motivation, and clear communication. Smartphones and PCs should be optimized for ease of use with high-quality exercise videos. Integrating motivational features such as goal setting, symptom tracking, and regular e-messages can enhance patient engagement. Personalized communication strategies are crucial, with men preferring straightforward interfaces and all users benefiting from explicit educational content. Addressing barriers such as inaccurate information, unclear instructions, and access issues is essential. Age-specific features should provide flexible scheduling for younger users and detailed support for older users. Ensuring that exercises can be replayed emphasizes the need for clear, repeatable instructions. These considerations can help develop effective, user-friendly app-based therapy that improves KOA management and increases patients' quality of life, especially in countries with limited access to physiotherapy, such as Slovenia and comparable countries.

Acknowledgments

The study is part of the Usefulness, Effectiveness, and Satisfaction With a Web-Based Integrated Clinical Pathway for Patients With Knee Cartilage Defects project, which focuses on a web-based exercise program (no. L7-50184). The Slovenian Agency for Research and Innovation and Artros cofunds the project.

Abstract

Background: Chronic pain in adolescents is a significant and growing concern, as it can have negative implications on physical and psychosocial development. Management can be complicated by the increasing risks associated with opioid misuse, highlighting the need for effective nonpharmacological interventions. Biofeedback is an empirically supported behavioral intervention for chronic pain that targets the self-regulation of physiological responses. Virtual reality (VR) is a novel delivery method for biofeedback that could serve as an engaging and effective platform for adolescents.

Objective: The goal of this study was to assess the feasibility, acceptability, and preliminary effectiveness of integrating a VR-delivered respiratory biofeedback intervention into an outpatient pediatric pain rehabilitation program (PPRP) for adolescents with chronic pain.

Methods: In this pilot study, we recruited 9 participants from those enrolled in the PPRP at Nemours Children's Hospital. Participants underwent 2 VR respiratory biofeedback sessions per week over a 4-week period using AppliedVR's "RelieVRx" program. Feasibility was defined as >60% of eligible patients enrolling with at least 80% of VR sessions completed. Acceptability was assessed via validated acceptability questionnaires, with high acceptability defined as an average acceptability rating score >3 on a 5-point Likert scale. Open-ended responses were analyzed via qualitative analysis. Preliminary effectiveness was assessed with questionnaires measuring the quality of life (Pediatric Quality of Life Inventory [PedsQL]) and level of pain interference in daily activities (Functional Disability Inventory) before and after participation in the pain program. Finally, heart rate (HR) and blood pressure (BP) were measured before and after each VR session.

Results: Of 14 eligible PPRP patients, 9 (64%) enrolled in the VR respiratory biofeedback study, and 7 (77% of study participants) completed at least 80% of biofeedback sessions. Participants reported high acceptability with average session ratings ranging from 3.89 to 4.16 on post-VR program questionnaires. Of 224 open-ended responses, participants reported changes in stress and somatic symptoms (ie, pain distraction and breathing regulation). There was a statistically significant increase in the average physical functioning score of the PedsQL among participants (P=.01) from pre- to postparticipation in the overall pain program. The cohort's average emotional functioning score of the PedsQL also increased, though this change was not statistically significant (P=.17). Participants' Functional Disability Inventory scores significantly decreased from an average of 25.1 to 11 from before to after the pain program (P=.002). There were no significant differences between pre- versus post-BP or HR for any session. However, decreased BP and HR were observed across most sessions.

Conclusions: AppliedVR respiratory biofeedback demonstrated initial feasibility, acceptability, and preliminary effectiveness when implemented as part of a PRPP. This study underscores the need for future larger-scale studies analyzing the use of VR biofeedback in adolescent populations with chronic pain.

Introduction

Chronic pain affects upward of 38% of youths and negatively affects multiple aspects of development, including physical and psychological well-being [1-3]. Patients with chronic pain are often initially treated with pharmacotherapy and nonsteroidal medications including ibuprofen, acetaminophen, and in more severe cases, opioids [4]. Given the risks associated with these medications and the misuse of prescription opioids among children and adolescents in the United States, it is imperative to advance nonpharmacological interventions for pain [5,6]. Currently, nonpharmacological treatment for chronic pain in adolescents often involves a multidisciplinary approach encompassing pain education, psychological interventions, integrative medicine (mind-body techniques), and physical and occupational therapies [7,8]. However, these methods can be enhanced. While the etiology of chronic pain is not fully understood, dysregulation of the autonomic nervous system (ANS) is considered an important factor in maintaining many forms of chronic pain [9-12]. There is evidence that stress and anxiety, which trigger sympathetic nervous system responses, can increase pain perception [12]. For example, studies have shown that elevated sympathetic activity is implicated in altering pain perception and sensitivity [11,13]. Activation of the parasympathetic nervous system can help regulate the ANS, decrease pain perception, and increase overall functioning [14,15].

Biofeedback is among the most effective behavioral interventions for chronic pain; with biofeedback training, individuals learn how to control and self-regulate ANS responses such as respiratory rate or heart rate (HR) [16,17]. Visual or auditory cues are provided regarding physiological states, such as breathing rates or patterns [18]. This feedback increases patients' awareness of the physiological processes occurring in real time inside their bodies and allows them to adjust these processes in a desired direction [19,20]. There are many types of biofeedback modalities, including respiratory, HR variability, thermal, and neurofeedback. For example, during respiratory biofeedback, changes in breathing rate and pattern are monitored and displayed to the patient (eg, on a computer screen). The patient uses this feedback to match their breathing rate and pattern to a computer program that displays a "relaxed" breathing pattern. When the patient's breathing is smooth and steady (representing an increase in parasympathetic activation), visual feedback from the computer provides positive cues to reward the patient for establishing a relaxed breathing pattern. If the breathing rate becomes irregular at any point, this is indicated on the monitor, and the patient can try to correct their breathing pattern and return to a relaxed pattern.

Recent research demonstrates that biofeedback is effective for adolescents. They are able to significantly modify their respiration rates and reduce muscle tension through increased physiologic control from biofeedback training sessions [21]. While these results are promising, clinical experience suggests that adolescents may lose interest in traditional biofeedback, if it is not sufficiently engaging [22,23]. As a result, efforts are being made to increase pediatric or adolescent engagement in biofeedback therapies through creative platforms like computer games and virtual reality (VR). For example, one study using video game–based biofeedback in adolescent patients showed good retention across 8 sessions and improvement in anxiety and depressive symptoms [24]. VR has the potential to be even more engaging than a computer-delivered biofeedback program because VR limits outside distractions and can increase one's ability to focus on what is being presented in the VR headset. The use of VR alone, using only relaxing scenes without a biofeedback component, has demonstrated decreases in patients' perception of pain in both acute and chronic pain management [25,26]. Additionally, advancements in VR technology and increases in the affordability and portability of VR headsets allow for patients to use headsets in various settings and may reduce barriers to participation in biofeedback programs. A technology start-up company, AppliedVR, has developed a respiratory biofeedback intervention delivered with a VR headset that has demonstrated efficacy among adults with chronic lower back pain [27,28]. It is possible that this product could be engaging and effective for adolescents with chronic pain. However, the AppliedVR biofeedback intervention has not yet been studied in this population.

Thus, this pilot study used mixed methods to address this gap by assessing the feasibility, acceptability, and preliminary effectiveness of the AppliedVR, respiratory biofeedback intervention, delivered as part of an integrated pediatric pain rehabilitation program (PPRP) for adolescents with chronic pain. We hypothesized that the AppliedVR, respiratory biofeedback intervention, would be feasible to deliver as part of an existing PPRP. We also expected that the AppliedVR intervention would be rated, on average, as acceptable by adolescents with chronic pain through both quantitative and qualitative assessments. Additionally, we explored the preliminary effectiveness of the VR intervention, such that we anticipated the participants would show improvements in functioning and quality of life before and after the PPRP and decreases in blood pressure (BP) and HR before and after each VR session.

Methods

Participants and Recruitment

We aimed to integrate the VR biofeedback sessions into the PPRP at Nemours Children's Hospital, Florida. The Nemours PPRP is well-established at the hospital and includes 4 weeks of multidisciplinary chronic pain interventions. As a part of this program, patients typically spend 5 hours per day, 5 days per week, for 4 weeks undergoing physical therapy, occupational therapy, individual psychotherapy (including biofeedback), family therapy, adjustments to pain medicine, and weekly team care conferences. The individual psychotherapy sessions occurred once a week throughout the PPRP. While these sessions did not always focus on biofeedback, it was offered when clinically indicated and based on the patient's personal interest. The goal of including the VR biofeedback sessions was to offer an enhanced, immersive biofeedback relaxation training that could compliment the PPRP by increasing engagement in learning and allowing for the practice of relaxation skills (ie, diaphragmatic breathing) that are typically taught in the

XSL•FO
RenderX

individual psychotherapy sessions. The VR intervention aligned with the goals of the overall PPRP, in that both aimed to reduce chronic pain among adolescents and help introduce coping mechanisms that may improve their overall quality of life.

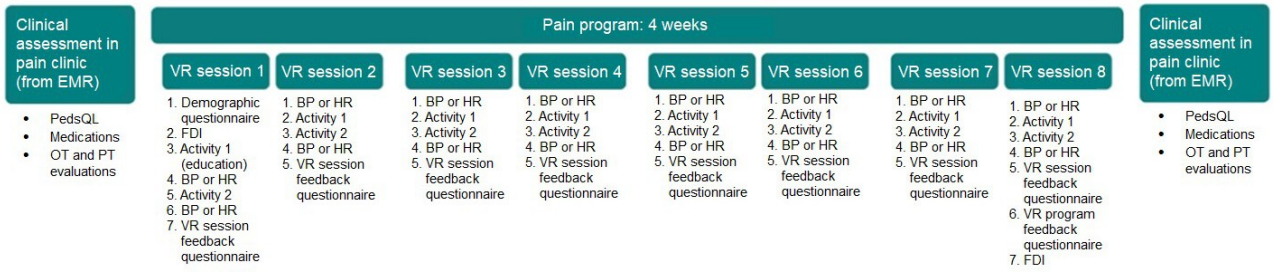
Given that the primary goal of this pilot study was to assess the continuous outcomes of the feasibility and acceptability of the VR intervention, we aimed to recruit a sample size of 15 participants, which is considered adequate for these objectives [29,30]. Eligibility criteria for this pilot study included (1) age range between 13 and 18 years (lower limit of 13 years because the VR headset manufacturer, Oculus, does not recommend the use of the headset by persons 13 years or younger and upper limit of 18 years because only patients 18 years or younger participate in the PPRP), (2) English fluency in verbal and reading or writing (measures were not validated in other languages), (3) participating in the PPRP at Nemours Children's Hospital during the data collection time frame, and (4) no history of epilepsy or seizures (Oculus does not recommend persons with these conditions to use their VR headset).

As a part of routine clinical care, the PPRP coordinator sends each family a packet with information about the PPRP prior to their participation. While the study was actively recruiting, the families received a study flyer in their pre-PPRP information packet.

Ethical Considerations

A research team member met with each family in the first week of their participation in the PPRP. During this meeting, the research team member provided information about the research study, answered questions about the study, and obtained written adolescent assent and parental permission for the adolescent to participate. The data was deidentified. This study was approved by the Nemours Children's Health Institutional Review Board (1552864).

The VR Intervention



VR biofeedback sessions were conducted using AppliedVR's "RelieVRx" (formerly "EaseVRx") application on a portable Oculus Go VR headset [31]. The RelieVRx application included several activities that aim to improve cognitive behavioral and mindfulness-based pain management skills [31]. The software program includes an immersive VR system that incorporates biopsychosocial pain education, diaphragmatic breathing training, mindfulness exercises, and relaxation-response exercises [31]. A microphone on the bottom of the VR headset detects the user's breath, which is shown in the VR environment as bubbles or a stream of air. In this way, the user learns to regulate their breathing with cues in the VR environment, such as waves of light that move toward and then away from the viewer in a pattern that mimics a relaxed breathing rate.

Consented participants engaged in up to 8 VR biofeedback sessions that occurred each Tuesday and Friday over the course of the 4-week pain program. Each session included 2 activities from the AppliedVR "RelieVRx" application. For the first 2 weeks of the pain program (sessions 1 - 4), the research team members (PP, JS, and KR) instructed participants on the specific activities to complete. These specific RelieVRx sessions were selected by a licensed pain psychologist on the research team, as they provided an introduction to the program, built mastery in diaphragmatic breathing, and provided exposure to mindfulness-based attention training. During the final 2 weeks (sessions 5 - 8), participants were instructed to choose the RelieVRx content they engaged with, providing them the opportunity to explore other content or revisit prior activities. Activity 1 was divided into 8 sessions. Session 1 was pain care introduction of 3 minutes, session 2 was paced breathing of 6 minutes, session 3 was building breath of 6 minutes, session 4 was deep relaxation of 5 minutes, and sessions 5 to 8 were patient's choice. Activity 2 began with session 1 breath of hope of 7 minutes, session 2 focus game 1 of 2 minutes, session 3 focus game 2 of 3 minutes, session 4 focus game 3 of 3 minutes, and sessions 5 to 8 patient's choice.

Outcome Measures

Prior to the PPRP, all patients underwent a clinical assessment as a part of standard clinical practice, and results from the assessment are included in the patient's electronic medical record (EMR). Patients underwent the same assessment after completing the PPRP. For the purposes of this study, research team members extracted results from the pre- and post-PPRP clinical assessments from each participant's EMR. Additionally, as a part of the research study, participants were asked to complete questionnaires before the first VR session, after each VR session, and after the final VR session (Figure 1).

Figure 1. Schedule for outcome measures. BP: blood pressure; EMR: electronic medical record; FDI: Functional Disability Inventory; HR: heart rate; OT: occupational therapy; PedsQL: Pediatric Quality of Life Inventory; PT: physical therapy; VR: virtual reality.

Demographic information was assessed via a self-report questionnaire prior to the first VR session. Feasibility was assessed via recruitment and attendance records. We operationalized the feasibility of the VR intervention as >60% of eligible patients enrolling with at least 80% of VR biofeedback sessions completed.

Acceptability was assessed via an acceptability questionnaire designed for this study by a team of clinical psychologists with

XSL•FO
RenderX

expertise in measure development. The items were adapted from a validated questionnaire (ie, Acceptability of Intervention Measure) that is commonly used to assess the acceptability of an intervention [32]. The session feedback questionnaire included 5 questions with Likert scale response options (modeled after the Acceptability of Intervention Measure questionnaire) and 3 open-ended questions (developed by the research team). Participants filled out this acceptability questionnaire after completing each VR session. An additional acceptability questionnaire was designed to assess patients' satisfaction with the VR biofeedback program as a whole. The overall program acceptability questionnaire included a similar structure (5-point Likert scale response items and 5 open-ended questions). We used the same 5-point Likert scale response (1=completely disagree to 5=completely agree) for both acceptability questionnaires. Negatively worded questions were reverse-coded, such that higher ratings indicated higher levels of acceptability. High acceptability was defined as an average acceptability rating score >3 (to capture more positive than "neutral" or negative responses). Open-ended responses were analyzed via qualitative analysis, as described below.

The preliminary effectiveness of the PPRP was assessed via 2 self-reported, validated questionnaires that were completed prior to and after the PPRP. Impairment in daily activities was assessed via the Functional Disability Inventory (FDI) [33,34]. The FDI is a self-report measure of how much pain interferes with day-to-day functioning for adolescents. Adolescents completed the self-report version of this measure prior to their first VR session and immediately after their last VR session. The FDI has excellent psychometric properties [33,34]. Quality of life was assessed with the Pediatric Quality of Life Inventory (PedsQL) Core Generic Scale [35]. The PedsQL is a well-validated and widely used 23-item measure of general quality of life, with separate forms for parental proxy report and a self-report form for youths in the 5 - 7, 8 - 12, and 13 - 18 year age ranges. The PedsQL yields a total score and reliable subscale scores for the child's physical, emotional, social, and school functioning. The PedsQL was delivered as a part of the standard pre- and postpain program clinical assessment. We obtained total PedsQL scores from the participant's EMR.

The preliminary effectiveness of the VR sessions was assessed via health outcomes. HR and BP were assessed via a Dinamap Carescape vital signs monitor. Research team members who were second-year medical students conducted each VR session. These team members were trained by a medical assistant on how to use the vitals machine and took noninvasive BP and HR readings using an upper arm cuff placement. These readings were assessed before and after each VR session.

Statistical Analysis

Demographic and clinical characteristics were summarized using descriptive statistics (mean, SD, and frequencies). Recruitment rate and acceptability questionnaires were analyzed using descriptive statistics. Preliminary effectiveness of VR biofeedback sessions was assessed using paired 2-tailed *t* tests evaluating changes in FDI and PedsQL scores from before and after the pain program as well as BP and HR change scores from each session. Given the main aims of the study were focused on acceptability and feasibility, we accepted any missing data as missing and analyzed means based on the data that were complete. Because surveys were completed with the research coordinator present and checked for completion, we only had 1 participant leave a single item blank on one of the postsession surveys. We dropped this missing item and averaged the remaining responses.

Qualitative Analysis

We conducted a thematic analysis to analyze open-ended responses on the acceptability questionnaire via the 6-phase approach to the thematic analysis described by Clarke and Braun [36]. First, we compiled all responses to each question into a Microsoft Excel sheet, collapsing across assessment time points. Second, 2 coders (JS and KR) reviewed all qualitative responses and coded each response to create initial codes. Coders were medical students who conducted the VR sessions with study participants. Because the qualitative data were limited due to the small sample size and open-ended questions on the questionnaire were typically short, 1-sentence responses, coding was not divided up but rather all of those involved reviewed all of the data. Although the Clarke and Braun [36] 6-phase approach does not require interrater reliability metrics, having all reviewers review all the data rather than dividing it enhanced the reliability of our coding procedure.

Third, themes were created by identifying broad areas of overlap among codes. Individual codes were collapsed into larger themes by identifying unifying features between them. For instance, codes associated with positive words and phrases about the VR sessions such as "relaxed or calming" were grouped into a larger theme of perceived effects on stress. Fourth, themes were quality-checked and reassessed again. Themes were checked against the extracted data to ensure that they worked in relation to the data. Occasionally, codes were relocated under a different theme, and some themes were collapsed into a broader, more coherent theme. Fifth, themes were named to encompass the overall essence of the individual codes that were grouped into them. Some themes were divided into subthemes. For example, our theme of perceived effects on stress was further split into subthemes of increased stress or decreased stress.

Finally, themes were organized into a flowchart to visualize subthemes with attached example excerpts from questionnaires. The themes and codes were reviewed and revised by the coding team and another research team member who has experience in thematic analysis (RW). Themes were summarized by one of the coders (JS) and distributed to coauthors for review.

Results

Feasibility

Over the course of a 12-month period (May 2021 to April 2022), 17 patients enrolled in PPRP at Nemours Children's Hospital. Of those, 3 were ineligible for the VR study due to age, and 5 declined due to scheduling conflicts or disinterest. Of the 14 eligible patients, 9 consented to the VR respiratory biofeedback study, resulting in a 64% recruitment rate. Participants were between the ages of 13 and 18 years, predominantly female (89%), and identified as Hispanic Latino (22%), non-Hispanic

XSL•FO
RenderX

Black or African American (33%), and non-Hispanic White (33%).

In total, 2 participants withdrew from the study (1 after 3 sessions and 1 after 1 session) due to scheduling conflicts or disinterest. Thus, 77% (7/9) of the participants completed at least 80% (7/8) of the biofeedback sessions.

Acceptability—Quantitative Results

Average acceptability was examined for each session and for the overall VR program. Average session-specific ratings ranged from 3.89 to 4.16, indicating neutral to positive responses (Table 1). For the VR program as a whole, average acceptability ratings ranged from 4.14 to 4.43 (indicating positive to very positive responses).

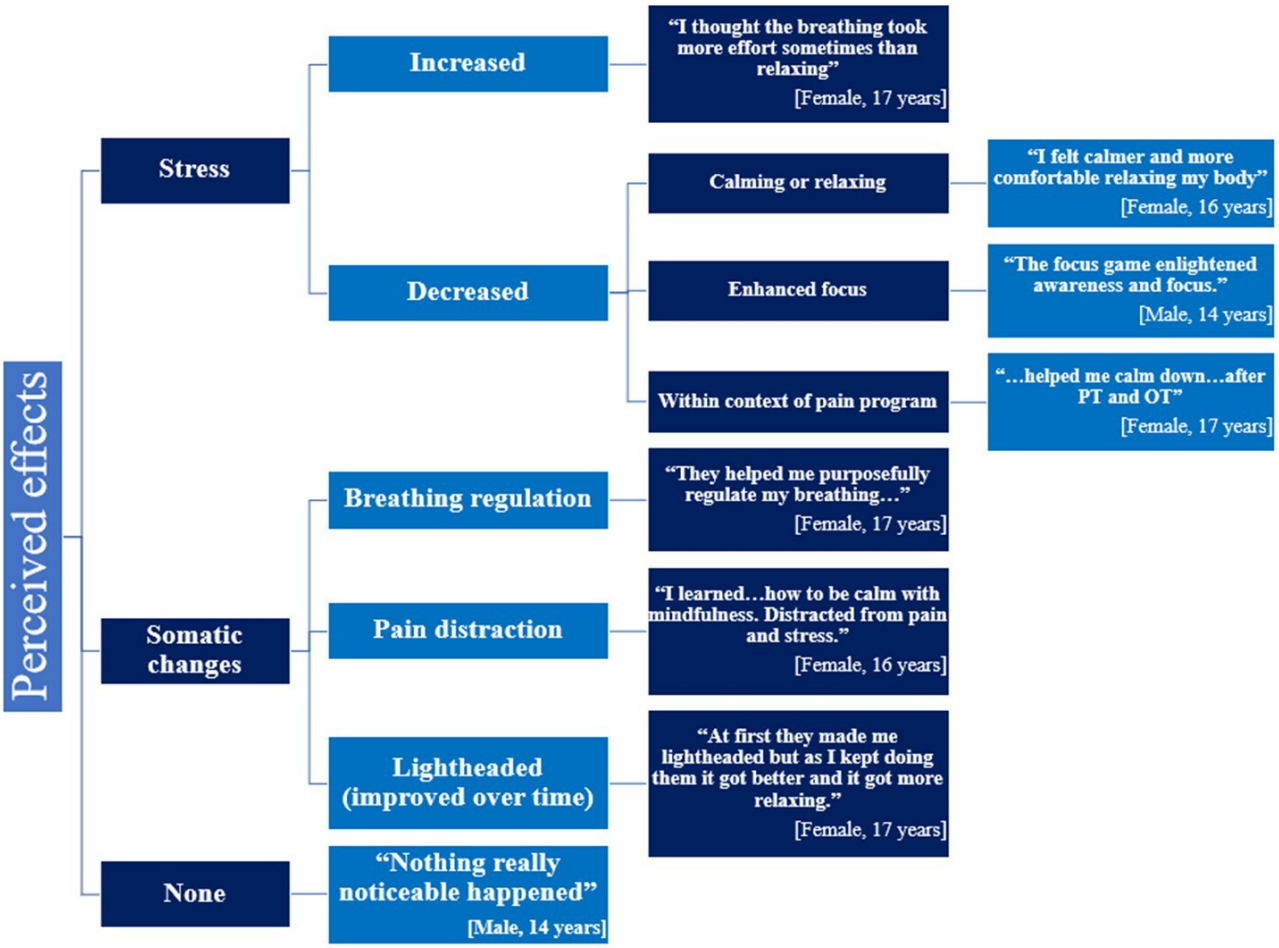
Table . Average (mean) acceptability ratings for sessions 1 - 8[a].

Questions	Session 1, mean (SD)	Session 2, mean (SD)	Session 3, mean (SD)	Session 4, mean (SD)	Session 5, mean (SD)	Session 6, mean (SD)	Session 7, mean (SD)	Session 8, mean (SD)
1. The session was too long[b].	3.56 (1.24)	4.13 (0.83)	4.25 (0.71)	3.71 (1.11)	3.86 (0.90)	3.86 (0.90)	4.14 (0.69)	4.20 (0.45)
2. The session was too short[b].	3.67 (0.87)	3.75 (1.16)	3.75 (0.89)	3.86 (0.90)	3.86 (0.90)	3.86 (0.90)	4.00 (0.82)	4.00 (0.71)
3. The virtual reality made me feel dizzy or light-headed[b].	4.13 (1.46)	3.88 (1.13)	4.00 (1.07)	3.86 (1.07)	4.00 (0.82)	3.71 (1.25)	4.00 (1.00)	4.20 (0.45)
4. The session was easy to follow.	4.56 (0.53)	4.12 (0.64)	4.13 (0.83)	4.14 (0.69)	4.14 (0.38)	3.86 (1.07)	4.29 (0.49)	4.00 (0.71)
5. Overall, I liked this session.	4.33 (0.50)	4.38 (0.52)	4.25 (0.71)	4.14 (0.69)	4.57 (0.53)	4.14 (0.69)	4.29 (0.49)	4.40 (0.55)
Average (items 1-5) session acceptability	4.05 (0.43)	4.05 (0.24)	4.08 (0.21)	3.94 (0.19)	4.09 (0.30)	3.89 (0.16)	4.14 (0.14)	4.16 (0.17)

[a]This table includes responses to a 5-point Likert scale questionnaire (1=completely disagree, 2=somewhat disagree, 3=neither agree nor disagree, 4=somewhat agree, and 5=completely agree.

[b]The results of questions 1-3 were reverse-coded for consistency, in that higher scores indicate greater acceptability.

Acceptability—Qualitative Results



Of a total of 224 responses to open-ended questions (provided by 9 participants), themes included (1) perceived effects of VR (eg, stress, no perceived effect, and somatic changes) and (2) VR feedback (eg, general vs specific; Figure 2).

In general, most participants described the VR sessions favorably, reporting that it was calming and relaxing and distracted them from their pain. Additionally, participants endorsed that they had enhanced awareness and focus after the completion of each individual session, and they enjoyed being able to regulate their breathing in a way that interacted with the VR environment. One person reported feeling lightheaded or dizzy during the first couple of VR sessions, though, by the end of the program, she stated that she acclimated to the VR and ultimately enjoyed the VR sessions.

Participants also provided some specific feedback on the sessions (Textbox 1). Participants mainly enjoyed the digital nature of the VR sessions and how the surrounding environment could be changed in relation to their breathing patterns. Participants additionally expressed positive comments about the autonomy to choose their own games and breathing exercises in the last 4 individual sessions, and they liked that the sessions were typically at a relaxing pace (Textbox 1).

XSL•FO
RenderX

Figure 2. Perceived effects of web-based subcategories. OT: occupational therapy; PT: physical therapy.

XSL•FO
RenderX

Textbox 1. Sample responses across participants regarding specific feedback subthemes.

Length of session and breathing intervals

- "... make it just a little shorter" [Female, 17 years].
- "in paced breathing the gaps between inhaling seemed a little too long" [Male, 14 years].

Clarity of instructions

- "simple, easy to follow" [Male, 14 years].
- "I disliked that the first one did not say what to do, so I assumed to breathe with the tree" [Female, 16 years].

Amount of interaction

- "[I liked] the blowing in and out of your breath to move the circular stone" [Female, 13 years].
- "I liked how the breathing 'class' synced with the tree and how the greenery of the plants were all around me" [Female, 16 years].

Voiceover language

- "I didn't enjoy the words talking about my energy because I believe Jesus is how you grow and relax" [Female, 17 years].
- "Everything was nice except for the repetitive phrases in the first part" [Female, 16 years].

Virtual reality scenery and music

- "I like the scenery and calming music. I liked how it changed between day and night" [Female, 16 years].
- "[I liked] the music and graphics" [Female, 17 years].

Autonomy of choice and pace

- "I liked that the first one was kind of on your own and you could go at your own pace" [Female, 17 years].
- "[I liked] the choice of what I could do" [Female, 15 years].

Preliminary Effectiveness

Paired 2-tailed *t* tests were conducted to examine changes in quality of life (PedsQL) and pain interference (FDI) from baseline to postpain program. PedsQL scores were calculated in terms of both physical and emotional functioning. There was a statistically significant increase in the average physical functioning score among participants (t_6=−3.752; *P*=.01; 95% CI −37.585 to −7.915; effect size [Hedges correction]=17.139) from pre- to postparticipation in the overall program. The cohort's average emotional functioning score also increased, though this change was not statistically significant (t_6=−1.534; *P*=.18; 95% CI −35.214 to 8.071; effect size [Hedges correction]=25.003; Multimedia Appendix 1). Participant FDI scores significantly decreased from an average of 25.1 to 11 from before to after the pain program (t_6=5.394; *P*=.002; Multimedia Appendix 2).

Paired sample 2-tailed *t* tests assessed differences in systolic BP, diastolic BP, and HR before and after each VR session. We used the Bonferroni correction method to adjust the threshold for significance due to multiple tests (*P*≤.002) [37]. There were no significant differences between pre- versus postsystolic BP, diastolic BP, and HR for any session. However, a signal toward decreased BP was observed across most sessions (see Table 2 for general trends in pre- vs postsession BP and HR). All sessions also resulted in decreased HR, though these changes were not statistically significant.

XSL•FO
RenderX

Table . Paired 2-tailed *t* test results of the average difference in systolic and diastolic blood pressures (in mm Hg) and heart rate (in bpm) before and after virtual reality (VR) session[a].

		Pre-VR	Post-VR	*t* test (*df*)	*P* value (2-tailed)
Session 1					
	Systolic	112.5	113.4	−0.214 (7)	.84
	Diastolic	65.4	66.1	−0.453 (7)	.66

[a]The threshold for significance was adjusted for multiple testing using the Bonferroni correction method.

Discussion

Principal Findings

AppliedVR respiratory biofeedback demonstrated initial feasibility, acceptability, and preliminary effectiveness when integrated into a PPRP. Additionally, open-ended, qualitative feedback on the overall VR program was positive. While not powered to detect changes over time, we did see changes in the expected direction in health outcomes (BP and HR) from pre- to post-VR sessions. The signal of generally decreased BP and HR after VR session is promising and should be further investigated in a large sample with greater power to detect changes.

The PPRP successfully improved reported functioning on 2 different self-report measures (the FDI and the PedsQL). This indicates that adding the VR sessions did not interfere with positive improvements, generally seen in the larger PPRP. Overall, this pilot study demonstrated that a larger implementation or effectiveness trial to assess the impact of integrating a VR-delivered relaxation and mindfulness training

XSL•FO
RenderX

program into a PPRP is feasible and would likely be acceptable to adolescents. Our results further suggest that VR platforms may serve as an important tool in keeping adolescents engaged in biofeedback training; however, allowing for customization and personalization within these platforms among users may allow for even higher acceptability and user satisfaction.

Comparison With Prior Work

Since the completion of this study, 3 other published pilot studies of VR-delivered biofeedback programs have also demonstrated the feasibility and acceptability of using this technology with adolescents in the following settings: inpatient during the perioperative period [38], inpatient for those undergoing port catheter needle insertion [39], and outpatient or home setting for migraines [40]. Each of these 3 studies use slightly different technology and software for the VR and biofeedback components and did not use the same technology as was used in this study. Similar to our findings, the acceptability ratings in these 3 studies were high, with participants reporting that the VR environment was engaging and relaxing [38-40]. One study compared VR with biofeedback to a tablet (iPad)-delivered augmented reality with biofeedback intervention. Interestingly, adolescents reported that both interventions were acceptable but reported a preference for the VR and biofeedback intervention [40]. One unique aspect of this study is that we examined the feasibility of including the VR-delivered intervention as a part of an integrated PPRP. Prior work has examined using VR as an engaging tool in the pediatric rehabilitation setting, but the intervention was focused on increasing movement and range of motion rather than teaching biofeedback and relaxation techniques [41].

Limitations

The main limitation of this prospective pilot study is the small sample size, which limits generalizability and our ability to examine effectiveness. While our initial sample size goal was 15, reductions in clinical volume correlating to the COVID-19 pandemic restricted participation and recruitment. Given the small sample size, the results of this study may not be applicable to the broader adolescent population. Another limitation of our study is the lack of diversity among student participants with the sample being predominantly female. However, this demographic composition aligns with existing research, which indicates that chronic pain treatment is more prevalent among women and non-Hispanic White people in the adult population, suggesting that our participant demographics are representative of this group [42].

Additionally, because the VR biofeedback intervention in this study was integrated into a PPRP, we were unable to assess the independent effect of VR biofeedback on improvements in adolescent-reported physical or emotional functioning. Furthermore, this study did not include a control group, which will be important in future research to more clearly demonstrate efficacy. In addition, the VR sessions were conducted by medical students as a part of this research study. Thus, these methods may not transfer to a real-world setting, and to assess feasibility for use in an existing pain program, future studies likely will need pain program interventionists to be using the VR program in their sessions rather than having the study team conduct separate sessions. Finally, the AppliedVR program was initially developed for the adult population and has not yet been validated for use with adolescents; thus, while acceptable to adolescents, future research is needed to demonstrate efficacy and effectiveness in this population.

Conclusions

This prospective pilot study is novel in its use of VR in a PPRP for pediatric chronic pain management and provides a foundation for future larger-scale studies of VR biofeedback. Research into nonpharmacological adjuncts is essential to identify acceptable, feasible, and effective alternatives to chronic pain management. Innovative technologies such as video games, VR, and augmented reality may provide a more immersive experience for biofeedback sessions, but given their novelty, require testing to determine whether it is acceptable and feasible to patients and families. This study provides initial support for the acceptability and feasibility for a VR-based biofeedback in the management of pediatric chronic pain within the context of a multidisciplinary treatment program. More research is needed with larger, more diverse groups of adolescents to further determine the usefulness of such a program and perhaps identify any areas for adaptation and improvement.

Abstract

Background: The number of patients undergoing open-heart surgery (OHS) is persistently increasing. Additionally, postoperative pulmonary complications have been reported after OHS, and an incentive spirometer has been suggested to prevent postoperative pulmonary complications. However, no commercial incentive spirometer provides the precise inhalation volume. We developed a digital incentive spirometer (DIS) that displays the relevant data.

Objective: In this study, we aimed to explore the beneficial effects of a DIS on respiratory function in patients who underwent OHS.

Methods: A randomized controlled trial was designed with 32 patients scheduled for OHS: 16 individuals each were assigned to the DIS and the flow-oriented incentive spirometer (ie, Triflow incentive spirometer) groups, respectively. The patients were requested to use the DIS and Triflow incentive spirometer 15 times/set, two sets/day, from day 1 to 5 postextubation. All participants underwent lung function and respiratory muscle strength assessments prior to OHS and on day 5 postextubation postoperatively. For comparison between and within the groups, we performed an intention-to-treat analysis with a two-way mixed analysis of variance.

Results: In both the DIS and Triflow incentive spirometer groups, pulmonary function parameters and maximal respiratory pressure were markedly reduced on day 5 postextubation when compared with those prior to OHS (P<.05). There were no significant differences in pulmonary function or respiratory muscle strength between the two groups (P>.05).

Conclusions: Pulmonary function and respiratory muscle strength did not differ significantly between the DIS and Triflow incentive spirometer groups among patients who underwent OHS.

KEYWORDS

digital incentive spirometer device; flow-oriented incentive spirometer; open-heart surgery; randomized controlled trial; respiratory function

Introduction

An incentive spirometer is typically used for patients with pulmonary issues and those at risk of postoperative pulmonary complications. This device exercises the lungs and necessitates deep breathing, requiring patients to inhale slowly and deeply to increase the volume of air entering the lungs [1,2].

A health professionals' survey on the perspective on the utility of an incentive spirometer among nursing and respiratory care staff reported that healthcare professionals agreed that an incentive spirometer is essential for patient care (92.7%) [3]. Furthermore, healthcare professionals believed that an incentive spirometer could improve pulmonary function (92.0%) and inspiratory capacity (93.0%). An incentive spirometer can also

XSL•FO
RenderX

help prevent and reverse atelectasis (96.6% and 90.0%, respectively) and prevent and reverse pneumonia (92.5% and 68.4%, respectively) [3]. Among patients who underwent lung surgery, the incidence of postoperative pulmonary complications was lower in those who used an incentive spirometer preoperatively and postoperatively than in those who did not use an incentive spirometer [4]. Thus, the use of an incentive spirometer pre- and postheart surgery can reduce the risk of postoperative pulmonary complications or hospitalization [1,5,6].

A review of the literature published between 2010 and 2021 revealed that the average total cardiac surgical volume in high-income countries was 123.2 per 100,000 people annually, which included coronary artery bypass graft (CABG) and valvular heart disease (36.7 and 30.8 per 100,000 people per year, respectively). In high-middle-income countries including Thailand, the average total cardiac surgical volume was 86.1 per 100,000 people annually, with CABG and valvular heart disease reaching values of 35.4 and 13.3/per 100,000 people per year [7].

Among patients undergoing CABG, the use of incentive spirometer devices can reduce the duration of postoperative mechanical ventilation and shorten hospitalization [6]. Additionally, both flow- and volume-oriented incentive spirometer devices can improve pulmonary function (ie, the forced vital capacity [FVC], forced expiratory volume in the 1st second [FEV1], and the peak expiratory flow rate [PEFR]) in patients undergoing surgery [8].

Both volume- and flow-oriented incentive spirometer devices reflect respiratory performance and capacity and encourage improvements in deep inspiration. However, these devices fail to provide a specific volume or airflow of inspiration; for example, the flow-oriented incentive spirometer is designed to improve lung volumes and employs a flow-controlled mechanism using three floating balls. The device displays airflow at 600, 900, and 1200 ml/s as three different colored balls. Additionally, some patients may be unable to elevate their floating balls, which may lead to a lack of motivation.

Therefore, we developed a digital incentive spirometer (DIS) capable of displaying both the volume of airflow entering the lungs and the volume of air inhaled as numerical indicators, graphical representations, colors, and auditory signals. Furthermore, we explored the benefit of DIS on the respiratory performance of patients who underwent open-heart surgery (OHS).

Methods

Study Design

The study was twofold. The first part aimed to design and develop the DIS. The second part was designed as a randomized control trial to explore the benefits of DIS on pulmonary function and respiratory muscle strength.

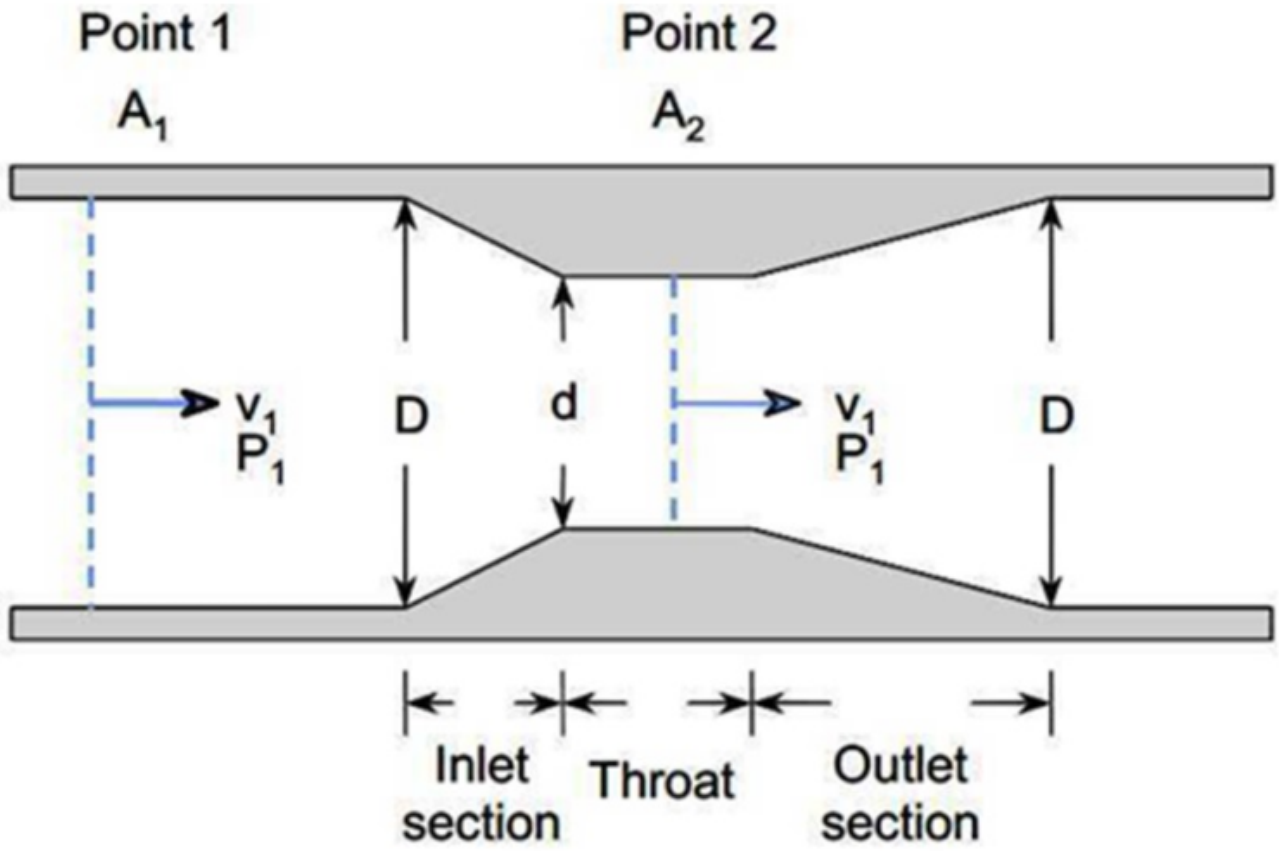
Ethical Considerations

The protocol of the study was approved by the Ethics Human Committee of Thammasat University based on the Declaration of Helsinki, the Belmont report, CIOMS guidelines and the International practice (ICH-GCP) with COA No. 074/2566. The study followed the 2010 CONSORT Reporting guidelines (Checklist 1). Informed consent was obtained from all subjects involved in the study. Written informed consent has been obtained from the participants to publish this paper.

Design and Development

We designed and developed the DIS based on the principles of differential pressure flow meters. The MPX10DP (NXP Semiconductors, Thailand Co., Ltd) is a pressure sensor designed to measure pressures ranging between 0 and 10 kPa or 0 to 1.45 psi. It operates by comparing differential inputs to determine the pressure and provides an analog output signal. The circuit design utilizes the ESP32 microcontroller to read the analog signals from the MPX10DP sensor. In addition, an LM358N operational amplifier was employed to amplify the output signal and convert the analog signal into electrical voltage. Therefore, this voltage was used to calculate the pressure, which was then compared with measurements obtained from the AWM720P1 airflow sensor. Furthermore, the AWM720P1 airflow sensor is a standard device to measure airflow, expressed in units of standard liters per minute. The AWM720P1 airflow sensor has low hysteresis and repeatability errors (less than 0.35% of reading), providing better system accuracy. This sensor employs a microcontroller to read the sensor data, convert the analog signal into an electrical voltage, and compute the airflow rate, which is the output in L/s. The conversion of pressure to airflow is achieved by correlating the pressure readings obtained from the MPX10DP sensor with the airflow measurements from the AWM720P1 sensor. This is accomplished by integrating both sensors into a unified system and recording data concurrently to determine the linear relationship between pressure and airflow.

According to the concept of air passing through different cross-sectional areas and air pressures, the airflow from the prototype DIS device into the lungs passes through a tube with varying cross-sectional areas and air pressures. Therefore, the air volume was transmitted to the sensor and calculated using a microcontroller that has an analog-to-digital conversion module.



The principle of flow rate measurement involves generating a pressure drop within the tube through which the fluid flows using the principles of the continuity equation and the Bernoulli equation. The continuity equation can be summarized as the product of the cross-sectional area of the tube and the flow velocity of an ideal fluid, which remains constant at any position within the tube. This relationship ensures that the airflow is consistent according to the flow equation (Figure 1),

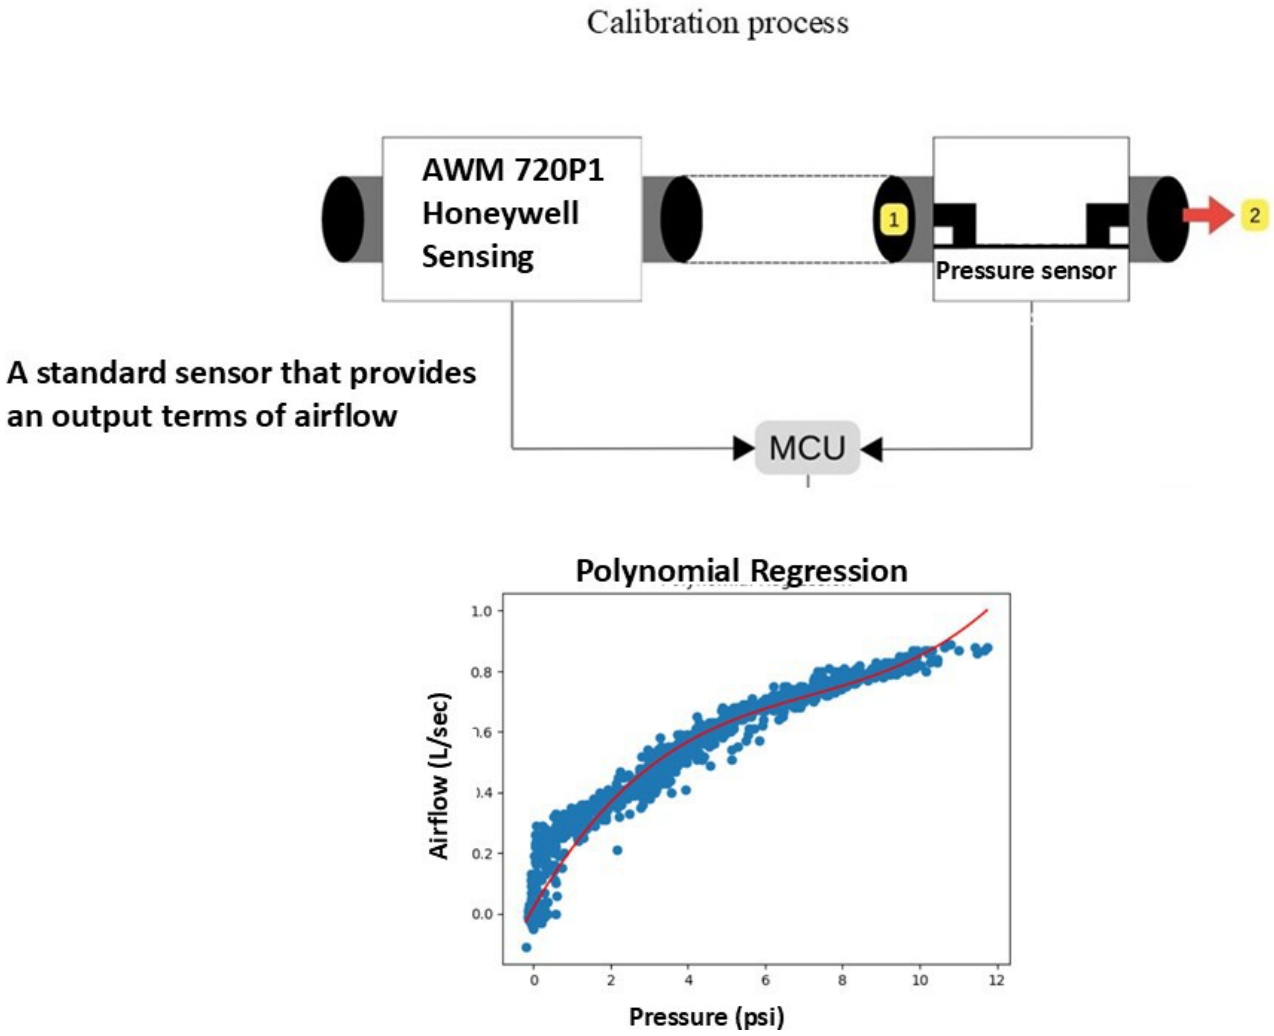
$$Q=v1\times A1=v2\times A2$$

where v denotes the mean velocity, A denotes the cross-section area normal to the direction of flow, and Q denotes the discharge or volume flow rate of water flowing at a given rate of time through any section of the area.

XSL•FO
RenderX

Figure 1. Principles of the continuity equation and the Bernoulli equation.

The DIS was calibrated via the sensor, and the air pathways were connected in series between the prototype DIS and the industrial sensor. The readings acquired from the DIS prototype were in the form of pressure levels (analogs), which were compared with the known airflow rates from the industrial-grade sensor, referenced from the characteristic graph shown in Figure 2. Air was drawn at various levels during data collection to obtain sufficient data to create a regression equation model, which was used to determine the airflow rate from the electrical potential input obtained from the differential pressure sensor, as follows:



0.01967741+(0.22080302×pressure1)+(−0.0257367×pressure2)+(0.00119711×pressure3)

Therefore, a DIS device consists of the following three main components: (1) incentive spirometer device: This device includes a mouthpiece, tubing, and a main unit, and captures the inhaled air of the user. (2) Display screen: This includes a color bar, airflow volume levels, and a display of the air volume, and provides visual feedback to the volunteers undergoing the test. (3) Pressure sensor: The pressure sensor MPX10DP measures the inhalation pressure via the mouth, and it is highly accurate and reliable for a differential pressure flow meter type.

Volunteers can read the airflow volume readings while performing breathing exercises using the prototype DIS. The air volume display screen presents the volume of air inhaled and exhaled during each breathing cycle (Figure 3).

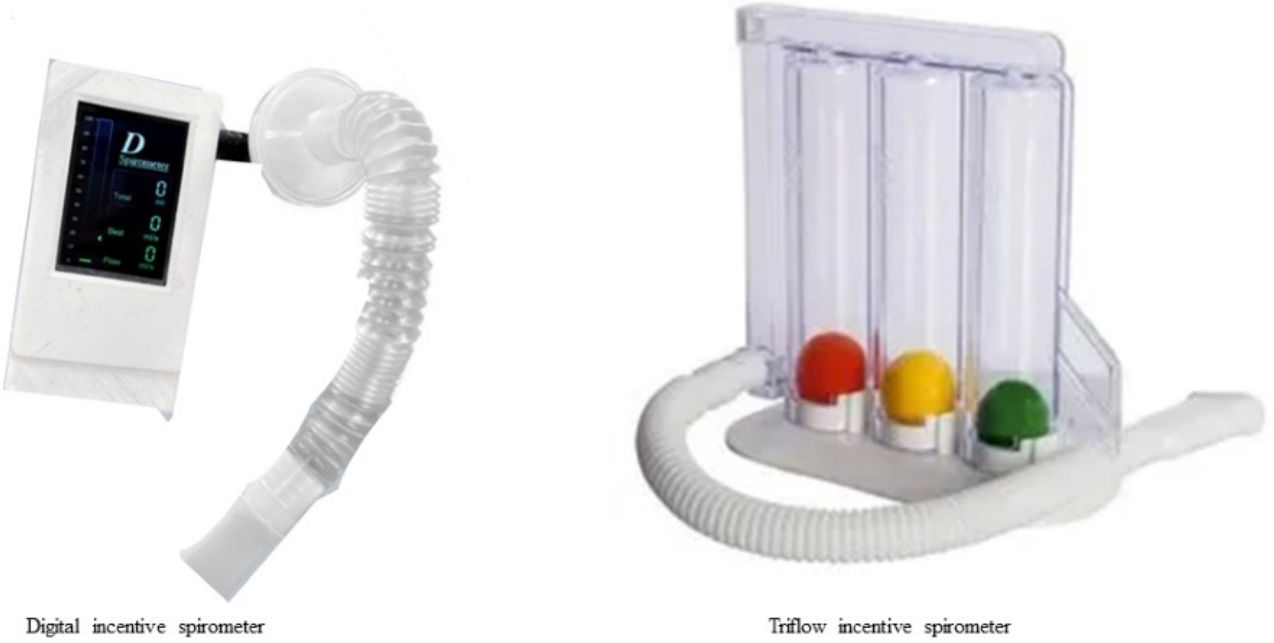
Experimental Design

We explored the benefits of using the DIS. In this study, we recruited patients who underwent OHS at Thammasat University Hospital. Patients who were scheduled to undergo CABG or valvular surgery, aged 35 - 80 years, both men and women, were enrolled. Patients with a history of heart surgery or arrhythmia 24 hours prior to the test and those with active respiratory infection (eg, tuberculosis, COVID-19, or multiple drug resistance) were excluded. In addition, the discontinuation criteria were patients who required reintubation, those with postsurgical infection, those with prolonged intubation exceeding 72 hours, and those who needed admission to the hospital less than 5 days after extubation.



The sample size was calculated by using G-power 3.1.9.4, the effect size was set at 0.25, the statistical power was 0.80, and the alpha was .05; therefore, a total of 28 participants were examined initially. However, to avoid missing data or to adjust for potential dropouts, 32 randomly selected participants were finally enrolled. All participants were provided with an information sheet, and a consent form was signed before participation.

All participants were required to undergo pulmonary function evaluation (ie, the predicted %FVC and the predicted PEFR) by using CareFusion MicroLab (a Micro Direct company, United Kingdom) and respiratory muscle strength tests (maximal inspiratory pressure [MIP] and maximal expiratory pressure [MEP]) measured by a MicroRPM Respiratory Pressure Meter (Micro Medical Micro RPM., United Kingdom) prior to OHS and on day 5 postextubation postoperatively. A standard protocol for pulmonary function and respiratory muscle strength testing was followed according to the recommendations of the European Respiratory Society (ERS)/American Thoracic Society technical standard and ERS statement on respiratory muscle testing, respectively [9-11]. A single-blind randomized clinical trial was conducted with two assessors who were physical therapists.

The selected 32 participants were assigned to use the DIS or Triflow incentive spirometer (control group; Figure 4). The patients were required to use the DIS and Triflow incentive spirometer 15 times/set and perform two sets daily (ie, in the morning and evening), from day 1 to 5 postextubation. All participants were instructed on how to use the DIS or Triflow incentive spirometer via an in-person demonstration by a physical therapist who was not the assessor. The participant was required to sit on the bed or upright position and hold the device (ie, DIS or Triflow incentive spirometer). After that, they were asked to breathe out normally and then take a deep breath in via the mouthpiece and try to hold the breath for 3 - 5 seconds or as long as possible. During the intervention, all participants were supervised by two physical therapists, while other physical therapists were assigned to be assessors. In addition, those participants underwent physical therapy protocol, for example, breathing exercises, cough training with pillow support, calisthenics exercise, and ambulation (sitting, standing, and walking). The participants received physical therapy once a day until discharged from the hospital.

Figure 4. Digital incentive spirometer and Triflow incentive spirometer.

Statistical Analysis

Data were analyzed using IBM SPSS Statistics version 24.0. The Shapiro-Wilk test was used for assessing normal data distribution. An intention-to-treat analysis with a two-way mixed analysis of variance (time (2) × type (2)) was used to compare between and within groups for pulmonary function and respiratory muscle strength. Statistical significance was set at $P<.05$.

Results

Patient Classification

Sixty patients scheduled for OHS were included in the initial study. Unfortunately, 6 patients were excluded because they were <35 years of age, and 22 participants were included in the study during the initial session; however, due to the cancellation of their surgery, they were excluded from the study. Ultimately, 32 patients were enrolled in the study. A simple random sampling (ie, using a random lottery) was performed, and the patients were divided into two groups based on the device used: the DIS group (n=16) and Triflow incentive spirometer group (n=16). All participants underwent pulmonary function tests (ie, the predicted %FVC and the predicted %PEFR) and respiratory muscle strength (MIP and MEP) assessment prior to surgery. Twenty-two patients were reassessed on day 5 postextubation. Of the 10 patients who did not complete the test, 3 required prolonged intubation (ie, greater than 72 hours), 4 underwent reintubation, and 1 was discharged before the assessment; surgery was canceled in the final excluded patient (n=1; Figure 5).

Of the 36 patients who underwent OHS, 11 male and 21 female patients were included in the current study (Table 1). Considering patients assigned to the DIS and Triflow incentive spirometer groups, there were no significant differences in terms of age, comorbidities, type of operation, pulmonary function, and respiratory muscle strength (Table 2).

Effect of the Intervention on Pulmonary Function and Respiratory Muscle Strength

Both groups exhibited markedly reduced pulmonary function and respiratory muscle strength on day 5 postextubation when compared with preoperative values (P<.05). However, patients who underwent DIS showed a slower decline in respiratory performance when compared with those who used the Triflow incentive spirometer device for MIP (mean difference [SE], −8.13 [3.86], P=.044 vs −9.94 [3.86], P=.015), MEP (mean difference [SE], −0.88 [3.99], P=.828 vs −6.38 [3.99], P=.121), %FVC (mean difference [SE], −19.63 [5.13], P=.001 vs −21.13 [5.13], P<.001) and %PEFR (mean difference [SE], −2.38 [6.76], P=.728 vs −11.81 [6.76], P=.091). In addition, there was no significant difference between DIS and the Triflow incentive spirometer after the intervention program (P>.05; Table 3).

Discussion

Principal Findings

Herein, we aimed to explore the effects of using the DIS on the respiratory performance of patients who underwent OHS. Based on our findings, the pulmonary function (predicted %FVC and %PEFR) and respiratory muscle strength (MIP and MEP) values did not differ significantly between the DIS and Triflow incentive spirometer groups.

Pulmonary Function and Respiratory Muscle Strength

Reduced respiratory performance after heart surgery has been well documented [12-14]. The results of the study are in line with those of previous studies on pulmonary function after heart surgery. Narayanan and Hamid [12] reported that the inspiratory capacity dropped to 41% on day 1 post-OHS, gradually increasing to 106% on day 5 post-OHS. In patients who underwent valvular surgery, Alaparthi et al [13] found that pulmonary function (FEV1, FVC, and PEFR) values were reduced when compared with preoperative values and these values improved after day 7 postoperation.

Reportedly, patients who undergo OHS experience functional impairment including functional capacity, physical performance, and psychological health problems [14]. In the present study, pulmonary function (ie, predicted %FVC and %PEFR) and respiratory muscle strength values 5 days postextubation

XSL•FO
RenderX

remained lower than the preoperative values. However, the benefit of a DIS gradually decreased when compared with that in the incentive spirometer group. The DIS device features specific attributes that enable the display of numerical values of visual and auditory elements as real-time feedback. Therefore, the use of this DIS device can enhance motivation while performing breathing exercises. Likewise, patients who underwent CABG and used an incentive spirometer experienced a markedly smaller reduction in pulmonary function values than those who performed only deep breathing therapy postoperatively [2,15]. Additionally, a systematic review and meta-analysis of postoperative cardiac surgery (n=1677 participants) revealed a small or no difference in incentive spirometer and standard respiratory care for postpulmonary complications (eg, atelectasis, pneumonia, and mortality) and lung function (eg, FVC, vital capacity, and FEV1), MIP, length of ICU stay or length of hospital stay after cardiac surgery [16]. In other words, the incentive spirometer is not superior to standard respiratory care in terms of clinical outcomes in postoperative cardiac surgery. However, another systematic review and meta-analysis in postoperative care in patients in the incentive spirometer group and without incentive spirometer group reported that patients undergoing incentive spirometryr had significantly shorter reduced risk of postpulmonary complications, and postoperative pneumonia compared with the control group without using IS [17]. Using incentive spirometers may be appropriate for lung re-expansion and oxygen uptake by taking long, slow deep breaths and a breath-hold of 3 - 5 seconds resulting in improved collateral ventilation and alveoli [18]. Therefore, a DIS, compared with incentive spirometers, may be an alternative tool for improving respiratory performance and preventing pulmonary complications.

Considering the limitations of this study, we could not compare participants who received the intervention (DIS or Triflow incentive spirometer) and those who did not receive any intervention. The severity of pulmonary function at baseline was not excluded from the study, which may have impacted the results. However, no significant differences were observed between the DIS and Triflow incentive spirometer at baseline. Additionally, the study had a short intervention period because it was conducted at a hospital. Finally, the medical reports and laboratory data were not recorded (eg, comorbidities, duration of operation, ejection fraction, or functional classification), which might affect the baseline characteristic data or initial health status.

Conclusion

There is a significant decrease in pulmonary function and respiratory muscle strength in the DIS and Triflow incentive spirometer on the 5th day postextubation when compared with preheart surgery values. Additionally, the effect of a DIS on pulmonary function and respiratory muscle strength was similar to a flow-oriented incentive spirometer. Therefore, the innovation of DIS motivates patients to increase their inspiratory effort, thereby encouraging deeper breathing.

Acknowledgments

The authors would like to thank all the patients for participating in the study. We also thank all the staff at Thammasat University Hospital for helping and supporting our team. We thank the Thammasat University Research Unit for Physical Therapy in Respiratory and Cardiovascular Systems, Thammasat University, Pathumthani, Thailand. In addition, this study was supported by the Thammasat University Research Fund Contract No TUFT 61/2567.

Abstract

Background: With the rapid advancement of technology, using wearable devices and mobile health (mHealth) apps to monitor and promote physical activity (PA) has become increasingly popular among individuals with various chronic conditions. However, such work remains limited among individuals with spinal cord injury (SCI), especially those who use a manual wheelchair for mobility.

Objectives: The study aims to describe the development of the WheelFit mHealth app for monitoring and promoting PA in manual wheelchair users (MWUs) with SCI and evaluate its feasibility and usability in free-living conditions.

Methods: The WheelFit app, based on the Fogg Behavioral Model with inputs from stakeholders, including MWUs, physical therapists, and personal trainers, was developed to promote PA in MWUs. It works with two commercial wearable devices, that is, an Android smartwatch and a wheel sensor, which stream users' upper extremity and wheelchair movement to the app to calculate PA variables using custom algorithms. Users can set personal goals, review daily progress and PA history, and access an adaptive workout library within the app. A 4-week single-group pre-post study, consisting of a 1-week baseline and 3-week intervention phase, was conducted to evaluate WheelFit's feasibility and usability. Feasibility was evaluated using the session attendance rate, device and app usage, and implementation of action plans. Usability was assessed using the system usability scale. The preliminary effectiveness was assessed by comparing preintervention and postintervention PA variables and scores from the SCI exercise self-efficacy scale.

Results: A total of 16 participants completed the study protocol with 100% session attendance and maintained 14.2 hours of daily device and app connection. Participants demonstrated varying levels of adherence to their action plans. The excellent usability of WheelFit was indicated by an average system usability scale score of 81.8 (SD 19.2) points. Statistically significant increases between pre-post daily exercise times (preintervention: mean 26.4, SD 16.9 minutes; postintervention: mean 33.3, SD 24.9 minutes; P=.049) and exercise self-efficacy scale scores (preintervention: mean 33.9, SD 4.5 points; postintervention: mean 35.9, SD 3.2 points; P=.043) were observed.

Conclusions: The WheelFit app demonstrated promising feasibility, usability, and a positive impact on promoting PA in MWUs with SCI. Future investigation exploring the potential integration of the WheelFit app into clinical practice is warranted.

Introduction

An estimated 302,000 people in the United States are living with spinal cord injury (SCI) as of 2023 [1]. On average, 39.3% of people in this population are manual wheelchair users (MWUs) [2]. In addition to direct changes in sensory and motor functions caused by the injury, 95% of people with SCI have at least one secondary complication [3]. Among these complications, obesity stands out with a prevalence of 66%

XSL•FO
RenderX

[4,5]. A primary cause of obesity is the positive energy balance caused by decreased energy expenditure, often linked to reduced fat-free mass and physical activity (PA) in the SCI population [6]. Despite published PA guidelines, nearly half of this population remains sedentary and does not meet the minimum recommended guideline of 20 minutes of moderate to vigorous aerobic activity twice a week and 3 sets of 10 reps of strength training twice a week [7,8].

With the rapid development and cost reduction of commercial wearable devices, using such devices with mobile health (mHealth) apps to promote PA has become increasingly popular and shown promising benefits among the general population [9,10]. However, such success has yet to be fully realized among MWUs with SCI. One significant barrier is that the majority of commercial wearable devices are developed and optimized for ambulatory individuals, lacking validity for MWUs with SCI. As of November 2024, only the Apple Watch and certain Garmin smartwatches provide a wheelchair mode for push count assessment [11-13]. While the Apple Watch accurately tracks push counts for wheelchair users, it is costly and requires an iPhone, limiting its use among Android users and those with limited financial resources [14,15]. Validation studies on the Garmin smartwatch in the wheelchair mode are still lacking.

Currently, only a few studies have explored the use of commercial wearable devices in mHealth interventions aimed at promoting PA in MWUs with SCI. The majority of these studies mainly use wearable devices as outcome measurement tools. The Workout on Wheels internet intervention (WOWii) developed by Froehlich-Grobe et al [16] used a Polar A300 fitness tracker to manually log workout durations from 143 participants during workout sessions delivered through the WOWii web portal. The workout minutes were used for workout progress monitoring, which was displayed on the WOWii site to help participants track their progress toward established goals. The 24-week study comprised a 16-week intervention phase followed by an 8-week maintenance phase. During the intervention phase, 73% (123/168) of participants logged their workouts using the Polar fitness tracker, while approximately 29% (48/168) to 41% (69/168) continued to do so during the maintenance phase. Analysis of workout minutes revealed a significant increase in aerobic and strength workout time among participants during the intervention phase, a trend that was maintained through the maintenance phase [16].

Another mHealth intervention that used commercial wearable devices is the Scale-Up Project Evaluating Responsiveness to Home Exercise And Lifestyle Tele-Health (SUPER-HEALTH) developed by Rimmer et al [17]. The SUPER-HEALTH intervention is designed for individuals with physical disabilities, including those who can ambulate independently as well as those who use wheelchairs. Similar to the WOWii project, the SUPER-HEALTH delivered workout content through the website and used a Fitbit Charge fitness tracker to monitor participants' PA data. The PA was displayed to the participant in the activity dashboard of the SUPER-HEALTH site, and the study personnel also monitored the PA data and manually issued reminders to maintain intervention fidelity. The full quantitative results of the SUPER-HEALTH study are not available yet. It is worth noting that the Fitbit devices were designed to measure PA in the general population, and their validity in people with SCI remains unknown. Using such PA data may lead to biased outcome measurement [18,19].

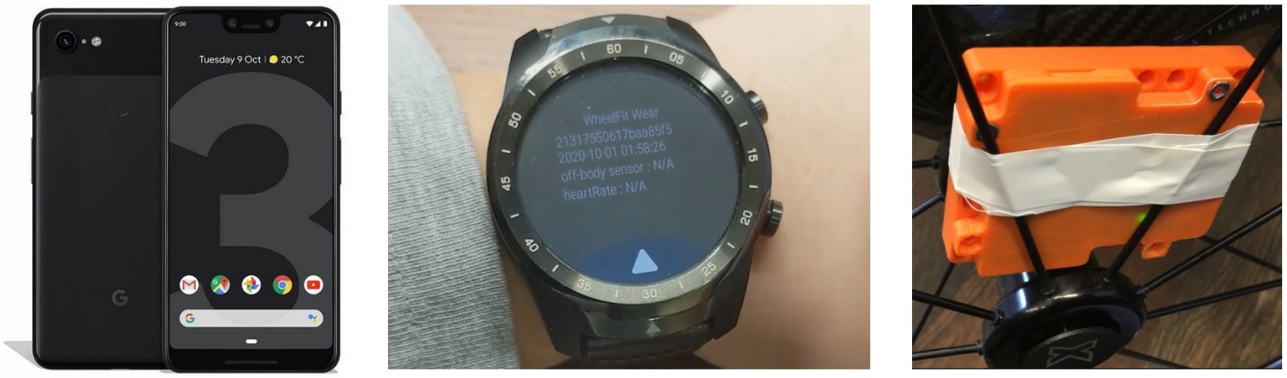
On the other hand, the Personal Health Informatics and Rehabilitation Engineering (PHIRE) app developed by Hiremath et al [20] is a wearable device-oriented mHealth PA intervention for MWUs with SCI. It provides PA measures using data from a commercial LG Android smartwatch and a wheel sensor, processed by custom algorithms for MWUs with SCI [20]. The app quantifies participants' daily PA as energy expenditure, wheelchair travel distance, and PA minutes. The app was designed following the Just-in-time Adaptive Intervention (JITAI) framework, which aims to provide the right intervention at the right time [21]. Once the user completes a bout of PA, defined as a minimum of 3 continuous moderate to vigorous physical activity (MVPA) minutes, the app provides congratulations and issues JITAI messages based on various circumstances. If the user has not met their daily MVPA minutes goal, the app displays the current progress and the remaining minutes needed to reach the goal. Upon achieving the goal, the app congratulates the user. If the user exceeds the goal, the app shows the current accumulated MVPA minutes. Their pilot study results indicated that out of 16 participants, 38% (6/16) and 69% (9/16) of participants experienced a considerable increase (>10%) in light and moderate intensity PA, respectively [20]. While the PHIRE app integrates a wearable device with a validated algorithm for MWUs with SCI, it lacked the adaptive workout features found in the SUPER-HEALTH and WOWii studies.

Incorporating both wearable-based PA monitoring and mHealth-delivered adaptive workouts, we conducted this WheelFit study with 2 main aims. The first was to develop the WheelFit fitness app for MWUs with SCI. This app integrates daily PA monitoring and feedback using data from a commercial smartwatch and a wheelchair sensor, processed with custom algorithms for this population. Additionally, the app includes an adaptive workout library created by health care professionals. The second aim was to evaluate the feasibility and usability of WheelFit as an mHealth intervention for individuals with SCI.

Methods

WheelFit Devices

The WheelFit app is designed for Android and is deployed to pixel 3 phones (Google LLC), as shown in Figure 1A. The app communicates with two wearable devices to calculate PA variables: a TicWatch Pro smartwatch (Mobvoi Information Technology LLC), shown in Figure 1B, and a SensorTag wheelchair sensor (Texas Instruments), shown in Figure 1C.



The TicWatch Pro is an Android WearOS-based smartwatch. We developed a WheelFit companion app for the smartwatch, which samples data from its accelerometer at 30 Hz and from the heart rate sensor at 1 Hz. Raw acceleration signal data are packed using the "batching" function of the WearOS and sent to the smartphone app each minute. The heart rate data are streamed to the smartphone app continuously. The companion app also shows the connection status and issues vibration

XSL•FO
RenderX

notifications when the watch is disconnected from the phone or a sedentary behavior is detected. The battery of the smartwatch lasts about 10 - 11 hours.

The SensorTag is a multisensor Internet-of-Things device [22]. We developed custom firmware that samples only the accelerometer and gyroscope, deactivating other sensors to conserve battery life. The accelerometer is used to activate the gyroscope when wheelchair movement is detected. The gyroscope registers the wheel rotation at 5 Hz. The device then converts the number of rotations to the distance traveled according to the wheel diameter specified in the settings and continuously streams all data to the smartphone app through Bluetooth Low Energy protocol. The SensorTag is attached to the wheelchair spokes using a custom 3D-printed case. Powered by 2 AAA batteries, it has a battery life of 1.5 months.

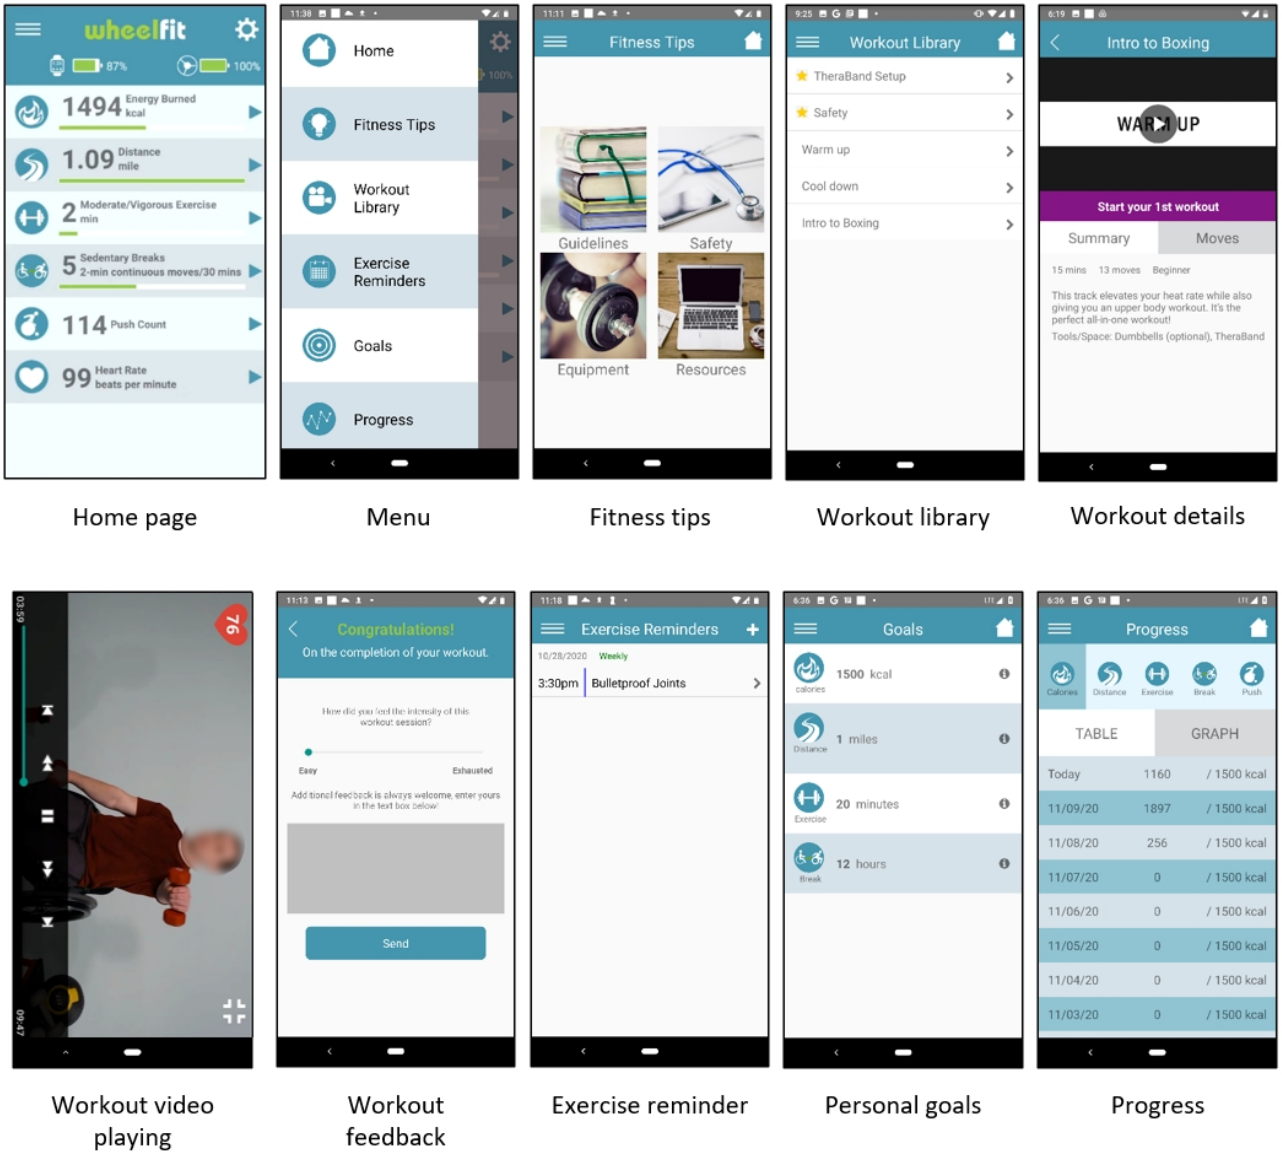
WheelFit App Development

Conceptual Framework

We developed the WheelFit app based on the Fogg Behavioral Model (FBM) with inputs from stakeholders, including MWUs, physical therapists (PTs), and personal trainers, to promote PA in MWUs. The FBM includes three key factors: motivation, ability, and triggers [23]. It suggests that for a target behavior to occur, an individual must be sufficiently motivated, have the ability to perform the behavior, and be prompted by a trigger.

The WheelFit App

The WheelFit app adopted the multicomponent design (Figure 2), which has proven to be more effective than the single-component design, to address the three FBM key factors [24].



To address ability, the FBM suggests that making desired behavior easier to perform is simpler than training individuals to have new skills [23]. The WheelFit app meets this requirement by offering an adaptive workout library with short, accessible workout videos designed to lower the knowledge and time barriers to PA, as identified in previous research [25].

The app incorporates triggers to prompt actions [23], using smartwatch push notification reminders and vibration alerts for sedentary behavior. These triggers encourage users to engage in both structured and unstructured PA, ensuring consistent engagement and adherence to PA routines.

To enhance motivation, the app includes daily PA monitoring, fitness tips, goal setting, and progress-monitoring modules. The daily PA-monitoring module, featured on the app's home page, offers objective monitoring to support self-regulation, while the fitness tips module provides educational content on the benefits of PA. The goals and progress modules further motivate users by highlighting their achievements and monitoring their PA history [26,27].

Figure 2. The WheelFit app.

Home Page (Daily PA Monitoring)

The home page layout includes a menu icon, a settings icon, device connection indicators for the watch and wheel sensor, and six daily PA measures. Users can navigate through the settings icon to the settings page to enter or update their demographic information and adjust the wheelchair wheel diameter for a more precise PA assessment. The device connection indicator shows the battery level of each connected sensor and displays the connection status. The six PA measures are (1) energy burned, (2) distance traveled, (3) moderate to vigorous exercise time, (4) sedentary breaks, (5) total push counts, and (6) real-time heart rate. The energy burned is estimated using a custom prediction model originally developed for ActiGraph devices in our previous studies and adapted to the Android platform [25,28]. The distance traveled is the cumulative distance calculated from the number of rotations by the wheelchair sensor. For the moderate to vigorous exercise time, the app first calculates the mean absolute deviation from the accelerometer data of the current minute and then applies the thresholds established by Shwetar et al [29] to classify the activity intensity into sedentary, light, or MVPA. The accumulated MVPA minutes are shown as moderate to vigorous exercise time. The sedentary break is defined as the total number of 30-minute periods where at least 2 consecutive minutes of activity above the light intensity are registered. For example, if a user is awake for 16 hours, the maximum possible number of sedentary breaks per day is 32. If the app detects that a sedentary break has not occurred within the initial 25 minutes of a 30-minute interval, it triggers a sedentary behavior alert through vibrations and texts on the smartwatch. The total push count shows the cumulative number of wheelchair pushes calculated through the application of algorithm by Veerubhotla [30] using the raw accelerometer data collected from the smartwatch. Finally, the real-time heart rate variable shows the most current measurement from the smartwatch's heart rate sensor.

Fitness Tips Page

The fitness tips page contains educational materials we have compiled regarding current PA guidelines, wheelchair exercise safety, exercise equipment and tools, and related resources, all formatted as web papers.

XSL•FO
RenderX

Workout Library Page

We provide an adaptive workout library containing 11 workout tracks in three categories: (1) aerobic (3 tracks), (2) strengthening (5 tracks), and (3) flexibility exercises (3 tracks). Each track, lasting approximately 15 minutes, comprises a warm-up, several brief movements (around 1 - 2 minutes each), and a cooldown. These workouts are developed by clinicians and feature wheelchair users, drawing on research evidence and incorporating feedback from users. The description page of each workout track provides details such as workout duration, the number of movements, difficulty level, required equipment or space, and explanations. Given the diverse physical abilities and impairments of individuals with SCI, certain movements may be appropriate for some users but could present risks to others who have reduced range of motion or muscle strength. Therefore, we introduced the workout edit function, enabling health care providers or personal trainers to categorize each movement as "safe to perform," "adapt with modification," or "skip movement" while also offering the ability to highlight or hide each workout. When playing the workout videos, users can use the media control to start, pause, fast forward, and rewind the video. Users' real-time heart rate is displayed at the top left corner to provide an estimation of workout intensity. Upon completion of a workout, the app will prompt the user to rate their perceived exertion and share any feedback they may have.

Exercise Reminders Page

The exercise reminders page provides functions for users to create, edit, and delete exercise reminders. Users can designate the start time, workout type, recurrence, and alarm for the reminders. The app syncs the reminders with the Google Calendar app on the phone to use its built-in notification functions.

Goals Page

The goals page allows users to set their daily goals for energy burned, distance traveled, moderate to vigorous exercise minutes, and sedentary breaks. Goals are also reflected as progress bars on the home page. Users can view the progress bars to track daily progress toward goals.

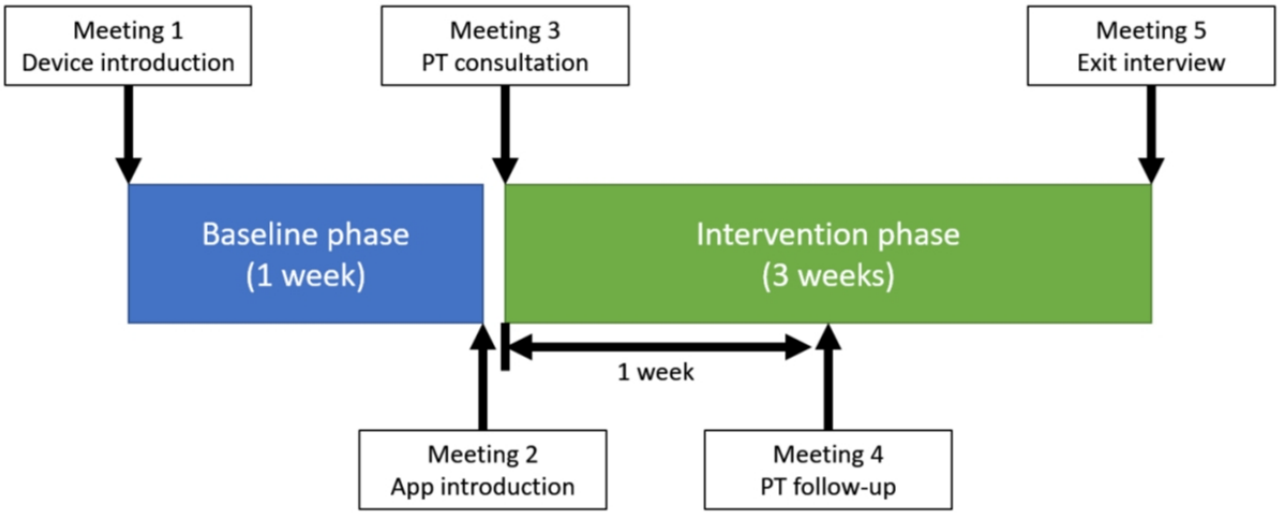
Progress Page

The progress page presents historical daily PA variables except for the heart rate. Users can review their past data with either a table view that shows detailed numbers or a graph view that visualizes the trends of the past 30 days.

Feasibility and Usability Evaluation

Participants

Participants were included in the study if they were (1) aged between 18 and 65 years, (2) diagnosed with an SCI, (3) at least 1-year postinjury (if acquired) and medically stable, (4) not consistently engaging in regular PA for at least 6 months, (5) using a manual wheelchair as their primary means of mobility, (6) living in a community, and (7) experienced in using a smartphone. Potential participants were excluded if they had any active pelvic or thigh wounds or were pregnant (based on self-report). They were also screened for medical conditions (eg, cardiovascular diseases, stroke, pressure ulcers, fracture, musculoskeletal injuries, or COVID) that could limit PA participation. This screening involved a series of questions regarding hospitalizations and therapy received during the past year, physician clearance, and self-perceived limitations as related to each condition identified. If any potential conditions were identified, our PT reviewed the responses, conducted necessary follow-up, and determined whether the participant could safely participate, required further clearance from their primary care provider, or should be excluded. Participants were recruited by convenience sampling through study registries, flyer distribution, and direct outreach.



Power analysis was conducted based on PA effectiveness measurement (ie, daily moderate to vigorous exercise minutes) using data from a mHealth study on adults with diabetes aimed at improving daily light activities (Cohen d=0.93), as no relevant literature on mHealth interventions for individuals with SCI was available [31]. Assuming a power of 0.8 and an α level of .05, G*Power (Heinrich-Heine-Universität Düsseldorf) indicated a required sample size of 13 [32]. To account for a potential 20% attrition and compliance rate, we planned to recruit 16 participants.

Study Design

The 4-week full-remote study consisted of a 1-week baseline phase and a 3-week intervention phase, with 5 virtual meetings held via Zoom (Zoom Video Communications, Inc) (Figure 3). After informed consent, participants completed the demographics and SCI exercise self-efficacy scale (ESES) questionnaire via REDCap (REDCap Consortium) [33]. A study package was mailed to participants that contained a Google Pixel 3 smartphone, a TicWatch Pro smartwatch, a Samsung Galaxy tablet, a SensorTag wheel sensor, two sets of TheraBands, a wheelchair pouch, a tablet stand, a universal charger, and written instructions. Upon receiving the study package, the participant had the first meeting with the researchers. During this first virtual meeting, a researcher provided instructions on how to use the devices, with the participant following along using the study devices. The researcher also addressed any questions raised. Then, the participant was asked to independently complete a series of tasks to ensure their proficiency in using the devices. In case of any unsuccessful attempts, additional explanations and instructions were provided.

XSL•FO
RenderX

Figure 3. Study procedure. PT: physical therapist.

Baseline Phase

The 7-day baseline phase began after the first meeting concluded. To maintain the integrity of participants' typical PA, most functions of the WheelFit app, including the home screen PA display and workout library, were deactivated. Participants were instructed to maintain the connection between all devices so that the app could record the PA silently. The participants were also asked to complete a daily log to record their bedtime and waketime and indicate whether each day was a typical day, defined as a day with routine activities without any unexpected events that affected their PA level (eg, illness). The daily log was sent to the participants' email every day throughout the study.

At the end of the baseline phase, participants were scheduled for a second meeting to introduce the WheelFit app. During this meeting, a researcher activated all functions of the WheelFit app and provided corresponding instructions. Participants were then asked to perform a series of tasks independently to demonstrate their understanding of the app. If participants were unable to complete a task, additional guidance was provided.

Intervention Phase

The day after the second meeting, participants had the third meeting with our licensed PT and personal trainer, both of whom had experience working with people with physical disabilities. Including both professionals ensured the safety of our study and provided flexibility in scheduling follow-up sessions. In the third meeting, our PT assessed the participant's knowledge of PA and gathered self-reported information, including wheelchair details, assistive technology use, medical and injury history, living situation, and transfer techniques. A functional assessment was conducted, covering the range of motion, muscle strength, and sensation. Due to the remote nature of the meeting, the PT visually assessed the range of motion via Zoom, guiding participants through various postures. Muscle strength and sensation information was collected based on participants' self-report. Traditional aerobic capacity assessments, which require emergency assistance personnel in laboratory settings, were not feasible in our remote format [34]. After the functional assessment, our personal trainer provided an educational session on PA, sedentary behavior, and the specific, measurable, achievable, relevant, and time-bound goal setting. The PT and personal trainer also assisted the participants in making an action plan for engaging in workouts according to the participant's functional assessments and personal goals. The PT and personal trainer directed the participants to perform all movements in each prescribed workout while observing their performance via Zoom. They provided feedback to correct improperly performed movements and suggested alternatives for movements that did not align with the participant's functional ability. If no alternative was available, the participant was instructed to skip the movement. All alternative or skipped recommendations were recorded in the WheelFit app. The completion of the third meeting marked the beginning of the 3-week intervention phase.

Participants followed their action plans using the WheelFit app for 1 week. Then, they had the fourth meeting held with the PT or personal trainer to address any questions and adjust the action plan as needed. Participants were instructed to adhere to their updated action plans for the remainder of the intervention phase. At the end of the intervention phase, participants had the fifth meeting with a researcher, where they completed the system usability scale (SUS) for WheelFit, the postintervention ESES, and a participant perception of use survey.

Outcome Measures

PA Measures

Since the goal of the WheelFit app is to promote PA and reduce sedentary behavior in MWUs with SCI, we consider "moderate to vigorous exercise time" and "sedentary breaks" as the primary outcomes for PA. The rest of the PA variables were not selected as they were not appropriate for goal setting and were only for participants' references. All calculated PA measures were stored on the study smartphone and retrieved after the participants mailed back the devices.

Exercise Self-Efficacy

Participants' exercise self-efficacy was assessed using the SCI ESES, a 10-item, 4-point Likert scale assessing an individual's confidence toward PA [33]. This scale has been validated in individuals with SCI [33]. The possible scores range from 10

XSL•FO
RenderX

to 40, with a higher score indicating higher confidence toward PA. The ESES was assessed before and after the study using REDCap questionnaires.

Intervention Feasibility

The feasibility of the WheelFit intervention was evaluated in three areas: (1) session attendance, (2) device and app usage, and (3) action plan implementation. The session attendance was assessed as attendance of all study meetings except for the exit meeting, which is not considered part of the WheelFit intervention. If a participant missed a meeting but attended a rescheduled session, it was counted as valid attendance. Conversely, if a participant missed a meeting and was unwilling to attend any rescheduled sessions, it was marked as not attended. The device and app usage were assessed as the time participants maintained a connection between the smartwatch and the smartphone. The implementation of the action plan was assessed based on the completion rate of the prescribed workouts in each participant's action plan.

WheelFit App Usability

The usability of the WheelFit app was assessed through the SUS. The SUS is a 10-item, 5-point Likert scale that assesses users' perceived usability of the app. The possible scores range from 20 to 100. An SUS score larger than 80.3 indicates excellent app usability, while a score between 68 and 80.3 indicates that the app has acceptable usability but there is a need for improvement. A score below 68 indicates that the app has poor usability and needs to be revised [35-37]. The SUS has been validated and widely used to assess the usability of mHealth apps [35,38-41].

The participant feedback was evaluated through a participant perception of use survey. The survey included three questions: (1) a 4-point Likert scale question regarding the efficacy of WheelFit in facilitating an active lifestyle (ie, very helpful/somewhat helpful/not very helpful/not at all helpful), (2) a 4-point Likert scale regarding participants' perception of any health or functional improvements (ie, to a great extent/somewhat/very little/not at all), and (3) a question regarding participants' willingness to recommend WheelFit to other MWUs (ie, yes/no/cannot decide).

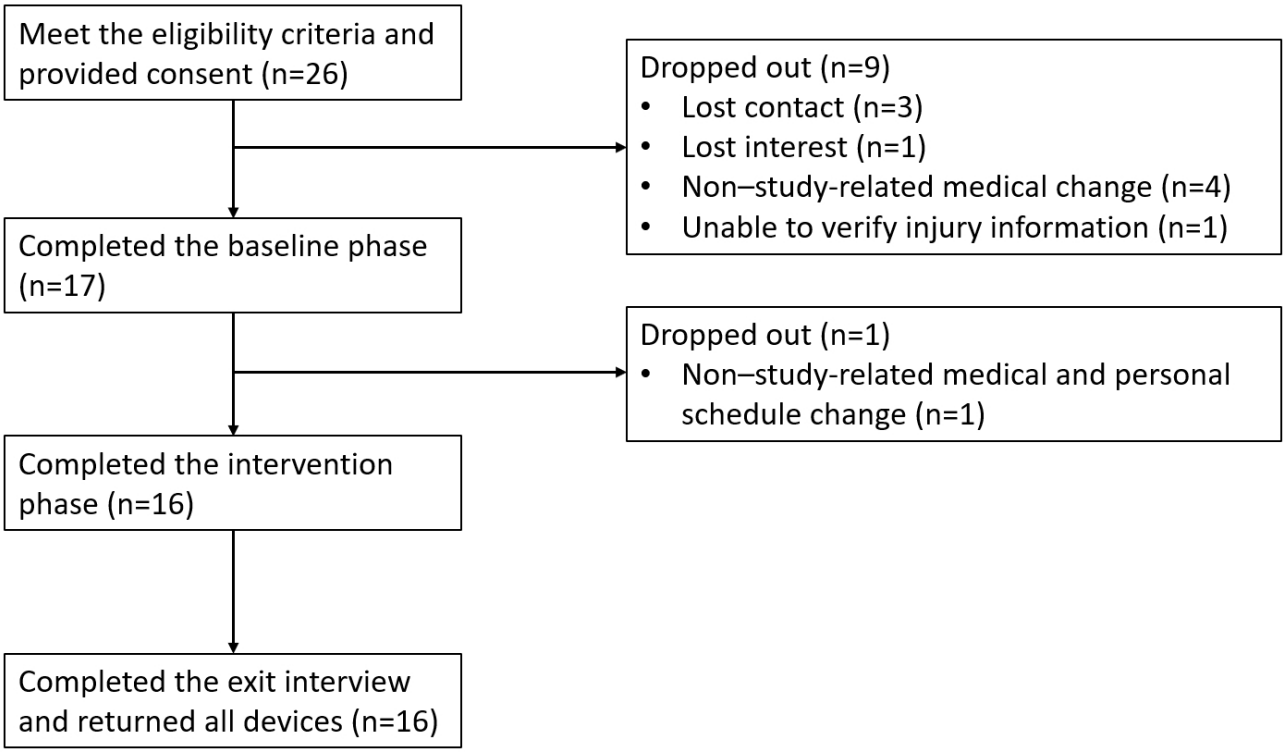
Data Preparation and Analysis

After retrieving PA data from the study phone, valid day data were extracted. A day is considered valid if it meets the following three criteria: (1) the daily data file must contain at least 30% of nonnull or nonzero smartwatch accelerometer data (approximately 8 hours, which is the minimum estimated smartwatch battery life after 1 full charge), (2) no abnormal data were observed (eg, zero wheelchair pushing distance), and (3) the participant confirmed in the daily log that the day was a typical day, with no events altering their daily routine. All other data were retrieved from REDCap.

The demographic data were analyzed at the group level. All valid day PA data were aggregated and averaged to the daily level for the baseline and intervention phase, respectively. Each participant's preintervention and postintervention PA data were presented in a table for a more detailed interpretation. The overall differences between PA variables (ie, moderate to vigorous exercise time, sedentary break, and travel distance) among all participants during the 2 phases and the ESES scores before and after the intervention were compared using a 2-tailed paired sample *t* test or its nonparametric equivalent if assumptions were not met. To further analyze individual PA change, we defined a ±10% change as the threshold for a "considerable" level of change for the "moderate to vigorous exercise time" based on prior studies [20]. Brief descriptions of participants' PA background, personal goals, and motivations were presented to aid in contextualizing the change in PA with the use of the app during post hoc analysis. The action plan workout prescription and execution were also presented. For feasibility and usability evaluation, the session attendance and device connection rate were reported. Descriptive analysis was used to summarize the SUS scores of WheelFit and participants' responses to the participant perception of use survey. Participants' digital literacy was assessed through observations of their interactions with the study devices and the WheelFit app, as well as relative information shared during all study meetings. This evaluation of their digital literacy level was used to enhance the comprehension of app usability during post hoc analysis. All statistical analyses were conducted using SPSS (version 28; IBM Corp), Microsoft Excel (Microsoft Corp), and Python (version 3.0; Python Software Foundation).

Ethical Considerations

This study was approved by the institutional review board at the University of Pittsburgh (STUDY19040049). Informed consent was obtained from all participants, who were also reminded of their right to withdraw from the study at any time. Identifiable data, such as meeting recordings, were securely stored on a university-approved drive with access restricted to the core research team. All data were deidentified prior to analysis to ensure participant confidentiality. Participants received a total compensation of US $225 for full participation in the study.



Results

The study commenced in November 2020 and ended in October 2022. A total of 26 participants enrolled in the study, with 16 participants completing the full study protocol. Of the 10 withdrawn participants, 9 dropped out before the study began (meeting 1) and 1 dropped out during the intervention phase. All dropouts are non–study-related. Figure 4 shows the participant diagram.

The demographics of the 16 participants who completed the study are provided in Table 1.

Table 2 shows the average daily PA levels of the 16 participants during the baseline and intervention phases, along with the corresponding percentage change. The Wilcoxon signed rank tests indicated that there is a significant increase in moderate to vigorous exercise time during the intervention phase (median= 28.4) compared with the baseline phase (median=26.9, Z=1.97;

XSL•FO
RenderX

P=.049; *r*=0.49), but no significant change in the sedentary break was found (*Z*=0.52; *P*=.605; *r*=0.13). Two-tailed paired sample *t* tests revealed that participants' ESES scores were significantly higher after the intervention (mean 35.9, SD 3.2) than before the study began (mean 33.9, SD 4.5; t_{15}=1.84; *P*=.043; *d*=4.35). A total of 9 participants (ie, participant numbers 2, 3, 4, 5, 8, 15, 16, 17, and 19) had a considerable increase in exercise time, 2 participants (ie, participant numbers 7 and 10) had a considerable decrease, while the remaining 5 participants (ie, participant numbers 11, 14, 21, 25, and 26) had no considerable change.

Table . Changes in physical activity outcomes.

ID	Moderate to vigorous exercise time (minutes)		Sedentary break (counts)		Travel distance (miles)		Exercise Self-Efficacy Scale (score)

Most participants were prescribed 2-3 workouts per week based on their functional assessments and personal goals. Strength training workouts were prescribed to 14 participants, aerobic workouts to 9 participants, and flexibility workouts to 9 participants. Among the 16 participants, 4 participants consistently adhered to or exceeded their workout action plan for all 3 intervention weeks. Three participants followed their action plan for 2 weeks but missed some workouts during 1 week. Four participants adhered to their prescriptions for 1 week, while the remaining participants practiced the workout occasionally but did not consistently follow the action plan throughout the intervention phase.

In terms of feasibility, all 16 participants had 100% attendance at all study meetings. On average, they maintained the connection between the smartwatch and the WheelFit app for about 59% of the time (14.2 hours) every day. This wear time satisfies the daily valid wear threshold of 10 hours per day, which has been commonly adopted in wearable device–based PA studies [42].

An average SUS score of 81.8 (SD 19.2) was found. Four participants (ie, nos. 2, 4, 10, and 16) reported an SUS score under the "poor" usability threshold of 68. In terms of the participant perception of use survey, all participants reported that the intervention was helpful in facilitating an active lifestyle, with 11 participants rating it as "very helpful," 4 rating it as "somewhat helpful," and 1 rating it as "helpful." For the subjective perception of health and function improvement, a total of 8 participants reported a "to a great extent," 6 participants reported "somewhat," and 2 participants reported "not at all." All participants expressed that they would recommend WheelFit to others.

Discussion

Principal Findings

In this study, we developed the WheelFit mHealth app to promote PA in MWUs with SCI. Following the FBM, we integrated wearable device-based PA monitoring to increase users' motivation, an adaptive workout library to enhance their abilities, and wearable push notifications and vibration alerts to trigger users to engage in PA and break sedentary behavior. We further evaluated the feasibility and usability of a PA intervention facilitated by WheelFit in MWUs with SCI through a 4-week single-group pre-post study. A total of 16 participants

XSL•FO
RenderX

completed the study protocol with a 100% session attendance rate. Significant improvements in PA outcomes and exercise self-efficacy were observed. The WheelFit app also received a high SUS score of 81.8, with all participants reporting favorable subjective perceptions regarding the intervention. The WheelFit appears to be a feasible and potentially effective mHealth intervention for promoting PA in MWUs with SCI.

Comparison With Prior Work

In terms of the WheelFit intervention's impact on participants' PA, our results showed a statistically significant increase in average MVPA (exercise time) minutes, indicating a positive effect on exercise time among participants.

These findings align with trends observed in other mHealth interventions for MWUs with SCI. Among these interventions, the PHIRE app study is most comparable with ours, as it also used wearable devices. However, it uses a different behavior intervention strategy based on the JITAI framework. Despite the difference in some behavioral components as well as the participants' age (WheelFit: mean 48.0, SD 9.8 years; PHIRE: mean 29.3, SD 28.1 minutes), the baseline MVPA (WheelFit: mean 26.4, SD 16.9 minutes; PHIRE: mean 29.3, SD 28.1 minutes) were similar [20]. Notably, in both studies, 56% (9/16) of participants experienced a considerable (>10%) increase in MVPA minutes [20]. The WOWii study involved participants of similar age (mean 48.0, SD 9.8 years). Its virtual workout intervention, accompanied by support linkage (eg, behavior skill promotion and peer support), focused on promoting structured exercises [16]. Over the 16-week intervention phase, participants successfully increased their aerobic exercise minutes from less than 100 minutes per week to more than 150 minutes per week and their strength training frequency from less than 3 days per week to more than 3.5 days per week. During the 8-week maintenance phase, participants maintained aerobic exercise levels above 150 minutes per week and achieved an average of 3.3 days per week of strength training [16].

After a closer look into participants who had a considerable increase in exercise time, we noticed that participant numbers 2, 16, and 19 had very low baseline PA, and all expressed a desire to use the WheelFit app to form a more physically active lifestyle. Participant numbers 4 and 17 in this group reported prior experience with wheelchair sports and tried to use the WheelFit app to enhance their PA training for the upcoming games. Participant numbers 5 and 8 reported that they were driven by a commitment to maintain good health and enhance body shape. Participant numbers 3 and 15 did not report any significant motivators and simply followed the recommendations of our PT and personal trainer. For the 2 participants who had a considerable decrease in exercise time, participant number 7 reported experiencing severe chronic neurological pain that prevented this participant from engaging in PA and any of the study workouts. Chronic pain has been identified as one of the barriers to daily PA by multiple studies, including the PHIRE study [20,43,44]. Therefore, pain management is an essential factor that should be considered in future mHealth studies. Participant number 10 reported recently starting a daily routine of visiting the local gym and opted not to engage in the prescribed workouts, deeming them too easy. The significant decrease in this participant's PA amount was presumably due to the high baseline PA status and normal fluctuation in the PA routine. Of the remaining 5 participants, 4 of whom experienced a slight increase in exercise time, and 1 experienced a minor decrease.

The participants in this study have varied preparticipation PA levels. Some participants had experience in wheelchair sports, while others were novices to structured training. Additionally, some participants had limited knowledge of PA and led a highly sedentary lifestyle. During the COVID-19 pandemic, MWUs with SCI had reduced access to health care providers and decreased PA amount due to the closure of facilities and concern about infection [45]. Under this circumstance, the WheelFit intervention may benefit people with SCI in 2 ways. For those who were actively seeking engagement in PA, the WheelFit app provided a new approach to increasing PA at home and potentially alleviating the pandemic's negative impact. Participant numbers 4 and 17 were the representative cases. Such benefit may also be generalized to potential users whose PA lifestyle is affected by factors such as cold weather and geographic location [46]. On the other hand, participants who lived a sedentary lifestyle experienced less impact from the pandemic as their baseline PA was already low. The WheelFit mHealth intervention assisted these participants in starting to engage in more PA by providing PA knowledge through consultation and PA monitoring through the app. Such a trend is further supported by participants' feedback, indicating that the WheelFit app facilitated them to adopt a physically healthier lifestyle.

Overall, the statistically significant increases in daily exercise time suggest that the use of WheelFit increased participants' PA levels. In addition, the statistically significant increase in ESES scores indicates that the participants became more confident in engaging in PA. As anticipated, there was no increase in wheelchair travel distance as our PT and personal trainer advised the participants not to use travel distance as an indicator of PA level and did not use this variable to compose their action plan. More specifically, excessive wheelchair pushing may increase the risk of shoulder injury instead of bringing health benefits [47]. Regarding the sedentary breaks, we noticed that many participants had a high number of breaks that were approaching the smartwatch's battery life, indicating a ceiling effect that highlights the limitation of our current definition of sedentary breaks—2 consecutive minutes of nonsedentary PA. Currently, in SCI research, there is no consensus on the definition of sedentary behavior or the ideal bout length [48]. It has been found that breaking up sedentary bouts to under 20 minutes with at least 1 minute of nonsedentary PA could yield health benefits [49]. Validating such effects could be valuable in the SCI population as it informs the development of future mHealth interventions. Strength training was the most commonly prescribed workout, with 14 out of 16 participants selecting it as a goal due to their limited knowledge and access to appropriate resources. Notably, flexibility training was prescribed to 9 out of 16 participants—the same as aerobic training—highlighting a strong interest in addressing joint tightness and muscle pain. Despite its importance, flexibility training is often overlooked in SCI exercise guidelines, which

XSL•FO
RenderX

primarily emphasize aerobic and strength training [7,44]. Given its role in managing muscle stiffness and pain and preventing injury, future PA studies and mHealth interventions should integrate flexibility training as a key component for this population [50].

In terms of usability, the high SUS score of 81.8 suggests that the WheelFit app had excellent usability. This is further supported by the participants' overall positive feedback regarding the app. However, the large SD of 19.2 indicates that there is a large variance in participants' perceived usability. Upon reviewing the meeting recordings and tech support records, it was found that participant numbers 2, 4, and 10 exhibited low digital literacy, a factor that has been found to negatively affect the usability of mHealth apps [51]. All 3 individuals experienced challenges in using the study smartphone and needed more assistance than others. Participant number 16, despite having good digital literacy, expressed frustration with the requirement to launch the WheelFit companion app on the smartwatch to maintain the connection. The participant also found it difficult to understand and remember the meanings of the PA variables displayed on the home page. In future studies, the assessment of digital and health literacy could be integrated into the mHealth intervention to investigate their effect on the intervention and provide personalized assistance in the MWU with the SCI population.

Given the promising outcomes, PTs can integrate WheelFit into rehabilitation by introducing adaptive workouts during sessions and empowering clients to use the app to perform and track their at-home exercises. Personal trainers working with MWUs with SCI can also leverage WheelFit to guide clients in establishing and maintaining a structured exercise routine. Additionally, WheelFit serves as a valuable self-guided tool, enabling users to independently engage in PA and adopt a more active lifestyle.

Limitations

This study was conducted during the COVID-19 pandemic. Similar to other studies during this time period, factors such as the city lockdown and the limitation of health care resources caused the high non–study-related dropout rate of our study [52]. Given its pilot nature, this study used a single-group pre-post design. Without a control group, the study is unable to draw a definitive conclusion regarding the efficacy of the WheelFit intervention on PA. The intervention comprises multiple components, such as the wearable device, WheelFit app, and personal trainer, making it challenging to discern the essential and necessary elements. The 4-week duration is relatively short compared with other mHealth intervention studies, which can range from 6 to 48 weeks. For the ESES score improvement, as the minimal clinically important difference was not established for ESES, the clinical meaningfulness of such improvement remained unknown. It is worth noting that our participants exhibited a relatively high baseline ESES score (mean 33.9, SD 4.5 points), similar to the score for "exercisers" (mean 33.7, SD 5.3 points) reported in the original ESES manuscript [33]. This is probably due to our convenience sampling approach. As a result, the efficacy of the WheelFit mHealth intervention on MWUs with SCI who live a very sedentary lifestyle remained unknown. To ensure compatibility, we provided participants with a dedicated Android study smartphone, potentially affecting their interaction with the WheelFit app compared with using the app on their personal devices. With the WheelFit companion app running continuously, the smartwatch lasts only about 10 - 11 hours before needing to be charged in the middle of the day. This limitation increased participants' burden and was the main reason for daily PA data loss. Currently, the WheelFit app connects only with 1 wheel sensor, which lacks a quick attach and detach feature, potentially limiting its ability to track wheelchair movements for individuals using multiple wheelchairs, such as a sports or backup wheelchair. Future studies should contemplate a large-scale, multistage randomized design to delve deeper into the efficacy of the WheelFit intervention and the individual contributions of its components. Exploring the use of validated tools to assess participants' digital and health literacy could offer a more nuanced understanding of its impact on app usage. Addressing pain management is also critical when developing PA interventions. Additionally, investigating strategies to enhance participants' adherence to their action plans is also valuable.

Conclusions

In this study, we developed WheelFit, a fitness app accompanied by wearable devices tailored for MWUs with SCI. The app offers population-specific PA monitoring with custom algorithms for MWUs with SCI, allowing these individuals to track their daily PA progress toward self-designated personal goals and review their PA history. It also provides an adaptive workout library, facilitating easy access to exercise options. We designed a pilot 4-week intervention using the WheelFit app, led by a PT and a personal trainer. The WheelFit app and intervention have shown promising feasibility and usability, suggesting the potential to promote PA in this population. Improvements in the app and device usability are essential for future development iterations.

Abstract

Background: Physical exercise and stretching programs are the best initial options to treat idiopathic toe walking (ITW). These programs are designed to improve the flexibility and strength of lower limb muscles, enhancing the ankle's range of motion and allowing for a normal gait pattern. In the pediatric population, one of the major limitations reported by therapists is low adherence to rehabilitation treatments or a lack of follow-up. In this context, children using mobile health (mHealth) tools could play an active and central role in their treatment of ITW, while mobile apps could also allow for daily monitoring by health care professionals.

Objective: This study aims to design and develop a mHealth platform for individuals with ITW. In addition, a feasibility and acceptance test of a home-based exercise program was conducted using a comprehensive mobile app intended to improve walking in children with ITW.

Methods: This study describes the context, content preparation, and mHealth platform design, as well as subsequent evaluation using a self-administered satisfaction questionnaire. Initially, the main features of the Active-Feet platform were discussed, focusing on its primary goal of helping children with ITW adhere to the rehabilitation program. However, this study did not evaluate the platform's effectiveness in improving adherence or ankle range of motion. A set of 3D avatars consisting of animated characters was designed. Posterior muscle chain stretching exercises were selected following the main guidelines. The Active-Feet development process was carried out in 5 stages: requirements specification, platform design, platform implementation, platform deployment, and alpha testing of the app.

Results: The final version of the Active-Feet app was evaluated from both the parents' and children's perspectives. Twenty patients and 1 parent per child assessed the app over 2 weeks and answered specially designed questionnaires. Parents rated the app's impact on their child's motivation and its overall effectiveness highly, with median scores of 4 (IQR 4-4). Notably, the item related to reconciling family life with rehabilitation treatment received a median score of 5 (IQR 4-5). Children's responses also indicated positive ratings for motivation and user-friendliness, with a median score of 4 (very good; IQR 3.25-4). Questions about the app's impact, helpfulness in learning, and exercise mirroring received a median score of 3 (good; IQR 3-4).

Conclusion: This study describes the development process and testing of Active-Feet, an mHealth-based platform designed to offer treatment for children with ITW. After the long process, an attractive and easy-to-use platform for ITW was developed for the first time.

Introduction

The normal gait pattern is acquired during growth. Toe-walking is generally regarded as the absence or limitation of heel strike during the initial contact phase of the gait cycle [1-3]. This condition is considered a common and normal deviation until the age of 3 years; however, to keep this gait pattern beyond that age could be pathological, and a specialist evaluation should be considered [4-7].

Toe-walking is a feature present in several neuromuscular conditions, such as cerebral palsy and muscular dystrophy, as well as behavioral disorders such as autism spectrum disorder [5]. However, it can be the result of a simple contraction or shortening of the lower limb muscles, specifically the hamstrings and triceps surae. Idiopathic toe walking (ITW) is a condition of unknown etiology. Currently, ITW is a diagnosis that can only be reached once other causes for a similar pattern of gait have been excluded, mainly cerebral palsy [8,9], muscular dystrophy [10], neuropathy [11], or foot malformation [12]. ITW represents a common referral to different specialists, and the prevalence was reported to be between 5% and 12% in the pediatric population, without gender differences [7].

A comprehensive assessment of children with ITW involves a detailed physical examination and observational gait analysis. This includes evaluating the range of motion (ROM) of lower limb joints, muscle strength, and performing muscle shortening tests, along with assessing the rotational profile of the lower limbs. This approach is essential to support a clinical diagnosis and to decide the proper and most effective individualized treatment for children with ITW. Electromyography, instrumented gait analysis [4,13], or the validated "Toe Walking Tool" can be used to support the presence of ITW [14,15].

The treatment options for ITW are based on age and the presence of limited ankle ROM due to muscle shortening. Nonsurgical treatments, stretching exercises, and orthotics are the main treatment options for children who have persistent toe walking with normal ankle ROM. However, if decreased ankle dorsiflexion flexibility exists, the treatment options are intended to improve the ankle ROM using serial casting, botulinum toxin, or surgery followed by orthosis to maintain the improvement and support gait training [16,17]. The 2019 Cochrane systematic review evaluated the effects of various interventions for ITW, including both conservative and surgical treatments. While the review aimed to assess improvements in ROM, it concluded that there were no significant differences in ROM between treatment groups due to the very low certainty of the evidence [18]. Physical exercise and stretching programs are designed to improve the flexibility and strength of lower limb muscles, improving the ankle ROM and reaching a normal gait pattern. Stretching exercises could contribute to maintaining the ROM obtained after surgical treatment [16]. Exercise and stretching programs can therefore be an effective and noninvasive option for the treatment of ITW.

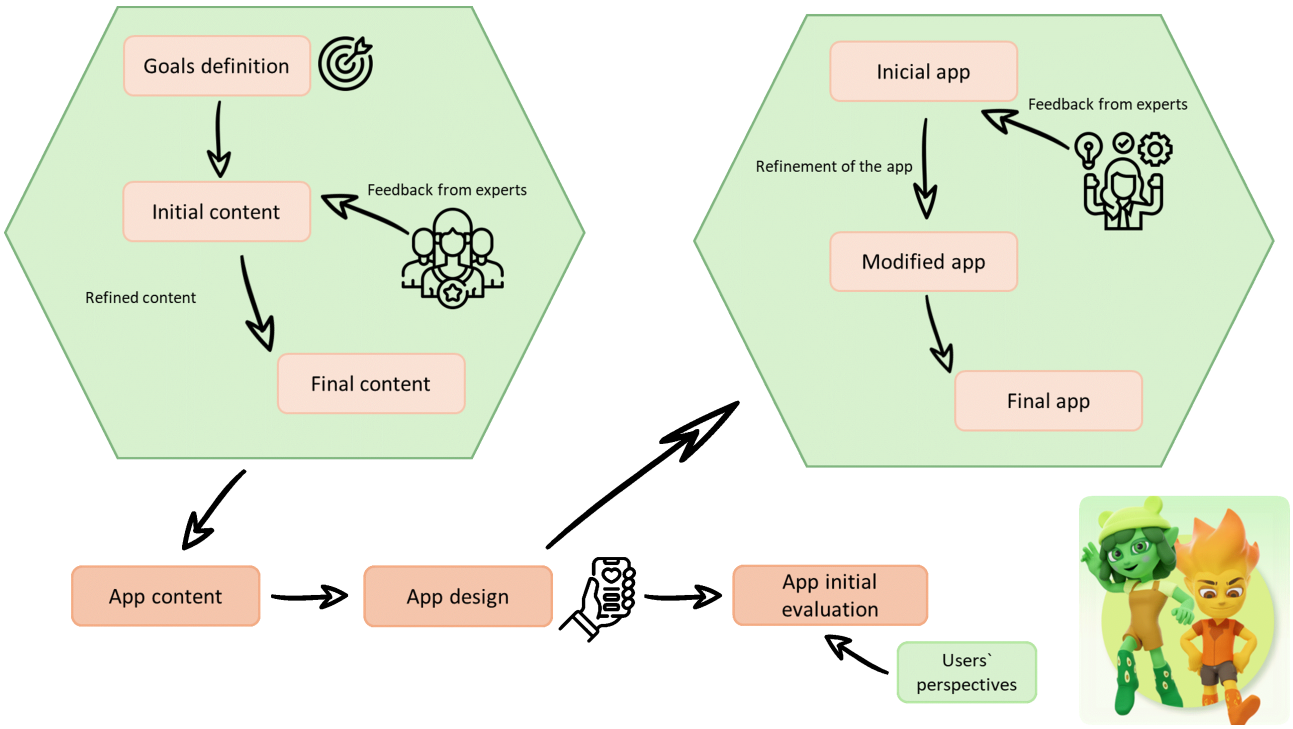
In recent years, there has been a great expansion of health interventions mediated through new technologies. This has been called eHealth, and it includes the use of electronic technologies and digital communication to improve health care delivery. Mobile health (mHealth) interventions have emerged to facilitate and simplify access to medical care. They allow the collection of patient care–relevant data in real time and the use of this information to monitor, diagnose, and treat patients [19]. There are different mHealth interventions that contribute to the management of certain pathologies in pediatric rehabilitation programs, such as tools developed for parents and caregivers for children with cerebral palsy [17,20,21]. These apps should be developed under the participation, advice, and supervision of health care professionals to ensure the proper functioning for the benefit of both patients and health care systems [21].

In the pediatric population, loss to follow-up is common in children with ITW [22]. One of the primary challenges reported by therapists is low adherence to home exercise programs after the conclusion of physiotherapy sessions. This observation is supported by clinical practice experiences and discussions among specialists, underscoring the necessity for innovative tools such as the Active-Feet app to enhance adherence and support long-term therapeutic outcomes. There is a growing body of evidence supporting examples where physiotherapy has benefited from digital health technologies, primarily existing in the management of musculoskeletal [23] or neurological issues [24,25]. Specific exercise tools, virtual reality, and gaming have positively influenced rehabilitation [26]. Telerehabilitation focused on children with ITW is supported by the concept that this population has grown up in a technological environment and that mobile devices are a common way for them to interact with others.

A mHealth platform specially designed to meet the needs of children with ITW would be an innovative approach to improve both adherence and effectiveness of rehabilitation programs. Furthermore, children using mHealth tools could play an active and central role in treatment and, at the same time, the mobile app would allow daily monitoring of treatment by the health care professional.

This study aims to develop and evaluate an mHealth-based platform for children with ITW. In addition, it tested the feasibility and acceptance of a home-based exercise program using a comprehensive mHealth tool to improve walking in patients with ITW. This study describes the context study, content preparation, and mobile app design, with subsequent evaluation using a self-administered satisfaction questionnaire from the perspective of parents and children.

Methods



Study Design Overview

The reference population for the content development was children aged between 7 to 12 years with a diagnosis of idiopathic toe walking who attended a pediatric rehabilitation outpatient clinic. This study was conducted in three phases: (1) assessment of children with ITW needs for a home-based rehabilitation program (content preparation phase), (2) designing an attractive mobile app for children (app design phase), and (3) evaluating the app from the user's perspective (app evaluation phase).

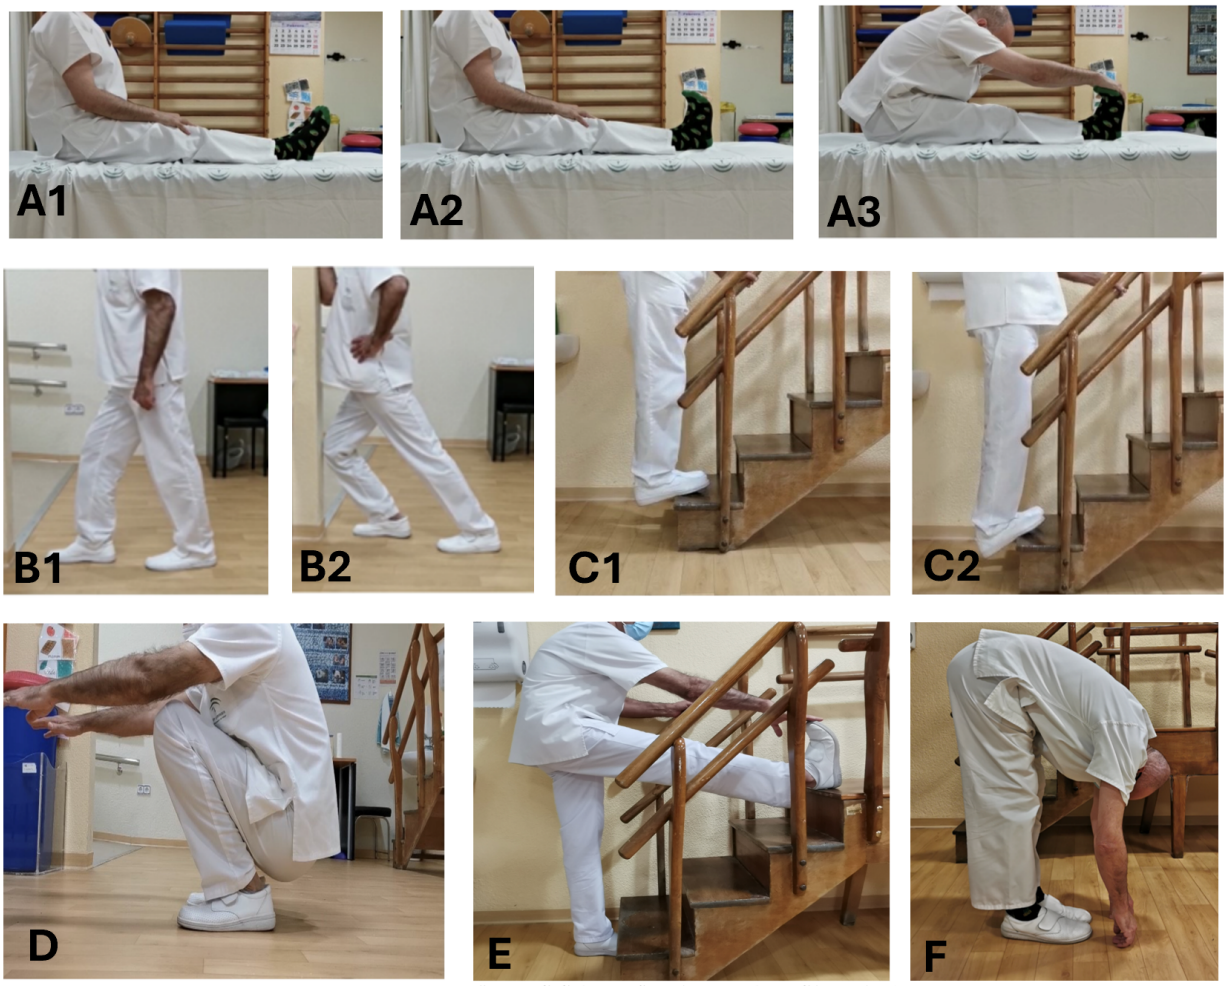
XSL•FO
RenderX

The development process, from conceptualization to pilot testing of the Active-Feet app, is outlined in Figure 1.

Figure 1. A schematic view of the main steps followed in the development of the Active-Feet app.

Content Preparation Phase

The original idea of developing a specific app for home-based exercise treatment in children with ITW arose from the monthly multidisciplinary meetings that take place in the pediatric outpatient rehabilitation clinic. A physiatrist, physiotherapist, and occupational therapist were involved in the initial content preparation. There were several reasons to consider a mHealth approach for rehabilitation in ITW, some of which are as follows: (1) an increasing number of referrals of children with ITW for physiotherapy treatment, (2) low post-treatment compliance with home-based exercise programs, despite written instructions on their execution. This observation is supported by clinical practice experiences and discussions among specialists, highlighting the need for tools such as an app to improve adherence, (3) the number of trips to the hospital for children and caregivers becomes disruptive for daily routines, so continuing physiotherapy sessions at the hospital was not an option for many families, and (4) performing repetitive exercises at home is not attractive for many children and could become a problem in the relationship between parents and children.



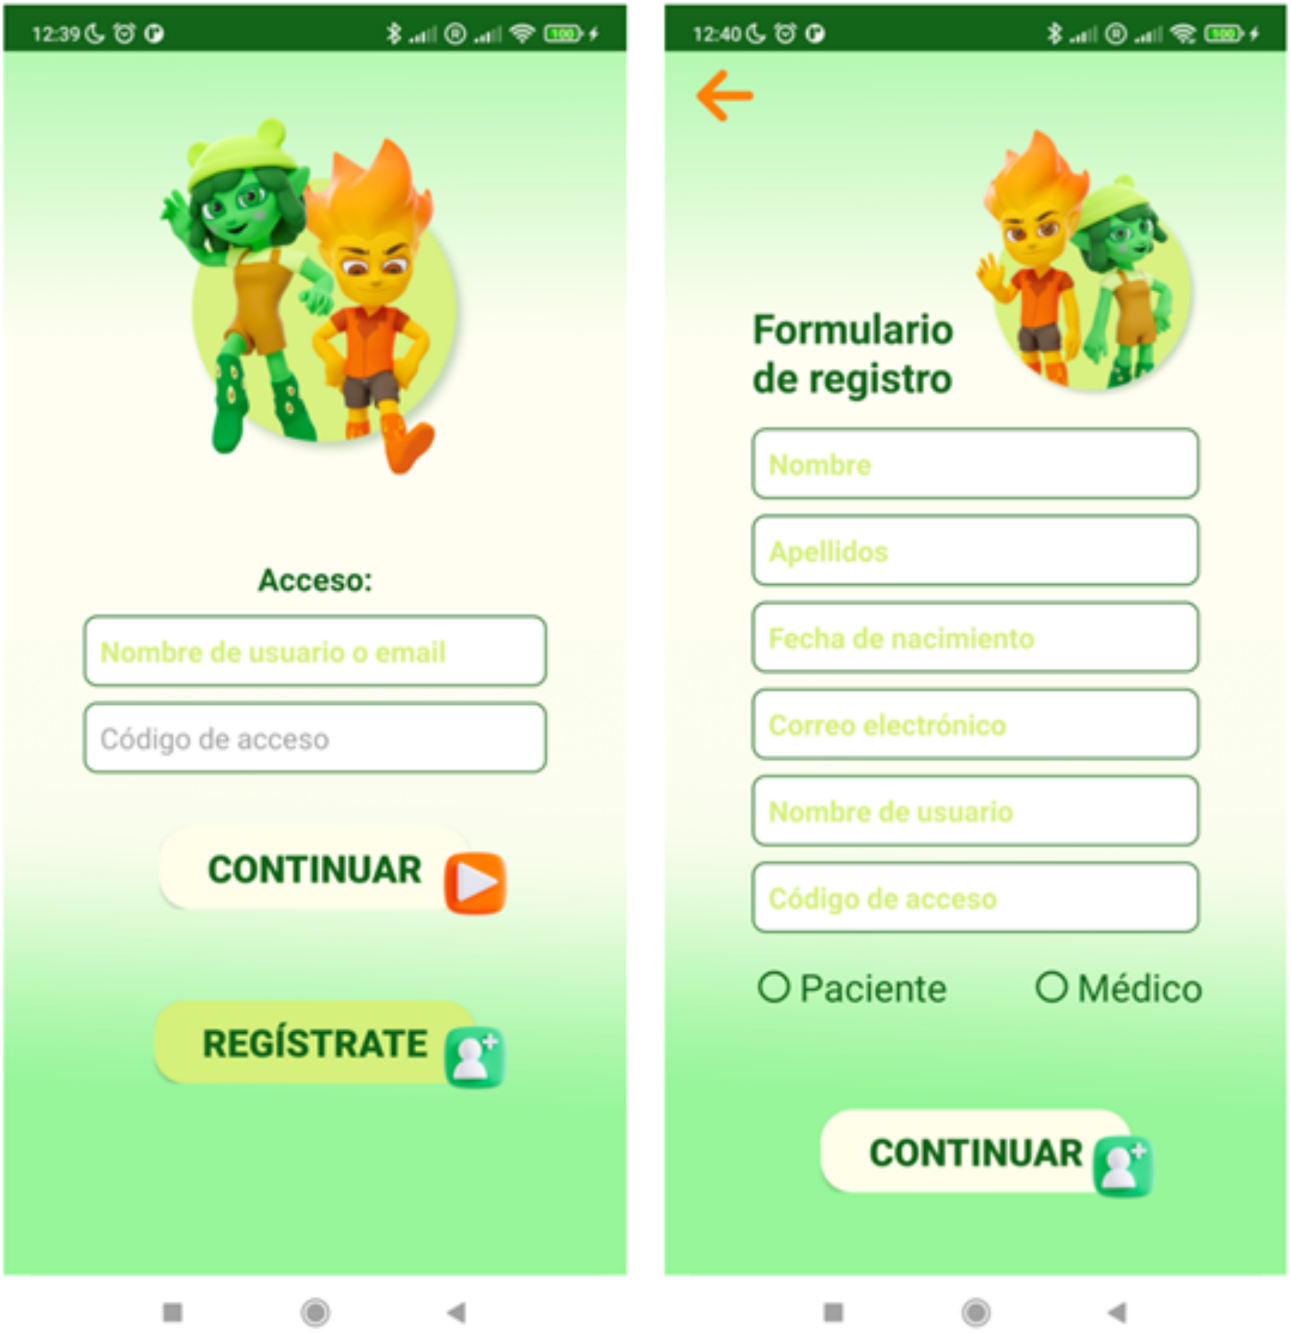
An exploratory search was carried out by researchers in PubMed, the Apple App Store, and Google Play Store, and no mobile app related to the treatment of children with ITW was found.

Initially, the main features of the Active-Feet platform were discussed, focusing on its primary goal of helping children with ITW adhere to the rehabilitation program. The app should allow health care professionals to view and to track children's compliance and execution of the exercises. At the same time, the patients could visualize themselves performing the exercises using the device's own camera. It was also considered important to develop a suitable and visually attractive app design for the pediatric population. The app should be intuitive, easy to use, and simple to access to avoid disuse. In addition, the app should be a communication channel between the physician or therapist and the patient.

In successive meetings of the multidisciplinary team, a consensus was reached regarding the type of exercises recommended for ITW. After reviewing different guidelines and considering that muscle shortening is a frequent finding, posterior muscle chain stretching exercises were chosen. The selected exercises are presented in Figure 2 and include posterior muscle chain stretches while sitting (A1-A3) and standing (F), triceps surae stretches standing (B1-B2) and using stairs (C1-C2), stretching the soleus (D), and one-leg hamstring stretch. Finally, the initial content was evaluated by senior specialists (1 physiatrist, 1 physiotherapist, and 1 occupational therapist) to get expert opinions. The initial content was finalized after applying the experts' recommendations.

XSL•FO
RenderX

Figure 2. Main exercises: (A1-A3) posterior muscle chain sitting stretch, (B1-B2) triceps surae stretch, (C1-C2) stair (ladder) stretch, (D) soleus stretch, (E) one-leg hamstring stretch, and (F) posterior muscle chain standing stretch.



The first meeting with the computer scientists involved in the creation of the app was established. It was decided that the app should include three user profiles: administrator, patient, and health care professional. The health care professional profile (physician or therapist) should include functionality to design a customized exercise protocol for each patient. The health care professional could increase or decrease the number or intensity of sessions, eliminating or changing some of the proposed exercises and reviewing the sessions already carried out. In the same way, communications between children and therapists could be performed using the chat included in the app. The administrator role is fulfilled by both the physician, who registers the child in the app, and the therapist, who selects and adjusts the exercises weekly based on the patient's progress, including the number of sessions completed and the time dedicated to the rehabilitation program. This collaborative approach ensures both medical oversight and personalized therapeutic guidance.

Once the first design was reviewed, the researchers concluded that the appearance of the app was unattractive for children, so it was suggested to design 3D animated avatars to demonstrate the exercises as tutors. It was agreed that the avatars should meet certain requirements. The proposed characters should be visually attractive; they should bring the attention to the feet, the most important part of the body in this case. Therefore, the feet should be well-defined and subtly larger to highlight their relevance, barefoot to better visualize their movement, but they should wear striking socks to add extra visual appeal to the design.

From this entire process, TOBI and TOE characters emerged, 3D avatars enabling the guiding of the patient with ITW in performing the exercises were designed (Figure 3). At this point, the physiotherapists specialized in carrying out the chosen stretching exercises recorded themselves, and the recordings were used as templates for the avatars' motion. The exercises performed by the 3D avatars were designed to be simple and at the same time easy to mirror by children.

XSL•FO
RenderX

Figure 3. Screenshots from the Active-Feet app showing the characters: TOBI and TOE. View to log in (left) and to request registration by a new user (right).

Platform Development Phase

The platform development process was carried out over five stages, executed sequentially: (1) requirements specification, (2) platform design, (3) platform implementation, (4) platform deployment and alpha testing of the mobile app, and (5) validation and performance testing of the mobile app (beta phase).

Stage 1: Requirements Specification

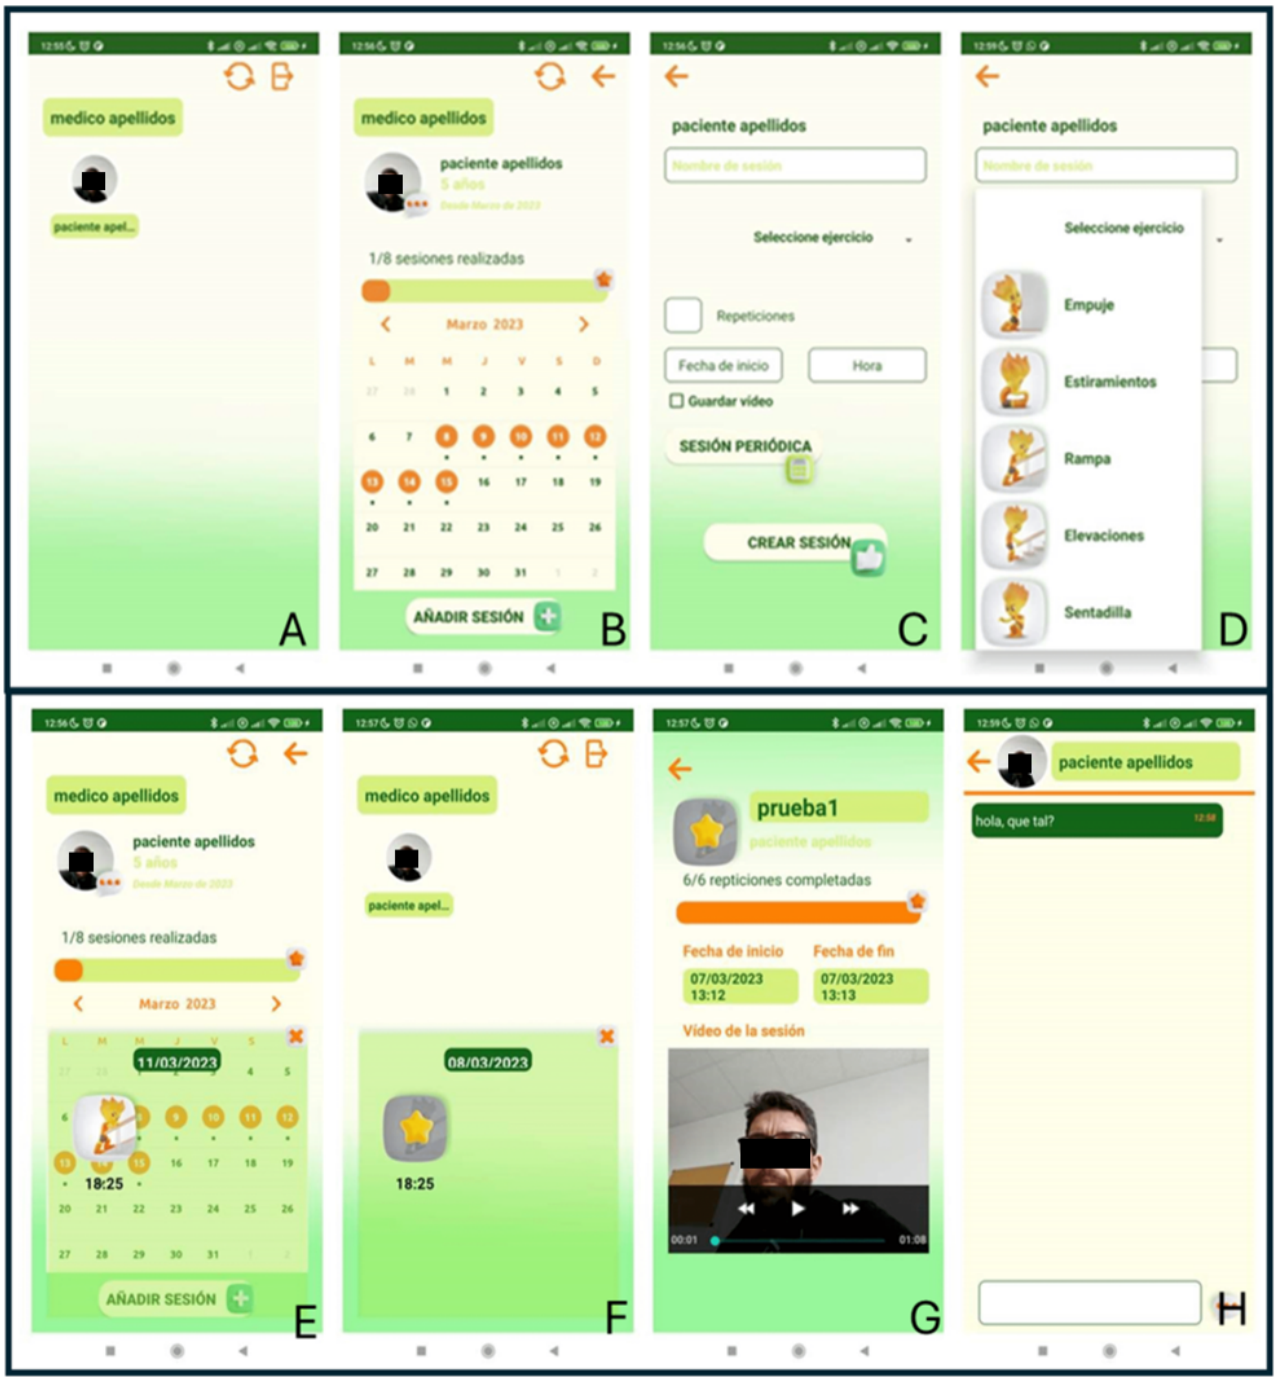
Tasks were conducted to gather both functional and nonfunctional requirements, aiming to specify the system's characteristics in terms of functionality (functional requirements): types of users, types of rehabilitation sessions, how interactions between patients and doctors would occur, and other details. In addition, nonfunctional requirements were addressed, primarily tackling three issues: (1) deployment architecture, (2) the need to enhance usability and ensure the accessibility of the app due to the needs of the end users (young patients), and (3) data protection.

Stage 2: Platform Design

In accordance with the requirements (functional and nonfunctional), a design phase was carried out. As a result of this phase, a list of use cases enumerating all the functionalities that should be present in the platform was obtained.

Furthermore, as a result of designing according to the nonfunctional requirements, it was agreed to use a client-server architecture with a single multiuser mobile app (for patients and doctors) that would display different views depending on

XSL•FO
RenderX



the role, as well as another view for the system administrator, which has typical administrative functions. (Figures 4 and 5 and Multimedia Appendix 1). The server is planned to serve as a provider of web services to implement part of the functionalities and as a database for information management and storage.

Figure 4. Sample of screenshots from the Active-Feet app patient profile.

To ensure usability, the services of a company specializing in mobile app interface design were used. This company provided wireframes for the mobile app designed with a user-centered approach, aiming for maximum usability and accessibility.

The Active-Feet platform comprises two deployment environments: a secure backend hosted on a private server and a mobile app. The backend operates on a virtual machine with robust security and reliability measures. The mobile app was tested on 4 physical devices (2 smartphones and 2 tablets) and 2 virtual devices. Physical devices, such as the Xiaomi Redmi Note 12 and Samsung Galaxy Tab A8, demonstrated superior performance due to their advanced hardware. Conversely, the Samsung Galaxy Tab A7 Lite exhibited the lowest performance, likely due to its limited RAM and internal processes. Virtual devices also performed adequately, showcasing the platform's adaptability across varying specifications. (More detailed information is included in Multimedia Appendix 2). Overall, the platform proved compatible with low-to-mid-range devices, ensuring broad accessibility and delivering a satisfactory user experience, particularly on devices with greater processing power.

Finally, to ensure access to information, protocols were established so that only a patient and their associated doctor could access the patient's data. Similarly, doctors cannot view

XSL•FO
RenderX

other doctors or patients for whom they are not responsible. Only the administrator can view all information. To achieve this, access control mechanisms were implemented. Furthermore, to ensure secure information exchange, all requests between the client (mobile app) and server are made securely using HTTPS and JSON Web Token.

Stage 3: Platform Implementation

The platform consists of blocks: the server-side (backend) and the mobile app (frontend). The server-side (backend) was developed using the Python programming language (Python Software Foundation) and the Flask framework (Pallet Projects) for web service creation. MongoDB (Mongo Inc.) has been used as the database management system. On the other hand, the mobile app (frontend) was implemented following the wireframes provided by the design company and implemented for the Android (Google LLC) operating system, compatible with versions 5.0 and later (since 2014).

Stage 4: Platform Deployment and Mobile App Alpha Testing

The backend (server) was deployed on a private server belonging to the University of Granada network, which was publicly accessible and equipped with security certificates. The mobile app was tested on three different devices: Xiaomi Redmi Note 8, Xiaomi Redmi Note 9, and Xiaomi Redmi Note 10. Validation tests were conducted to assess functionalities, and common errors derived from the implementation were corrected.

Stage 5: Validation and Mobile App Performance Testing (Beta Phase)

This stage is currently under development. The evaluation of the direct impact on clinical outcomes is being conducted as a second phase of the study by the research group. These follow-up investigations aim to evaluate the app's effectiveness in achieving functional improvements in children with ITW. The evaluation of exercise accuracy using the Active-Feet app will be carried out by the therapist through visual monitoring during each session. The therapist would observe the patient's posture to ensure proper alignment and movement, focusing on potential compensations at the pelvis, hips, or knees. In addition, the therapist will check whether the patient dedicates the correct amount of time to each stretch, typically 15 seconds, as specified in the treatment protocol. This process ensures that exercises are performed correctly and safely.

Exercise intensity will be monitored by progressively increasing the number of weekly repetitions for each exercise. Since patients may experience discomfort due to muscle shortening at the start of the intervention, the progression will be carefully adjusted to allow gradual adaptation and avoid excessive strain. Similarly, frequency measurements will include tracking the number of patient connections to the app, the number of days the patient engages in sessions, and the duration of each session. These combined metrics aim to provide a comprehensive understanding of patient adherence, engagement, and rehabilitation progress.

Evaluation of the App From the Users' Perspective (App Evaluation Phase)

The final version of Active-Feet app was assessed considering the perspectives of parents and children on the usefulness and attractiveness of the app, as well as the ability to encourage children to follow the home-based exercise program.

Participants for this feasibility and acceptance pilot study were required to meet the following inclusion criteria: diagnosis of ITW, aged between 7- 12 years, and ability to use an Android smartphone (with appropriate parental supervision and support). Twenty selected participants who were available and willing to cooperate assessed the app for 2 weeks. To facilitate the use of the app, a first guided use of the Active-Feet app was carried out face-to-face in the outpatient clinic by a therapist, with a detailed explanation provided to the children and parents.

Specific questionnaires were designed by the researchers (refer to Multimedia Appendix 3) and administered to both parents and children following the 2-week app testing period. The answers from adults were measured based on a 5-point Likert scale, while the questionnaire for the pediatric population was evaluated using a 4-point visual analog scale. To summarize data distributions, the median and IQR (25th-75th percentile) were calculated for all Likert scale responses. After collecting the questionnaires from parents and children, the data were analyzed using SPSS software (version 24; IBM Corp).

Ethical Considerations

Ethical approval for this study was obtained from the Granada Research Ethics Committee (CEI Granada; approval code: 95133). Written informed consent was obtained from all adult participants and from the parents or legal guardians of the children involved in the app evaluation. Children also provided assent prior to participation. All personal data collected during the study were anonymized to ensure participant privacy and confidentiality in accordance with applicable data protection regulations. No monetary compensation was provided to participants for their involvement in the study.

Results

Demographic and Physical Characteristics of the Participants

A total of 20 children participated in the study. The median age of the children was 10 (IQR 9-11) years, the median weight was 42.8 (IQR 35.6 - 55.7) kg, and the median height was 148 (IQR 138 - 160) cm.

Regarding ROM and flexibility measurements, the median plantar flexion was 70° for both the right and left sides, with IQRs of 60° - 75.5° for the right and 60° - 74° for the left. Median dorsiflexion with the knee extended was 0° on the right side (IQR −3.5° to 0°) and 1° on the left side (IQR −5° to 4°). With the knee flexed, median dorsiflexion was 10° bilaterally, with IQRs of 6° - 12° for the right and 8.5° - 13.5° for the left. The Silfverskiöld test was positive in all participants, confirming restricted dorsiflexion with the knee extended. Further details of the measurements conducted on the participants can be found in Multimedia Appendix 4.

XSL•FO
RenderX

Characteristics of Parental and Children Questionnaires

Three main sections were considered in each questionnaire: (1) questions about the ease of use or user-friendliness, (2) questions about the impact of the app, and (3) attractiveness of the app and user feedback. All these aspects were addressed in both questionnaires using appropriate language for each group—parents and children.

A total of 20 parents, 1 per child in the study, completed the questionnaire. The ease of the registration process, learning to run the app, and access to different sections were the main questions assessed from parents (questions 1, 2, and 3). Regarding the impact of using the app, a question was addressed to the enhancement of their child's motivation with the app (question 4). Finally, acceptance and attractiveness were addressed by asking whether the content was appropriate for their children (question 5) and whether the app was helpful for the reconciliation of family life and the rehabilitation process (question 6).

In the questionnaire addressed to the children (n=20), questions were asked about how much fun they found (question 1) and their motivation to do the exercises daily (question 5). They were also asked whether they liked the avatars, as a measure of acceptance and attractiveness (question 2). Regarding the impact of using the app, questions addressed how the avatars helped them do the exercises (question 3) and whether the exercises shown by the avatars were easy to mirror (question 4).

Questionnaire Results From Parents and Children

The interaction between children and parents with the app technology was well received by all participants. In general, they were pleased with the quality of the graphical user interface, ease of navigation, and the overall impression of how patients interact with the mHealth system.

The parental question regarding the improvement of the child's motivation to perform the exercises (question 4) received one of the highest scores, followed by the section addressing the impact of using the app (question 5). Finally, the aspects related to the app's ease of use (questions 1 and 3) and learnability (question 2) were also rated highly by participants (Multimedia Appendix 5). The median score for the first 5 questions was 4 (IQR 4-4). The item referring to the reconciliation of family life with the rehabilitation treatment of their children (question 6) was highly appreciated by parents, showing a median of 5 (IQR 4-5). The overall mean percentage of parents responding "4" across all parental questions was 72.5%. Only 5% of the parents' responses scored 3 or lower on the Likert scale.

Children's responses to questions on user-friendliness and motivation demonstrated positive outcomes. For question 1, which assessed whether performing the exercises was an enjoyable experience, the median score was 4 (very good) with an IQR of 3.25-4. Similarly, for question 5, which evaluated whether children remembered to perform the exercises daily with TOBI and TOE, the median score was also 4, with an IQR of 4-4. Questions regarding the impact of use, the app's helpfulness in learning (question 3), and the ease of mirroring exercises (question 4) received a median score of 3 (good) with an IQR of 3-4. Regarding the acceptance and attractiveness of the app (question 2), children expressed positive feedback, with a median score of 3 (IQR 3-4). They found the avatars to be delightful and engaging. The overall mean percentage of participants responding with a score of 4 across all children's questions was 52%. No responses of "Bad" or "Very Bad" were recorded.

Discussion

Principal Findings

The aim of this study was to develop and implement an app for telerehabilitation in children with ITW. The findings of this research suggest that the Active-Feet mHealth-based platform is feasible for children. An attractive and easy-to-use app, designed to help patients perform exercises following the instructions of 3D avatars, was developed during the process. At the same time, the Active-Feet app allows for recording completed exercises, enabling the therapist to track the frequency, intensity, and accuracy of performance through their app profile. Corrections or recommendations via chat between the therapist and patient can improve interaction quality and provide guidance to users in the event of errors. Collecting real-time health care data from patients and using this information to monitor, diagnose, and treat them is one of the main advantages of mHealth tools [19].

The approach of ITW shows a lack of consensus regarding optimal conservative management. A wide variation in treatment across providers and institutions exists. However, stretching exercises are advocated as the core management for ITW [16,18]. Mobile apps can incorporate positive behavior change techniques to improve exercise adherence and thus optimize clinical benefits. In children with ITW, loss to follow-up is common [22], and long-term adherence remains challenging. Promoting the reconciliation of daily routines and rehabilitation treatment is important to avoid noncompliance to the treatment. Moreover, telerehabilitation improves patients' access to rehabilitation services and saves patient time traveling to the hospital or rehabilitation center. Evidence suggests that there are many potential applications to be explored to enhance connectivity of the interdisciplinary rehabilitation team in the pediatric population [27]. All these elements were considered in developing the Active-Feet platform.

Although the evaluation of the Active-Feet app did not use the Mobile App Rating Scale (MARS) used in previous studies, the questionnaires administered to assess the app revealed higher user engagement and satisfaction scores compared to similar mHealth apps. For example, pain-related apps evaluated with MARS achieved an average overall score of 3.17 out of 5, with functionality rated the highest and engagement often scoring lower [28]. In contrast, the Active-Feet app demonstrated strong user satisfaction and engagement among parents and children, highlighting its ability to effectively meet the needs of its target population. These findings emphasize the potential of the Active-Feet app to serve as a valuable tool for enhancing adherence and motivation in rehabilitation contexts.

XSL•FO
RenderX

App Usability and Acceptability

This study describes the entire process of developing a specific app to perform the rehabilitation treatment for ITW in a complex population. The Active-Feet app showed to be attractive and easy enough to use for children and parents. Currently, there is no other app that has been developed for this condition, so no comparison can be made. The reference for this research was supported and guided by previous home rehabilitation interventions administered from our group of researchers in developing mHealth systems [29,30]. This paper assembles the preliminary qualitative and quantitative data on usability and acceptability of the Active-Feet app for conducting the home-based exercise program and to explore potential outcomes of the intervention. The direct impact on clinical outcomes such as adherence to rehabilitation protocols or improvements in ROM was not assessed in this study. Future research should focus on overcoming these limitations by using longitudinal studies with objective measures to assess how effective the app is in improving adherence and functional outcomes in children with ITW.

Potential Broader Applications

It is important to consider the impact on special groups of children using digital characters or avatars during rehabilitation treatment and the advantages of these kinds of mHealth systems. It was reported that patients with autism have shown benefits, such as being able to resemble the movements of the avatar [31]; improved the ability to recognize and express basic emotions [32]; and increased the capability for social interactions by practicing verbal and nonverbal behavior in virtual reality environments [33]. Autistic children who exhibit toe walking are generally not classified as ITW, and additional considerations may be needed for their cognitive and behavioral differences. Consequently, while this app is primarily designed for idiopathic toe walkers, it could also serve as a valuable tool for children with toe-walking behaviors associated with conditions such as autism or other motor impairments, provided appropriate adaptations are made. In addition, a recent systematic review of mobile apps for patients with chronic conditions or multimorbidity has called for further research to develop and evaluate apps that are both high quality and have a high capacity to promote positive behavior change in patients [34].

Limitations

This study had additional limitations. Twenty participants collaborated with the researchers to assess the app. Although some studies suggest that this sample size in usability tests can identify over 80% of usability issues [35,36], it may not capture all potential problems. In future research, we should consider a larger sample size and a more extended period of follow-up. The missing information regarding the participants' previous knowledge of the exercises was another limitation of this study. In addition, the assessment of exercise accuracy relied on visual monitoring by the therapist; however, the lack of quantitative metrics such as joint movement tracking may limit the precision and consistency of exercise evaluation. Future research could benefit from incorporating motion tracking technologies to provide more objective and accurate assessments of exercise performance.

The use of a custom-designed satisfaction questionnaire instead of a standardized usability assessment tool, such as the System Usability Scale (SUS), was also a constraint in our research. While our questionnaire was specifically tailored to suit the linguistic and cognitive needs of a pediatric population, it limits the comparability of our findings with those of other studies. Future studies should consider incorporating validated and widely used scales to enhance the generalizability of results.

Strengths and Future Directions

Finally, the findings of this study reveal the structure and process aspects of developing and optimizing a mobile app aimed at the pediatric population. However, the implementation of the Active-Feet app is not recommended until feasibility and effectiveness have been demonstrated in appropriately designed randomized controlled trials. This study also has strengths. First, the acceptance and satisfaction of the intervention have been demonstrated by users and parents. Second, the Active-Feet app was developed for both mobile and tablet devices. Third, to our knowledge, this is the first study showing the entire process of a mHealth platform created to deliver telerehabilitation programs for children with ITW.

Conclusions

Exercise and stretching programs can be an effective, noninvasive option for the treatment of ITW in children, and the use of mobile apps is an alternative for home-based treatment programs. Although the Active-Feet app has been implemented in patients with ITW, its use could potentially be extended to children who exhibit toe walking as a frequent finding, such as those with autism spectrum disorders. This study describes the entire process of developing a mHealth system, and an attractive, easy-to-use mHealth platform for children with ITW was developed for the first time. Future studies should evaluate long-term effectiveness of the app and determine whether it should be recommended for patients, relatives, or health care professionals.

Acknowledgments

The authors thank all patients and their parents for their participation in this research. Abstract

Background: Knee osteoarthritis (OA) is a common chronic condition that impairs mobility and diminishes quality of life. Despite the proven benefits of exercise therapy and patient education in managing OA pain and functional limitations, these strategies are often underused. To motivate and enhance patient engagement, personalized outcome prediction models can be used. However, the accuracy of existing models in predicting changes in knee pain outcomes remains insufficiently examined.

Objective: This study aims to validate existing models and introduce a concise personalized model predicting changes in knee pain from before to after participating in a supervised patient education and exercise therapy program (GLA:D) among patients with knee OA.

Methods: Our prediction models leverage self-reported patient information and functional measures. To refine the number of variables, we evaluated the variable importance and applied clinical reasoning. We trained random forest regression models and compared the rate of true predictions of our models with those using average values. In supplementary analyses, we additionally considered recently added variables to the GLA:D registry.

Results: We evaluated the performance of a full, continuous, and concise model including all 34 variables, all 11 continuous variables, and the 6 most predictive variables, respectively. All three models performed similarly and were comparable to the existing model, with R^2 values of 0.31 - 0.32 and root-mean-squared errors of 18.65 - 18.85—despite our increased sample size. Allowing a deviation of 15 (visual analog scale) points from the true change in pain, our concise model correctly estimated the change in pain in 58% of cases, while using average values that resulted in 51% accuracy. Our supplementary analysis led to similar outcomes.

Conclusions: Our concise personalized prediction model provides more often accurate predictions for changes in knee pain after the GLA:D program than using average pain improvement values. Neither the increase in sample size nor the inclusion of additional variables improved previous models. Based on current knowledge and available data, no better predictions are possible. Guidance is needed on when a model's performance is good enough for clinical practice use.

Introduction

Background

Osteoarthritis (OA) is a chronic disease characterized by persistent joint pain and limited mobility, especially for those who experience from OA of the knee [1]. In the United States alone, the overall economic burden of OA is estimated at almost US $140 billion annually, highlighting the substantial societal and personal costs associated with the condition [2]. Pain is the most important outcome for patients with OA, with moderate to severe pain associated with greater functional limitations, treatment dissatisfaction, and reduced quality of life [3]. In managing OA, patient education and exercise therapy, which are the recommended first-line treatments according to clinical guidelines, play a critical role [4-6]. Treatment programs that combine therapeutic exercise with other treatments such as weight loss [7], manual therapy, and pain education have shown promising results in managing mild to moderate OA symptoms and provide complementary options to improve patient's pain, function, and quality of life [8,9]. Patient education further empowers individuals by enhancing their understanding of the disease and emphasizing the importance of lifestyle adjustments such as a balanced diet and regular exercise [10].

Prior Work

However, the implementation of recommended treatments could be improved [11]. The discrepancy between recommended and provided treatments has been attributed to several factors, including health care providers offering no evidence-based care and patients' lack of motivation and awareness about the long-term benefits of the recommended therapies [12,13]. Furthermore, some patients are hesitant to participate in exercise therapy programs, either because they are uninterested or face logistical difficulties [14,15]. It is relevant to develop strategies that assist clinicians and patients in an engaging way in the treatment decision process such as offering personalized outcome predictions.

Digital technology presents a promising solution to address such challenges in health care. Prediction models, particularly, have emerged as powerful tools to support patients and health care professionals in the treatment decisions and management of chronic diseases like OA [16-18].

The Goal of This Work

The GLA:D (Good Life with osteoArthritis in Denmark) program has garnered significant attention as a pioneering initiative in OA management [19]. Comprising three components—training for physiotherapists, a patient education and neuromuscular exercise therapy program delivered to patients, and clinical data collection—the program stands out as an example of evidence-based care [19]. To support shared decision-making, the acceptance, and participation rate of programs like GLA:D, we aimed to validate an existing model and introduce an updated concise personalized prediction model that estimates changes in knee pain intensity for patients with OA considering participation in the GLA:D program [20].

Methods

Overview

This paper follows the guidelines of TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) [21].

In this paper, we reproduced and validated the results of previous work [20] with some methodological changes as described below.

Source of Data and Participants

We used data from the Danish GLA:D initiative for patients with knee and hip OA. The initiative consists of a 2-day course for physiotherapists, a patient treatment program delivered in clinical practice, and a registry of data reported by patients and clinicians. The patient program combines 2 patient education and 12 supervised exercise therapy sessions aiming at improving symptoms, physical function, and quality of life. Patients can join the GLA:D program through referrals from health care professionals (eg, general practitioners or orthopedic surgeons) or via self-referral, followed by an assessment by a certified GLA:D clinician to confirm the OA diagnosis [22-25]. By 2023, in total, 257 clinics were offering the GLA:D program for knee or hip OA [26]. Of these, most clinics were private practices, but 20 clinics were public municipalities, and 2 municipalities offered the treatment for employees.

The GLA:D registry collects data from participants, which includes demographic details, medical history, pain intensity, and physical function measures [27]. The data are collected at three time points: at baseline, immediately following the program, and at 12 months follow-up. GLA:D was established in 2013 and is regularly updated to include new evidence. Comprehensive details about GLA:D's education, neuromuscular exercise program, and general information are previously available [19]. For this paper, we followed the inclusion criteria of a previous publication [20] but with an extended inclusion period from October 9, 2014, to November 12, 2022, instead of ending on August 31, 2017. We included patients who indicated their knee as the primary joint of complaint and provided complete data. We excluded participants for specific time periods due to technical problems in the registry, meaning one of our variables of interest was not collected. This was the case between May 13, 2016, and November 12, 2016, and April 10, 2018, and August 05, 2019.

Variable Selection

Outcome

"Change in pain intensity" was our outcome of interest. This measure was calculated by determining the difference in pain scores on the visual analog scale (VAS) from baseline to immediately after the program (after about 3 mo). The question asked to the patients was "On a scale that goes from no pain (0 mm) to worst pain imaginable (100 mm), what score best represents your knee pain during the last week?" [28]. We examined various thresholds, ranging from 5 to 20 mm, to define a significant change in pain intensity.

XSL•FO
RenderX

Predictor Variable Selection

Our analysis incorporated 34 potential predictor variables: 11 continuous, 22 binary, and 1 with three categories. These variables were chosen for their relevance to knee OA and health outcomes, encompassing factors like clinical symptoms, lifestyle influences, and demographic details, to provide a comprehensive understanding of the disease's impact and patient outcomes. In comparison to the earlier study, we included 17 fewer variables (diabetes, S12 physical component and mental score, American Shoulder and Elbow Surgeons Shoulder Score pain and other symptoms score, and some medical disease) since their collection stopped (for 4 variables in 2018, for 2 variables in 2020, and for 12 variables, their collection stopped in 2021).

Selection of Important Variables

We used random forest regressions during variable selection and model development. The random forest regressor is an ensemble model that efficiently reduces variables without overfitting and captures complex, nonlinear relationships between predictors and the outcome variable [29]. Random forest regression was previously used on the GLA:D dataset to predict changes in VAS pain considering 51 variables in the training process; its performance is similar to a linear regression [20]. The preprocessing of our dataset was performed according to the previous study results, which we aim to validate [20].

We applied a 2-step variable selection process to optimize our predictive model and attempt to achieve clinical acceptance. Initially, we started with 34 predictor variables. To reduce the number of variables, we first evaluated the variable importance using Gini impurity [30]. The Gini index or impurity measures the probability of a random instance being misclassified when chosen randomly. The Gini impurity method evaluates the importance of each variable by examining how much it contributes to reducing impurity when used as a split criterion in decision trees [31]. Variables with higher Gini importance scores are considered more important in making accurate predictions. In many implementations, like scikit-learn's random forest, the Gini importance scores are normalized such that they all sum up to 1. Therefore, each variable's importance score will range between 0 and 1, with higher values indicating greater importance. We built and trained random forest regressor models, incorporating the top k variables, with k determined using the elbow method. The elbow method is a straightforward technique for determining the optimal number of variables in a model. It involves identifying the point at which adding more variables leads to diminishing returns, meaning their contribution to overall model performance becomes negligible [32]. To enhance the robustness of our analysis, we used cross-validation during the variable importance assessment.

The Gini coefficient is mathematically represented as:

$$Gini=1-\sum i=1C(pi)2$$

In the second step, we respected the importance of the individual variables and the elbow technique, as well as applying clinical reasoning to reduce and find the ideal set of variables. While this reduction of variables could potentially reduce the model's performance, we limited the number of questions, such that it would be convenient for end users to use the model, thereby increasing the likelihood of its clinical value.

With this 2-step approach, incorporating both Gini impurity and clinical reasoning, we aimed to achieve a balanced model that is both predictive and user-friendly.

Model Development and Evaluation

To develop and evaluate our predictive model, we began by splitting our dataset into two subsets: a training set for model development and a test set for validation. The training process was consistently applied on all models, regardless of training on all variables, on the top k predictor variables, or on a concise set of variables. To enhance the robustness and generalizability of our models, we integrated 10-fold cross-validation with random forest regression. Using the test sets, we validated our findings, ensuring that our results were not biased or limited to specific data instances by averaging results across the cross-validation test sets.

To evaluate the performance of the models, we used the root-mean-squared error (RMSE) and R^2 metrics. RMSE measures the average deviation between the predicted and actual values, providing an assessment of the model's accuracy. The R^2 represents the proportion of variance the model explains and indicates how well the model fits the data. To compare our personalized outcome predictions with predictions of the average model, we evaluated the number of correct predictions, in contrast to the previous publication, which used the absolute mean differences in a test dataset [20].

The predicted changes in pain intensity by our random forest regression constitute the personalized predictions. The average model prediction was defined as a mean function of the VAS pain change score of the training samples, $\mu=\sum n=1NVASChangeScoreN$. The average model always provides μ, regardless of the features of the unseen samples, as the predicted change in pain intensity. In this paper, we are always focused on the VAS pain change score, rather than the pain score at a specific time point. Recognizing that predictions inherently have some margin of error, we incorporated in our evaluation a margin of error that corresponds to a clinically relevant threshold.

$$In=\{1:if\ Ln\leq Predn\leq Un0:otherwise$$

In is the indicator value that will be one for cases where their predicted change in pain value is inside the interval. For all other samples, it is zero. $Ln=VASChangeScore-R$ and $Un=VASChangeScore+R$ show the lower and upper bound based on the clinical relevance threshold R. Finally, we calculate the percentage of predictions inside the interval ρ to evaluate and compare our model against the average model:

$$\rho=\sum n=1NInN.$$

Since the value of a clinical relevance R is debatable and ranges up to 20 mm [33-35] points, we evaluated the number of correct predictions with different tolerable margins of error, ranging from 5 to 20 points. Thus, we calculated the number of correct predictions for several cases, the first allowing a deviation of 5 points and the last allowing a deviation of 20 points from the true change in pain.

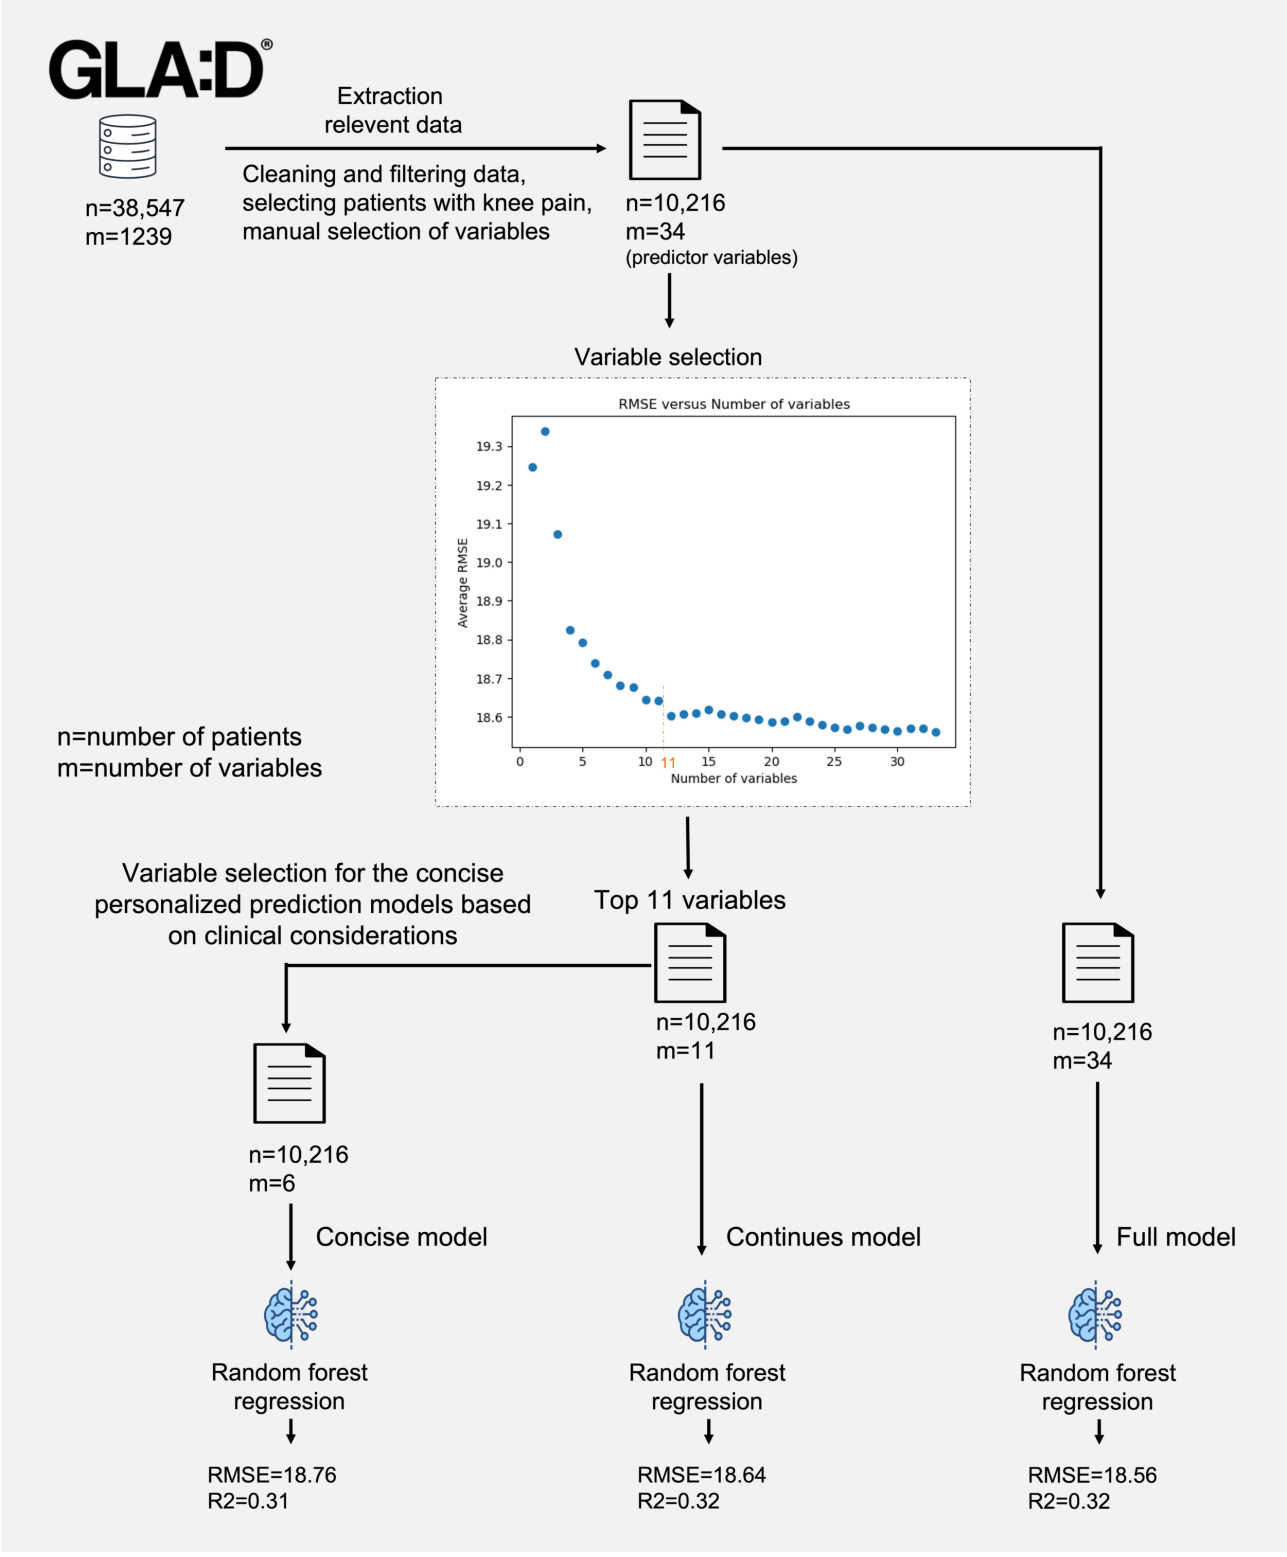
XSL•FO
RenderX

All data analyses were performed in Python (Python Software Foundation) using Scikit-learn, Pandas, and NumPy libraries [36]. We used Pandas and NumPy for data preprocessing tasks, such as cleaning and variable scaling. Scikit-learn was used for validation techniques, including train-test split, cross-validation, and stratified sampling. We used standard hyperparameters for the random forest regression: n_estimators set to 100, max_depth limited to 10, and random_state fixed at 42. We chose to use them to provide a baseline performance that can be compared with other standard implementations.

Supplementary Analyses

To evaluate if the inclusion of recently added variables to the GLA:D registry improved our outcome predictions, we additionally developed and evaluated models following the same process as described above, but including 12 additional variables (load-related pain, reduced functional capacity, morning stiffness, crepitus, reduced knee movement, bony enlargement, previous joint injury, occupational or recreational overuse, family members with OA, Knee Injury and Osteoarthritis Outcome Score-12 pain, functioning, and Knee Injury and Osteoarthritis Outcome Score-12 summary score, which were added to the registry in May 2018). A flowchart for this additional analysis is provided in Figure S2 in Multimedia Appendix 1 [37].

Ethical Considerations



This study did not require ethics approval or clinical trial registration, as determined by the local ethics committee of the North Denmark Region, since it was a register-based study rather than a clinical trial. The GLA:D registry has been approved by the Danish Data Protection Agency, ensuring compliance with data protection regulations. In accordance with the Danish Data Protection Act, patient consent was not required, as personal data were processed solely for research and statistical purposes. To protect participant confidentiality, all data were anonymized before analysis, with no access to personally identifiable information. Data handling followed the regulations of the Danish Data Protection Agency. No compensation was provided to participants, as this study relied on secondary data analysis of the GLA:D registry.

Results

A brief overview of our results is displayed in Figure 1.

Source of Data and Participants

A total of 38,547 patients fulfilled our inclusion criteria for participating in the GLA:D program between October 9, 2014, and November 12, 2022. We considered patients with knee pain as the primary complaint and our analytical dataset was reduced to 10,216 patients. Details on the process of patient inclusion and exclusion are available in Figure 2.

Variable Selection

The Gini impurity scores for all variables are presented in Figure S2 in Multimedia Appendix 1 [37]. The characteristics of all included and excluded samples are provided in Table 1. Based on these findings, we applied the elbow method and included the top 11 variables (Figure 3).

Elbow method to find top 11 variables:

Model Development and Model Evaluation

In total, we built 3 models each including a different set of variables (Table 2). The first includes all 34 variables (full model). The second one includes the 11 most important variables identified with the Gini impurity and elbow method (continuous model), highlighting the importance of these baseline variables in making predictions. The third includes the 6 predictive variables, which were chosen based on their importance and clinical reasoning—it is assumed that answering the underlying 11 questions would be applicable in routine clinical practice. These 6 variables are baseline pain, duration of symptoms, the EQ-5D score, time to complete a 40-meter walking test, age,

XSL•FO
RenderX

and BMI. Each of those 6 variables contains 1 item but BMI and EQ-5D include 2 and 5 items, respectively.

The model performances are presented in Table 3 based on the average performance on the test sets in a 10-fold cross-validation process. Accordingly, the full model's average RMSE was 18.56 (SD 0.59), while the coefficient of determination (R^2) was 0.32. The continuous model displayed an RMSE of 18.64 (SD 0.58) and an R^2 of 0.32. Moreover, when considering variables in the concise model, the RMSE and R^2 were 18.76 (SD 0.64) and 0.31, respectively.

The comparison between true predictions based on our concise model including the top six most important variables and predictions using the average model is illustrated in Figure 4. It shows a small but distinct advantage of our personalized predictions over average-based predictions. Our personalized prediction method, based on random forest regression, performed better than the average prediction model by a margin of about 7% when allowing a difference of 15 points in each direction between the predicted and the true change on the test data [35]. Specifically, our results showed that the average model predicts 51.47% and our personalized model predicts about 57.82% of the cases correctly. We found that personalized predictions were slightly and consistently better than those based on the average improvement, regardless of the deviation allowed (5 points or 20 points). Table 3 shows correct personalized predictions and correct average predictions within the interval of ±15 points for all models. An illustration using these numerical values is as follows: if a patient, for instance, has a pain score of 45 before GLA:D and our personalized model estimates a change of 20 points, this means that it is estimated that the patient will have pain between 10 and 40 after the program with a 58% certainty.

Table . Overview of included variables per model.

Name of variable combination	Included variables
Full model	All variables
Continues model	The 11 most important variables were selected by Gini. Identified by variable selection
Concise model for clinical practice	Age, BMI, change in pain, duration of symptoms, time to complete 40 m walking test, EQ-5D score

Figure 4. Comparison of the percentage of correct predictions of our concise model and using the average model, allowing deviations between 5 and 20 points.

Supplementary Analyses

Including the 12 additional variables reduced our sample with complete cases to n=1458, since these variables were first added later. However, the evaluation of the variable importance followed a similar pattern highlighting that the now 14 continuous variables were the most important (Figure S2 in Multimedia Appendix 1 [37]). Similarly, the model performances and evaluations remained comparable among all three models (Table 4).

Table . Overview of performance summary of all random forest regression models of our supplementary analyses, incorporating 46 variables with 12 additional variables relative to the prior model[a].

Variable combination	VAS[b] pain: GLA:D personalized prediction			
	RMSE[c]	R^2	Correct personalized predictions (within the interval of ±15 points)	Correct average predictions (within the interval of ±15 points)
Full model	19.24	0.32	56.37%	49.45%

Discussion

Principal Findings

In this study, we developed personalized prediction models for changes in knee OA pain after supervised patient education and exercise therapy (GLA:D) and compared them to existing prediction and average-based models. Our findings validate the two previously developed models from Baumbach et al [20] and introduce a new concise personalized prediction model for estimating changes in knee pain intensity among patients with knee OA considering participating in the GLA:D program. Neither the increase in sample size nor the inclusion of additional variables improved the previous prediction model. Nonetheless, our concise model correctly predicted 58% of the cases and demonstrated a 7% improvement in the rate of correct predictions over the use of currently used average values for informing patients about their expected changes in knee pain.

In clinical decision-making, predictive models serve as pivotal tools across various disciplines. These models, akin to those used in cancer prognosis or the optimization of exercise regimens, underline the significance of personalized predictions in enhancing patient outcomes [38-42]. This study delves into this paradigm by comparing prediction models and validating the findings of an earlier study. As in the previous study [20], we used the GLA:D data and presented a full and continuous model to predict personalized outcomes. The latter was chosen based on the variable importance. While we used the Gini impurity and elbow method, the previous study determined the most important variables by the reduction in RMSE for out-of-bag cases and applying the elbow method [20]. Despite the difference in the used method, our findings that the continuous variables were most important align with the previous study. Our outcomes match those of the previous study, despite our model's sample size being doubled and the variables being reduced by 17 and 4 in the full and continuous model, respectively. For the full and continuous models, there was no difference, and a difference of 0.01 in the R^2 values, respectively. In addition, the RMSE aligned closely. In our supplementary analysis, we incorporated 12 new variables, included in the GLA:D registry between 2017 and 2018, which reduced our sample size to 1458 but maintained consistent variable importance and model performance. Thus, we found that neither an increase in sample size nor the added variables could improve the personalized outcome predictions compared to the earlier study [20].

Recent research [43,44] highlights that patients using analgesics, experiencing constant pain, or preferring the GLA:D program over saline injection demonstrated greater benefits from the program. Unfortunately, our data did not include "constant pain" or "preference for the GLA:D program." However, we considered "intake of analgesics," although it was not among the top predictive variables. The random forest method inherently models nonlinear relationships and interactions, enabling relevant subgroup distinctions within the data. This approach avoids reducing sample sizes and maintains robustness by incorporating all relevant variables in the model [45]. Including the variables "constant pain" and "preference for the GLA:D program" in future analyses could provide deeper insights into personalized outcomes and patient stratification. Additionally, it is important to note that our sample probably differs from the randomized controlled trial–based group in the study by Henriksen et al [43,44], as not all patients in our real-world cohort would have agreed to participate in a controlled trial.

To compare the personalized predictions with predictions based on average values, we again used a different approach than the previous prediction study. The previous study took the absolute mean difference and concluded that the difference between their model and the average improvements was not clinically relevant. In this study, we focused on the number of correct predictions, assessing a range of clinical relevance thresholds to determine whether our personalized model surpasses the average model's performance, despite changing the clinical relevance threshold. Here, we emphasize this incremental progress of increasing the clinical relevance threshold. As a result, allowing a higher deviation from the true change resulted in a higher number of correct predictions, for both our personalized predictions and the average prediction. Overall, we found that our personalized prediction model was able to predict about 7% more cases correctly compared to using average predictions, independent of the threshold allowed from the true change.

However, the question of whether these findings are sufficient for implementation into clinical practice remains open. Existing shared decision-making tools often concentrate on comparing different treatments and assisting patients in making informed choices [18]. Specifically, in the context of OA, where education and exercises are universally recommended and surgery is considered a last resort after the failure of previous treatments, the potential of improved prediction models to alter this recommendation landscape is significant [46]. If future models could reliably predict the likelihood of initial treatment failures for specific patient groups, clinical guidelines to treat OA could evolve. Future models could benefit from including more comprehensive patient characteristics, such as constant pain and treatment preferences [43,44], to further explore patient-specific responses to the GLA:D program. Yet, it is crucial to acknowledge that the current performance of our models is too preliminary for such decisive changes in clinical practice. This underscores the necessity for further research to enhance model accuracy and reliability, as well as to understand the needs and preferences of patients and clinicians, potentially reshaping treatment protocols for OA based on predictive insights.

Limitations

This study also has some limitations. Selection bias is possible in any registry-based study due to the cases lost to follow-up. However, we only excluded 28.44% due to missing information on the outcome at follow-up, suggesting no serious threats to its external validity [47]. Furthermore, from previous studies using the GLA:D data, we know that these patients do not differ to a clinically relevant level from the included patients [20]. Two periods of technical flaws in data collection were identified, and these missing values, unrelated to patient characteristics or variables, meet the criteria for missing completely at random.

XSL•FO
RenderX

Participation in the GLA:D program may also be influenced by factors contributing to selection bias, such as limited accessibility, financial constraints, awareness and referral issues, perceived severity of OA, and language barriers [22,25,48-52]. Our sample's greater representation of female participants reflects known trends of greater knee OA prevalence and greater participation in exercise programs like GLA:D [53-55]. While this enhances relevance to real-world treatment populations, it should be considered when generalizing findings. This study suggests that the increased sample size does not significantly affect the predictive performance outcome [20]. However, it should be noted that we included fewer variables in comparison to the previous study [20]. These variables were deemed of less relevance and therefore excluded from the registry, nonetheless, they contributed to the predictions of the previous models. Therefore, to be precise, we can only conclude that the increased sample size was able to compensate for the reduced number of variables. Hence, to improve our models' predictability, new variables would probably need to be integrated. The newly integrated variables (12 additional variables) in our supplementary analyses, led to a reduction in the sample size (n=1458), however, the model performance remained similar. Consequently, we can (only) conclude that the newly added variables could compensate for the reduced sample size.

Based on these observations, we can point toward the limitation of available predictor variables. Implementing more detailed questionnaire-based measures for anxiety and depression might enhance pain predictions [56]. Weight loss is another recommended first-line treatment for individuals with overweight or obesity with knee OA [57] that is known to moderate systemic inflammation [58], extending the questionnaire to enquire about patients' dietary habits might thus be another possibility to increase the predictive value [59]. However, due to the clinical applicability, the extent of the GLA:D registry questionnaire needs to balance the collection of information against patient burden, adding additional variables with minor importance is not desired. In conclusion, we currently do not know which variables could have an additional major positive influence on the personalized outcome predictions over those already included [60].

Future Directions and Considerations

The precision of our model aligns with existing clinical studies, suggesting a need for future investigations into the practical value of such predictive accuracy within clinical settings [61]. Current initiatives like the A.S.K. report and Movement is Life have begun to explore the integration of predictive models and patient-reported outcomes to guide shared decision-making, demonstrating the utility of these tools in clinical practice [18,62]. However, there is a noticeable gap in the literature concerning the specific performance benchmarks required for predictive models in physiotherapy to be deemed clinically relevant, particularly in the management of OA. Therefore, before a decision on implementing our model as a web tool into clinical practice can be drawn, guidance on which metrics and predictive values need to be achieved in a model to be feasible for clinical practice needs to be investigated. Furthermore, it remains uncertain if the implementation of a model, like ours, which provides more correct predictions than what is currently used, but still several wrong predictions, is valuable enough for patients and clinicians to be implemented in clinical practice. Further, to the best of our knowledge, it is yet unknown if personalized outcome predictions regarding a treatment lead to different expectations than average outcome predictions in patients. Moreover, on ethical aspects, the consequences of wrong predictions in general on a patient's treatment, and mental and emotional well-being should be investigated. For patients with estimated worsening pain predicting other health outcomes additionally could be essential to motivate them to participate in the program. For example, prediction tools within GLA:D for secondary outcomes such as physical activity, which changes independently of changes in pain, could support participation rates, given the overarching health benefits associated with increased physical activity [27,60]. Similarly, patients might be more motivated if they knew about the expected changes in physical function and quality of life. Finally, any prediction tool needs to be comprehensively evaluated based on its role in treatment decisions, patient satisfaction, and overall treatment outcomes in clinical settings, before implementation.

Generalizability

The methodology used in this study, which leverages machine learning techniques to analyze questionnaire data and functional test data for predicting treatment outcomes has been used before and is a promising advancement in the field of personalized medicine [63,64]. This approach is characterized by the selection of predictive variables from data and can be used in similar questioning. Thus, our method extends beyond the specific context of the GLA:D program and could be applied to other exercise therapy programs targeting knee OA, and potentially, for a broader range of conditions [62,65-67].

Generalizing our findings, the model predictions of the GLA:D program for knee OA to other exercise and physiotherapy interventions are challenging. The unique combination of group-based exercises and education in GLA:D may be crucial and not present in all physiotherapeutic settings. Therefore, our outcome predictions specific to GLA:D cannot be expected universally. However, if the core principle of structured exercise therapy and education are incorporated into the treatment of a patient with OA, our model might be applicable. Nonetheless, the personalized predictions would likely deviate even further from the true changes than in patients participating at GLA:D, therefore, they should not be generalized.

Conclusions

We developed and validated a personalized prediction model for pain intensity changes in patients with knee OA participating in the GLA:D program. Our model's 58% accuracy is 7% better than using average pain improvement as a prediction. This likely represents the best possible prediction given current knowledge and available data. Although performance is improved, further guidance is needed to determine when such models are suitable for clinical implementation. This study highlights both the potential and current limitations of personalized prediction in knee OA management.

Acknowledgments

The authors would like to thank the clinicians and patients collecting data for the GLA:D registry. This study was developed as part of the PhysioAI project and is funded by the German Federal Ministry of Education and Research (BMBF) and by the NextGenerationEU Fund of the European Union under grant 16DKWN115A. The initiation of GLA:D was partly funded by the Danish Physiotherapy Association's fund for research, education, and practice development; the Danish Rheumatism Association; and the Physiotherapy Practice Foundation. The responsibility for the content of this publication lies with the author.

Data Availability

All the data for this study were acquired following a request to the GLA:D Denmark [22]. The codes for data preprocessing and prediction models analyzed during this study are available in the KneePainPrognosticModelGLA-D repository [68].

Conflicts of Interest

EMR is on the Editorial Board of Osteoarthritis and Cartilage, the developer of the Knee Injury and Osteoarthritis Outcome Score and several other freely available patient-reported outcome measures and cofounder of GLA:D, a not-for-profit initiative hosted at the University of Southern Denmark aimed at implementing clinical guidelines for osteoarthritis in clinical practice. STS has received personal fees from Munksgaard, TrustMe-Ed, and Nestlé Health Science, outside the submitted work, and is cofounder of GLA:D.

Abstract

Background: Chronic musculoskeletal pain (CMP) impacts around 20% of people globally, resulting in patients living with pain, fatigue, restricted social and employment capacity, and reduced quality of life. Interdisciplinary multimodal pain treatment (IMPT) programs have been shown to provide positive and sustained outcomes where all other interventions have failed. IMPT programs combined with multidimensional machine learning predictive patient profiles aim to improve clinical decision support and personalized patient assessments, potentially leading to better treatment outcomes.

Objective: We aimed to investigate integrating machine learning with IMPT programs and its potential contribution to clinical decision support and treatment outcomes for patients with CMP.

Methods: This prospective pilot study used a machine learning prognostic patient profile of 7 outcome measures across 4 clinically relevant domains, including activity or disability, pain, fatigue, and quality of life. Prognostic profiles were created for new IMPT patients in the Netherlands in November 2023 (N=17). New summary indicators were developed, including defined categories for positive, negative, and mixed prognostic profiles; an accuracy indicator with high, medium, and low levels based on weighted true- or false-positive values; and an indicator for consistently positive or negative outcomes. The consolidated reporting guidelines checklist for prognostic machine learning modeling studies was completed to provide transparency of data quality, model development methodology, and validation.

Results: The machine learning IMPT prognostic patient profiles demonstrated high accuracy and consistency in predicting patient outcomes. The profile, combined with extended new prognostic summary indicators, provided improved identification of patients with predicted positive, negative, and mixed outcomes, supporting more comprehensive assessment. Overall, 82.4% (14/17) of prognostic patient profiles were consistent with clinician assessments. Notably, clinician case notes indicated the stratified prognostic profiles were directly discussed with around half (8/17, 47.1%) of patients. Clinicians found the prognostic patient profiles helpful in 88.2% (15/17) of initial IMPT assessments to support shared clinician and patient decision-making and discussion of individualized treatment planning.

Conclusions: Machine learning prognostic patient profiles showed promising contributions for IMPT clinical decision support and improving treatment outcomes for patients with CMP. Further research is needed to validate these findings in larger, more diverse populations.

Introduction

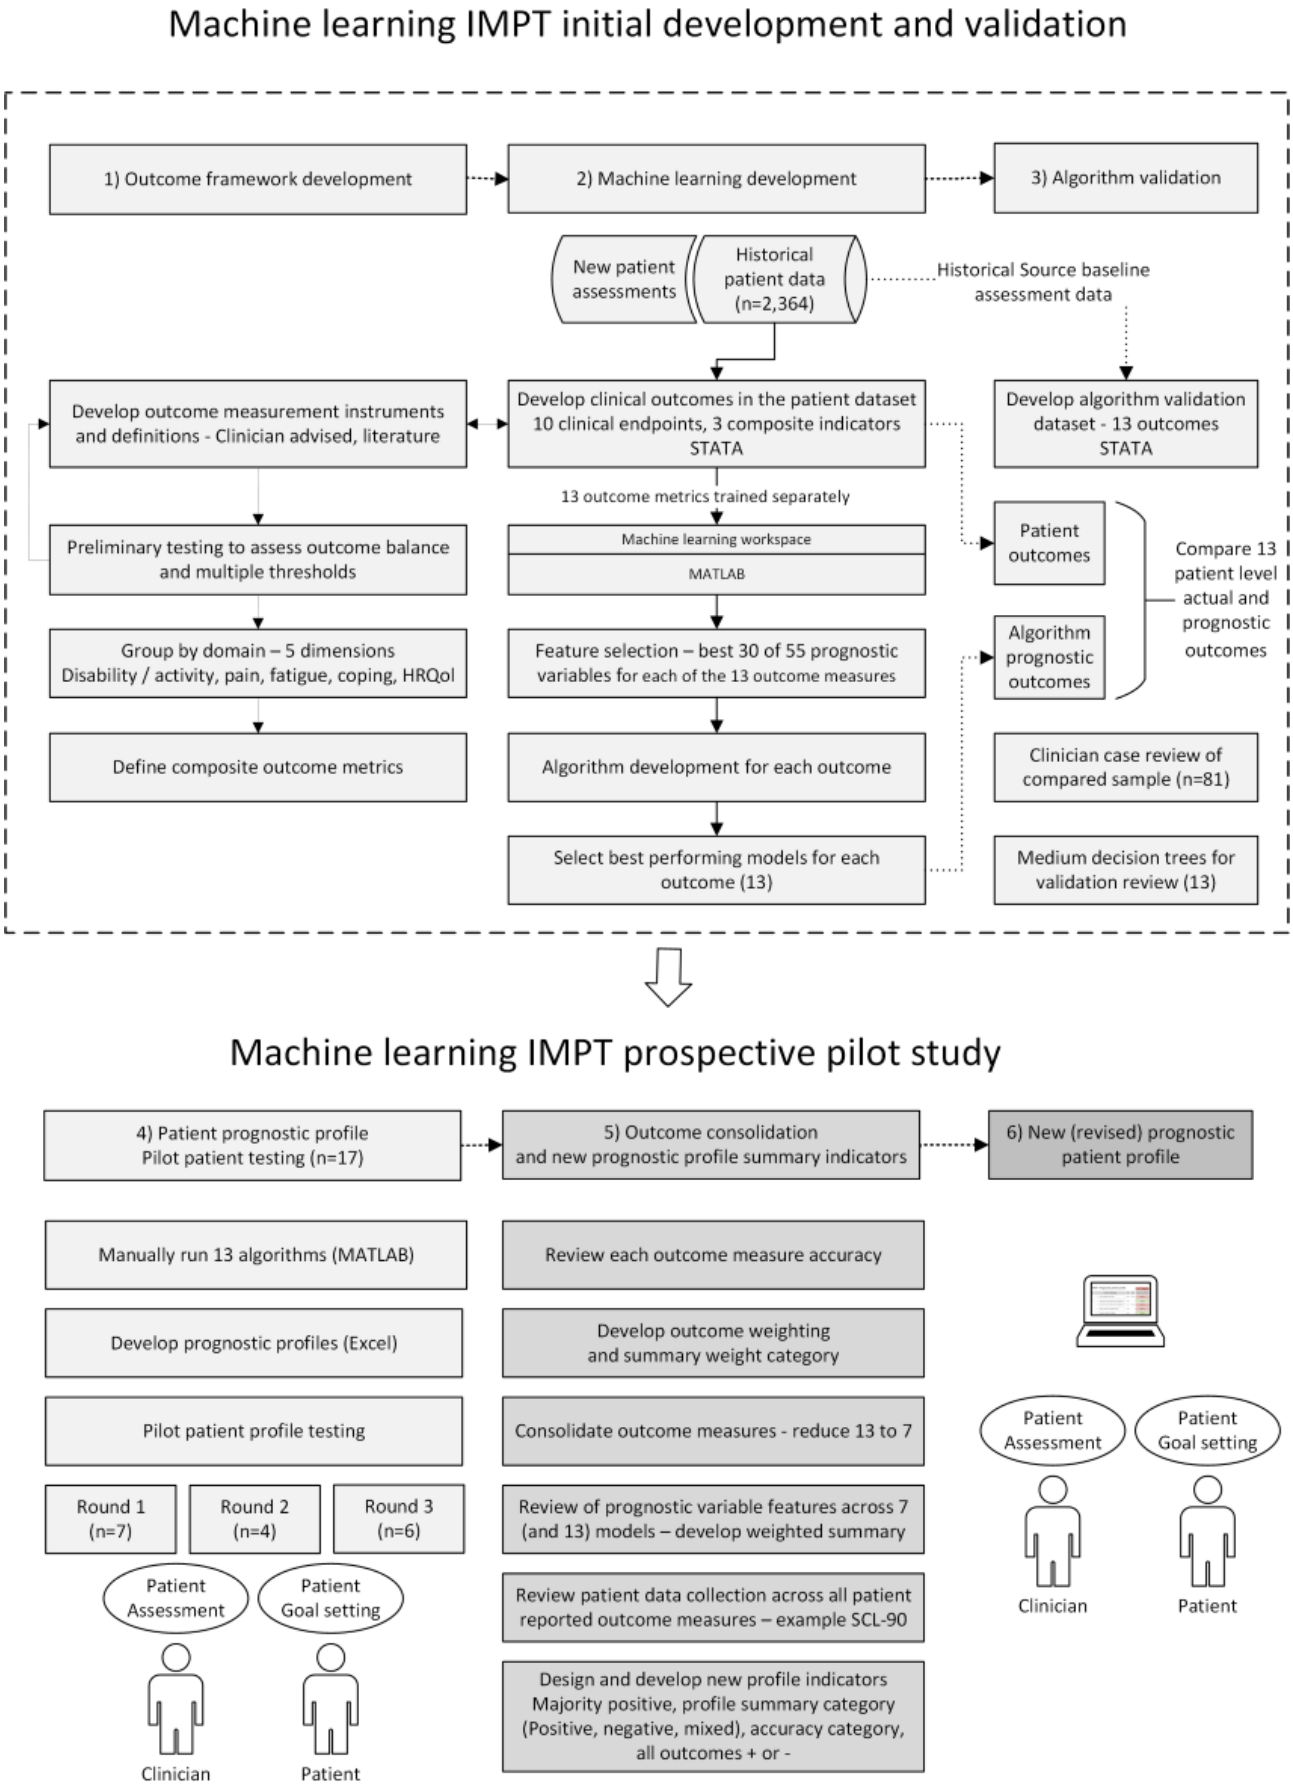
Chronic musculoskeletal pain (CMP) is a prevalent and debilitating condition that significantly impacts the quality of life for millions of individuals worldwide [1]. Patients with CMP often experience long-term pain, where all available treatments have been ineffective, resulting in debilitating pain; fatigue; limited mobility; and associated reduced social activity, employment, and quality of life. Interdisciplinary multimodal pain treatment (IMPT) has shown positive outcomes for CMP, with over 50% of patients reporting positive and sustained improvement [2-8]. CIR (Expertisecentrum chronische pijn), a multicenter pain rehabilitation clinic in the Netherlands, provides a 10-week IMPT program for patients with CMP, reporting consistent positive outcomes [8,9]. The IMPT program supports patients with CMP in modifying their behavior and assisting with pain management, focusing patient attention on specific value-based goals rather than fighting pain.

Recent advancements in machine learning have opened new avenues for enhancing clinical decision support and personalizing IMPT patient assessments. The promising potential of machine learning models to assist clinical decision support for IMPT patients has been previously reported [10-12]. Specifically, machine learning methods can assist with assessing multiple predictive outcomes to provide a stratified prognostic patient profile. This multidimensional approach is essential because, given the complexity of evaluating CMP, no single outcome measure is sufficiently reliable. Clinicians consider various dimensions when assessing patients for IMPT. Machine learning prognostic profiles have demonstrated potential in enhancing clinician assessments for IMPT and identifying individual patient objectives.

The primary objectives of this study were to (1) assess the effectiveness of machine learning predictive patient profiles in improving clinical decision support for IMPT programs; (2) evaluate the accuracy and consistency of prognostic assessments derived from multidimensional machine learning models; and (3) develop new summary indicators, including redefined prognostic categories and accuracy guides, to better assist clinicians and patients in interpreting the prognostic profiles and making informed treatment decisions.

Implementing machine learning prognostic profiles requires clinician collaboration and clear demonstration of their capabilities. Recent research has shown potential pathways to validate and build clinicians' confidence in using machine learning for IMPT decision support [13,14]. This pilot study aimed to investigate integrating machine learning with IMPT programs and its potential contribution to clinical decision support and treatment outcomes for patients with CMP.

Methods



Study Design

This pilot study evaluated integrating machine learning predictive patient profiles with IMPT programs. Data included all patients with CMP referred for CIR program assessments in Eindhoven over 3 weeks in November 2023 (N=18). Eligible participants were adults 18 or older with CMP and at least 6 months of pain history, excluding those with severe psychiatric disorders, active substance abuse, or ongoing pain-related litigation [8,9]. One pilot study patient had experienced severe traumatic events and was clinician-assessed for referral to seek proper care in mental health and was not suitable for IMPT. For this patient, the IMPT prognostic profile was not relevant, as the IMPT outcome framework questionnaires do not include instruments to assess trauma. Due to the incorrect referral, this patient was excluded from the study, resulting in the final IMPT patient pilot study group (N=17).

The pilot study used multidimensional machine learning models that were previously developed to predict patient outcomes based on a comprehensive set of clinical, demographic, and psychosocial variables derived from historical data of previous IMPT patients (N=2364) [10]. The present pilot testing study applied these machine learning algorithms to generate prognostic profiles for new IMPT patients prior to their initial assessment. As illustrated in Figure 1, over the course of 3 weeks, each profile was prepared manually, involving finalization of patient data and multiple processing steps.

Algorithm development was previously undertaken for multiple classification models, selecting the best performing model for each of the final 7 outcome measures. Dashed section indicates previously reported IMPT model development [10]. HRQoL: health-related quality of life; IMPT: interdisciplinary multimodal pain treatment; SCL-90: Symptom Checklist-90.

XSL•FO
RenderX

Data Sources and Preprocessing

Data collected from IMPT-referred patients in preparation for baseline assessments included demographics, clinical conditions, patient-reported outcomes, and a comprehensive evaluation of pain intensity, physical function, emotional well-being, social participation, and other relevant variables. The baseline data were used with previously trained algorithms to generate prognostic profiles for new patients using CIR data from the Asterisque system (electronic patient file). Clinicians assess some prognostic data items during initial patient examinations, such as indication for eye movement desensitization and reprocessing registration and pain diagnosis (level of complexity known as WPN classification). Other assessments, like the 6-minute walking test and 5 times sit-stand trials (performed at the actual start of the IMPT), were imputed based on age and gender averages from IMPT patient data, with supplementary checks to confirm consistency in prognostic profiles.

A machine learning development and validation checklist was used to ensure the quality and consistency of the models [15]. The checklist included steps for data preprocessing, model training, validation, and evaluation; details are provided in Multimedia Appendix 1.

Ethical Considerations

All records in the patient dataset were deidentified with a unique patient number, and clinician patient assessments of positive or negative IMPT referrals and case notes were reported for validation of each patient prognostic profile. The Medical Research Ethics Committee Isala Zwolle, the Netherlands, previously reviewed the initial study (case number assigned: 200510), and as all patients have consented to the use of their data for research, further ethics approval was not required. This satisfies that the study was conducted in accordance with the principles outlined in the Declaration of Helsinki.

Revised and New Prognostic Profile Summary Indicators

The primary pilot validation outcome measure was the accuracy and consistency of prognostic assessments derived from the machine learning models in support of clinician and IMPT team-assessed prognosis. Secondary outcome measures included the effectiveness of the predictive patient profiles in improving clinical decision support, the development of new summary indicators, and the value of these indicators for clinician and patient shared decision-making. In this context, in line with the complexity of IMPT treatment and clinician assessment, a review of the multidimensional outcome framework was undertaken to consider how the results across the prognostic profile could best be summarized to assist clinician and patient interpretation.

Five new summary indicators were established (Table 1). The initial indicator shows positive or negative based on a majority count of positive outcomes (indicator 1), as well as the actual number of positive outcomes (indicator 2). A new prognostic profile summary indicator (indicator 3) was created to more clearly identify positive or negative profiles. The negative profile is defined as all 7 outcomes being consistently negative (zero positive), while the positive profile requires 3 or more positive outcomes. Profiles that do not fit either category are labeled as “mixed” and need further assessment. These summary categories supplement the complete set of stratified prognostic outcomes that are individually provided for clinician evaluation and optional patient discussion.

Additionally, each prognostic model was evaluated to create a weighted summary indicator of overall accuracy (summary indicator 4). This accuracy category was developed by summing true-positive rates (TPRs) and true-negative rates (TNRs) across each machine learning model for each outcome. This figure provides a weighted proxy indicator to adjust for outcome models with high TPRs or TNRs, derived by summing the opposite TPR or TNR for each predicted positive or negative outcome. For example, an outcome with an estimated TPR of 0.98 added the related TNR of 0.02 to the weighted accuracy score, reflecting a low contribution to the total profile. The resulting true-positive and true-negative weighted scores were then grouped into a prognostic profile accuracy category defined as low (<3), medium (≥3 and <4), and high (≥4). A supplementary indicator (indicator 5) was also developed to emphasize profiles where all 7 indicators were consistently positive or negative. While the full profile shows the number of positive or negative outcomes, this indicator clearly highlights these significant cases compared to mixed outcomes.

Table . Revised and new interdisciplinary multimodal pain treatment (IMPT) prognostic patient profile summary indicators. Source: Machine learning IMPT prognostic patient profile pilot study (n=17).

IMPT prognostic patient profile indicator	Positive	Other	Negative
1. Positive majority (positive outcomes)	≥4 of 7	N/A[a]	<4 of 7
2. Number of positive outcomes (outcome count)	4, 5, 6, or 7	N/A	1, 2, or 3
3. Prognostic profile summary (positive outcomes)	≥3 of 7	Mixed=1 or 2	0
4. Profile accuracy category (weighted TPR[b] and TNR[c])	High	Medium	Low
5. All outcomes, positive or negative	All of 7	N/A	All of 7

[a]N/A: not applicable.

[b]TPR: true-positive rate.

[c]TNR: true-negative rate.

Statistical Analysis

Statistical analyses compared the accuracy and consistency of the IMPT machine learning prognostic profiles with clinician assessments in the context of IMPT clinical decision support; that is, how consistent are the machine learning profiles with clinician prognoses to start IMPT. Descriptive statistics summarized baseline characteristics and outcomes; categorical variables are presented as numbers and percentages, and continuous variables as mean and SD. Fisher exact test was used to measure associations due to the small pilot study sample (N=17) versus initial models (N=2364). Details on feature selection and individual machine learning model IMPT outcomes have been previously reported [10].

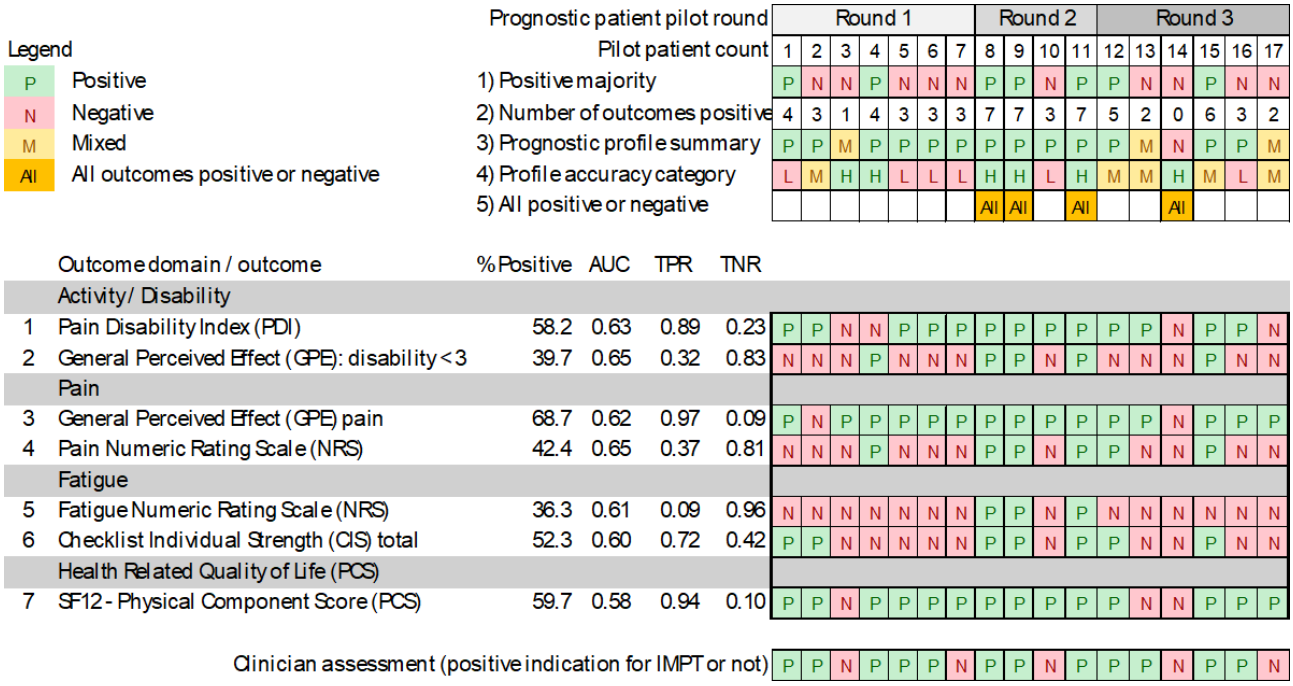
Data analysis and preprocessing were completed with Microsoft Excel 365 and STATA (version 16.1; StataCorp LP). Algorithm prediction was undertaken individually for each of the 7 outcome models using the MATLAB Statistics and Machine Learning Toolbox (Release 2023b). Prognostic patient profile results were transposed back to Microsoft Excel for clinician and patient review.

Results

In total, 17 patients with CMP participated in the study. The mean age of the participants was 45.3 (SD 12.4) years, with 10 females and 7 males. Most participants had a history of pain lasting more than 5 years. Baseline characteristics are detailed in Multimedia Appendix 1. As all patients have been referred for IMPT, patients in the pilot study group were diagnosed with CMP and classified through the Working Group on Pain Rehabilitation in the Netherlands (Werkgroep Pijnrevalidatie Nederland (WPN)). Based on this rating of the complexity of pain symptoms, the majority (64.7%) were assessed as WPN 3 chronic pain syndrome and 35.3% as WPN 4 (maximal score), consistently showing a clear indication of psychosocial factors underlying chronic pain and disability. Most participants lived with a partner, were employed, and used pain medication.

The machine learning IMPT prognostic patient profile with new summary indicators demonstrated high accuracy and consistency with clinician assessment in 82.4% (14/17) of cases (Figure 2). In 2 of the 3 mixed cases, the profiles were predominantly negative (patients 3 and 17 in Figure 2), and the clinician confirmed them as negative during assessment. The remaining mixed profile (patient 13) included 2 positive prognostic outcomes and was clinician-confirmed as positive. The prognostic profile was not used in 2 cases, one where the patient turned out to have no request for help with pain rehabilitation and another where the planned assessment was rescheduled beyond the pilot study period.

Notably, clinician assessment indicated the stratified prognostic profiles were directly discussed with around half (8/17, 47.1%) of patients and were reported as helpful for IMPT discussion, shared decision-making, and individualized planning. The patient review discussion was valuable for confirming profiles that were mostly positive, verifying the positive decision. The review discussions were also reported as helpful in 2 additional mixed profile cases, one where review of predicted negative outcomes helped the patient decide not to proceed with IMPT, even though one summary indicator was positive (patient 3), and another with mostly negative outcomes, which also helped confirm a decision not to proceed with IMPT (patient 17).



Collectively the prognostic patient profile indicators were clearly consistent with positive and the single negative clinician assessment in 12 cases and indirectly consistent through 2 mixed profiles (14/17), as above. A further example of machine learning prognostic profile value was a predicted positive profile (patient 10), even though the joint clinician and patient decision was not to proceed with treatment. In this case the profile showed the minimum of 3 positive outcomes out of 7, and the profile accuracy category was low. Combining this case with the previous 14 clinician-consistent results showed the prognostic patient profiles were helpful in 88.2% (15/17) of initial IMPT assessments. Clinician experience during the study indicated that the predictive profiles provided valuable insights into patient outcomes and facilitated more informed decision-making regarding individualized treatment plans.

The new prognostic profile summary indicators included a profile accuracy category (indicator 4). Although the pilot study

XSL•FO
RenderX

is a small sample, the results consistently indicated that all 6 patients with a "high" accuracy category were confirmed to have a clinician-consistent prognostic profile. Many of this high-accuracy category group (4/6) had a clear positive or negative profile summary, highlighted by the final indicator where all 7 outcomes are consistently positive or negative.

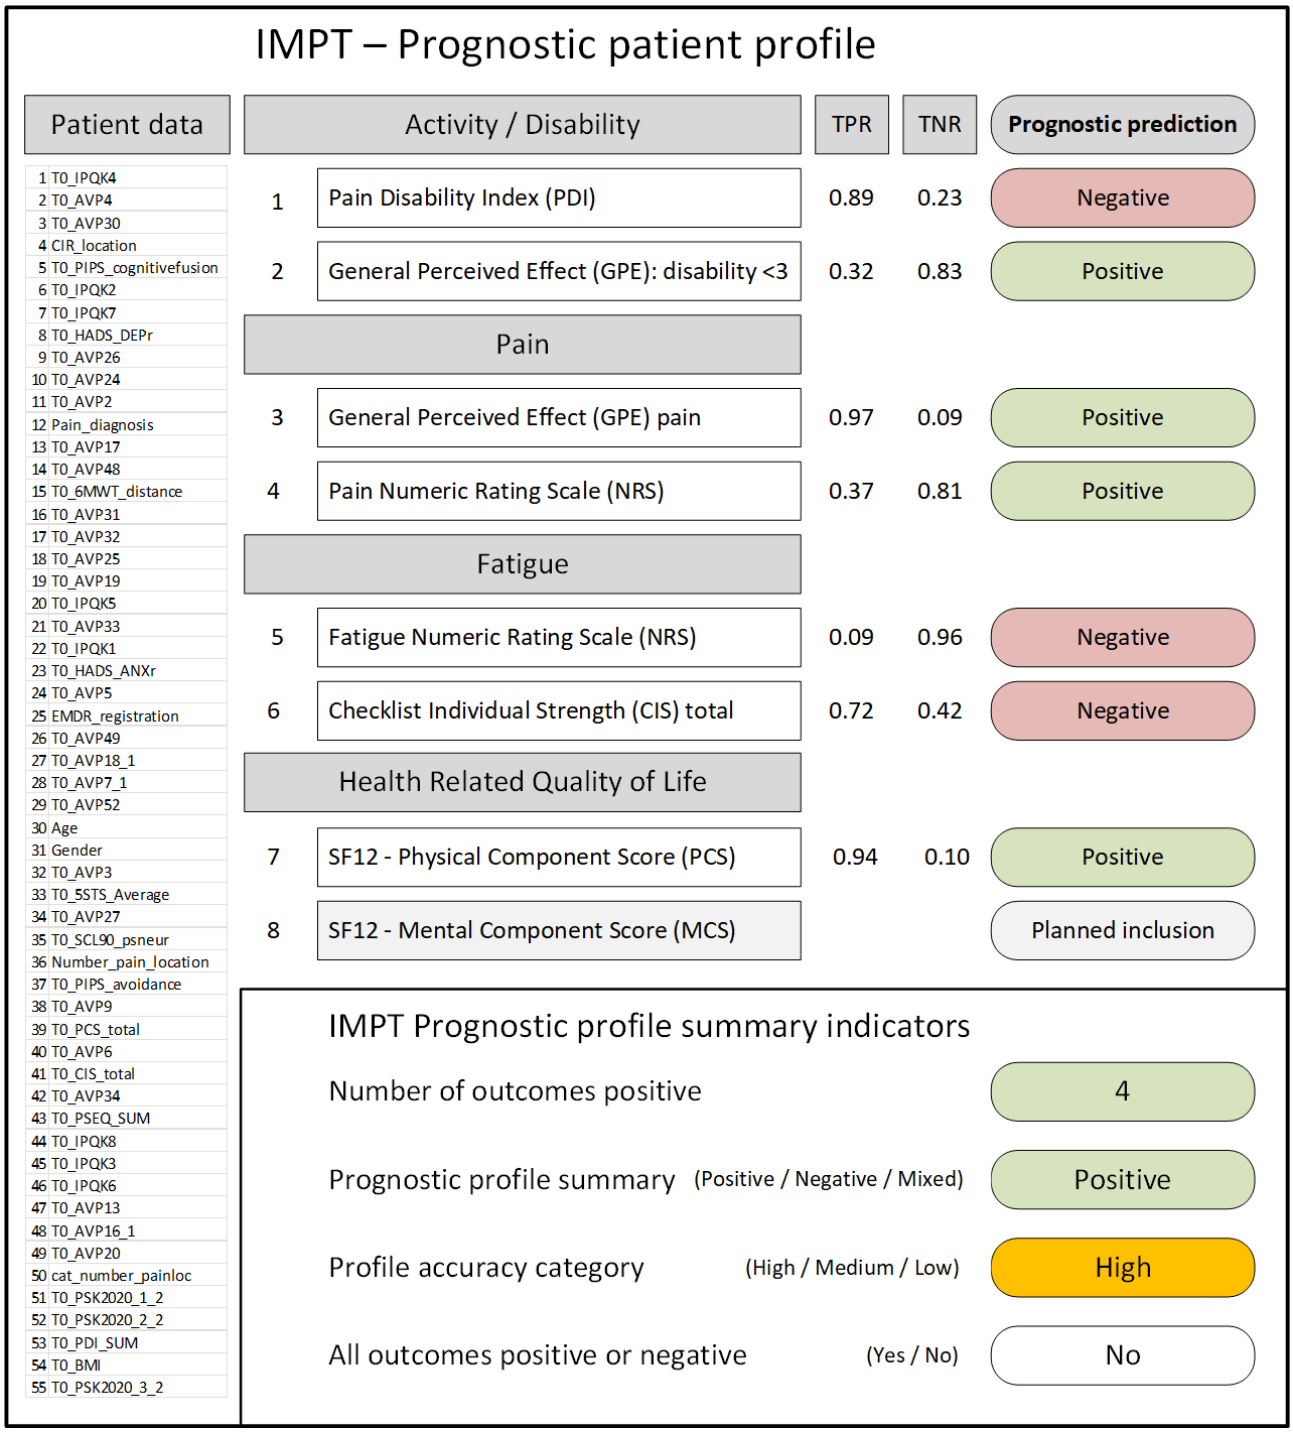


Figure 2. Pilot study prognostic patient profiles with 7 outcome measures and new summary indicators. Source: Machine learning interdisciplinary multimodal pain treatment (IMPT) prognostic patient profile pilot study (N=17). Profile accuracy: H=high, M=medium, L=low. AUC: area under the curve; M: mixed; N: negative; P: positive; TPR: true-positive rate; TNR: true-negative rate.

The above summary (Figure 2) presents results for all pilot study patients to show performance and overall results. However, the individual prognostic patient profile as used in IMPT clinical assessment provides clearly presented summary results for each patient. The IMPT prognostic patient profile included all patient baseline and demographic data for reference, the stratified outcomes by outcome dimension, and the prognostic prediction clearly displayed for each outcome. The example in Figure 3 shows indicative profile content, which would potentially be further designed and customized into a patient prognostic profile application. This illustration indicates the planned inclusion of an additional outcome measure for the Short-Form Quality of Life Survey (SF-12) Mental Component Score (MCS), as IMPT data for this scale is now available. The bottom section presents the prognostic profile summary indicators, in this case showing a positive summary with a high level of accuracy confidence.

XSL•FO
RenderX

Figure 3. IMPT prognostic patient profile and summary indicators—pilot study example. Example patient number 4 prognostic profile with actual pilot testing study data results. Patient data section is shown for illustrative purposes, representing the 55 baseline prognostic variables and values that would appear on the patient profile. CIS: Checklist Individual Strength; GPE: Global Perceived Effect (disability); IMPT: interdisciplinary multimodal pain treatment; NRS: Numeric Rating Scale; PDI: Pain Disability Index; SF-12 MCS: Short-Form Quality of Life Survey Mental Component Score; SF-12 PCS: Short-Form Quality of Life Survey Physical Component Score; TNR: true-negative rate; TPR: true-positive rate.

Discussion

Overview

Chronic pain is a complex condition that needs assessment of multiple patient outcomes to create personalized treatments. Managing chronic pain is complicated due to its subjective nature and the variability in patient responses to treatments. In this context, the pilot study investigated the performance of a novel machine learning prognostic patient profile, which combined 7 separately trained outcome models across 4 clinically meaningful domains into a single prognostic patient profile [10]. The study investigated how this multidimensional approach assisted clinical decision support, shared clinician and patient decision-making, and individualized treatment planning.

IMPT Improved Program Outcomes and Efficiency

The pilot study externally validated the IMPT predictive patient profile, showing its potential to enhance chronic pain treatment and cost-effectiveness. By introducing new summary indicators

XSL•FO
RenderX

and weighted accuracy measures, the study improved the tool's precision in predicting patient outcomes. It also identified key variables for better data utilization, suggesting that some, like the Symptom Checklist-90 (SCL-90) questionnaire, could be removed to reduce patient burden. The machine learning feature selection process can help minimize redundant information and optimize high-impact variables, leading to more effective chronic pain management. The IMPT prognostic variables weighted by minimum redundancy maximum relevance scores are provided in Multimedia Appendix 1.

Additionally, the overlap with current IMPT patient systems indicates potential for optimizing data usage. The pilot study revealed that clinicians spend approximately 15 minutes per patient collecting initial baseline data. Having the comprehensive prognostic profile available could save this time for more complex assessments. Separately, the prognostic patient profile might play a more nuanced role in patient assessment. These profiles could help identify a subgroup of patients who might benefit from an initial 4-week treatment period to further evaluate IMPT potential before proceeding to the full 10-week program. This approach could contribute to better assessment pathways and improved patient outcomes.

Furthermore, in a longer term perspective, the societal value of IMPT is linked to the positive patient pathways that emerge following participation in the program, which may persist for many years or even decades. Preliminary research indicates that the CIR program is likely to be cost-effective, with long-term results demonstrating significantly enhanced self-rated work capacity [2,8]. This offers a promising outlook for further efficiency gains and improved patient outcomes, where machine learning-driven predictive patient profiles may assist clinicians and patients in assessment and program engagement. Long-term outcomes could facilitate a return to working life, reduce the need for formal and informal care, and enhance quality of life.

Artificial Intelligence Advances in Chronic Pain Health Care

The use of artificial intelligence in health care, including chronic pain diagnosis and treatment, has become increasingly prominent [11,16-18]. However, most machine learning research has investigated pain diagnosis and progression to chronic pain, which had already been completed for the pilot study group, which consisted of patients with long-term CMP. All patients had previous consultations with at least 1, and up to 20, care providers for diagnostics and treatment, in addition to visiting a physical therapist in primary care. Patient pain complexity was reflected in WPN levels 3 or 4, indicating the presence of multiple biopsychosocial factors contributing to persistent pain, associated disability, and reduced quality of life. This suggested that monodisciplinary treatment would have been insufficient. This pilot study, however, went beyond diagnosing chronic pain and used machine learning to predict the success of IMPT for patients with CMP, especially when other treatments had failed.

Single Versus Multidimensional Outcomes

Many machine learning studies focus on predicting single outcomes for chronic pain treatment, such as whether a patient's pain will improve with specific therapy. These studies primarily address binary clinical decisions rather than developing multioutcome patient profiles. For example, one study used machine learning with features from dynamic surface electromyography readings to predict which patients with low back pain would respond to rehabilitation [19], showing high accuracy, possibly due to a specific signal in the data. Another study evaluated if patients with low back pain should seek professional care or self-manage, achieving around 70% accuracy [20].

A further single-outcome approach developed a neural network model to predict which patients with chronic pain and foraminal spinal stenosis would benefit from a transforaminal epidural steroid injection [11]. These single-outcome approaches focus on clinical procedures rather than personalized multimodal treatments. Overall, while high-resolution imaging may provide precise diagnoses, it cannot be compared directly to complex patient-reported chronic pain data.

Supervised and Unsupervised Learning

In addition to supervised machine learning investigated in the pilot study, unsupervised methods have been used to identify patient subgroups for better pain treatment selection [21]. For example, clustering has been applied to patients with fibromyalgia to find distinct subgroups based on symptom profiles like pain intensity, anxiety, and sleep quality [22]. Clustering helps understand mechanisms or prognoses for varied treatments. It aids in patient stratification and decision support but does not give direct recommendations. Clinicians can use clusters to guide treatment by matching new patients to typical outcomes. Clustering differs from supervised approaches as it explores and identifies patterns without assumptions. Furthermore, clusters require clinical interpretation and validation and do not have accuracy metrics like those found in predictive models. Recent research has also explored the mix of supervised and unsupervised methods to investigate underlying subgroups of patients with chronic pain [23]. Given the characteristic heterogeneity of patients with CMP, this research may help better identify prognostic subgroups, which could provide improved direction for ongoing supervised and reinforced IMPT machine learning development.

Prognostic Profile Implementation

An implicit machine learning research direction highlights the importance of carefully planned implementation to build confidence in these new methods and achieve acceptance from clinicians and patients. The challenges to successful implementation included training data quality, complexity of pain physiology, comprehensive validation of predictive models, privacy, biases, and ethical considerations [10-12,24]. Proactively anticipating and addressing each of these barriers from the outset is essential for the successful integration of machine learning into IMPT clinical decision support systems.

The machine learning pilot study involved continuous clinician collaboration in line with research indicating that clinician involvement during the design and validation phases is crucial for supporting potential implementation acceptance [25]. To further support design consistency and transparency, the pilot study built on a previously completed clinician checklist for

XSL•FO
RenderX

algorithm assessment, which considered aspects like data quality, validation, and ethical concerns [10,26]. This checklist has now been extended with the Consolidated Reporting Guidelines for Prognostic and Diagnostic Machine Learning Modeling Studies, further enhancing standardization and building confidence for clinical integration [15].

External Validation

The pilot study has demonstrated initial external validation, as the prognostic profiles have been prospectively investigated with new patients who were not included in algorithm training data. A further interesting aspect has been the consistency with conventional logistic regression models as a form of cross-validation for the machine learning prognostic profiles. Separate research into IMPT logistic regression prediction models has investigated 3 of the 7 outcome dimensions used in the machine learning profiles and found consistent results for corresponding outcomes [27]. The logistic regression study examined the Pain Disability Index (outcome 1 in Figure 2), the General Perceived Effect (outcome 2), and the SF-12 Physical Component Score (outcome 7). These results reinforce the reliability and validity of the machine learning methods, and this cross-validation strengthens confidence in the prognostic tool's ability to provide accurate and useful predictions for IMPT patient outcomes. Importantly, the logistic regression results indicate that the SF-12 MCS was the highest performing model, and is a second outcome measure in the health-related quality of life dimension. This outcome was not trained during initial IMPT machine learning development as the data were not yet available. However, this measure is currently being integrated into the machine learning prognostic patient profile (shown as outcome 8 in Figure 2), suggesting further potential positive contribution beyond the pilot study results.

Limitations

Although the results are promising, this study has some limitations. As the IMPT patient data extraction and preparation were time-consuming and the machine learning models involved substantial manual effort to individually run across each outcome and collate into each patient profile, it was not feasible to run the pilot study for an extended period. This limited the pilot study group to a small sample of 17 patients over the 3-week project. For this reason, the results are presented as preliminary and have focused on individual profile analysis and clinician validation, rather than statistical significance.

Additionally, all pilot study patients were assessed at a single CIR location in Eindhoven, limiting the scope to examine other patient cohorts, clinicians, and potentially other IMPT program characteristics. The results are provided as indicative and descriptive, and the small sample and single-center study may affect the generalizability of the findings. Future research should aim to confirm these findings in larger, more diverse IMPT populations and investigate the long-term contribution of machine learning to clinical decision support and patient outcomes.

Conclusions

Integrating machine learning with IMPT programs can enhance clinical decision support and potentially improve treatment outcomes for patients with CMP. Machine learning predictive patient profiles can complement clinician assessments by providing insights into specific patient outcomes and facilitating informed clinician and patient shared decision-making. New summary indicators can further enhance predictive profile interpretation for consideration of whether IMPT is likely to provide a positive treatment pathway. Continued research and development in this area are necessary to fully realize the potential of machine learning in clinical practice and to ensure its successful implementation and acceptance by clinicians and patients.

Acknowledgments

We thank the CIR (Expertisecentrum chronische pijn) research team for assistance with validation and data extraction for the machine learning pilot testing project. This manuscript benefited from valuable peer review comments and writing assistance provided by Microsoft Copilot (Microsoft 365) to summarize the original manuscript. Suggestions generated by Copilot were reviewed and modified by the authors to ensure accuracy and compliance with academic standards. The interdisciplinary multimodal pain treatment (IMPT) pilot patient testing was funded by CIR; funding for open access publication of this research was provided by Maastricht Medical Faculty, Maastricht University, Netherlands.

Data Availability

The study group patient dataset is confidential, managed by CIR (Expertisecentrum chronische pijn), and is not available for public access.

Authors' Contributions

FZ and RJEMS conceived the pilot machine learning patient validation project. The clinical patient dataset was developed and funded by CIR (Expertisecentrum chronische pijn). All clinical patient assessment of the machine learning prognostic patient profiles across outcome measures was provided by RJEMS. JSG provided clinical advice during the initial patient profile testing and assistance with initial patient data validation and clinical assessment of outcome measures, which are not routinely available at baseline. EVDG managed the patient data extraction and validation for each of the pilot study rounds as well as guidance on

XSL•FO
RenderX

potential patient data enhancement and potential systems development. FZ developed the 3 rounds of machine learning patient test prognostic profiles from live data provided by CIR. The manuscript was prepared by FZ, with review and clinical advice from RJEMS and JSG, as well as data systems design and implementation perspectives from EVDG. All authors revised and approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Virtually delivered health care services can offer numerous benefits, and the demand for virtual care continues to grow among subgroups facing mobility challenges. The experience of compassion in health care is linked to patient satisfaction and clinical outcomes; however, this link in virtual rehabilitation settings is underexplored.

Objective: The objectives of this study were to explore what compassionate care means to rehabilitation patients in a virtual rehabilitation context and explore patients' experiences of how the technology associated with virtual rehabilitation impacted their experience of care.

Methods: We conducted one-on-one semistructured qualitative interviews with patients with limb loss and chronic obstructive pulmonary disease. A reflexive thematic analysis approach was used to generate domain summaries and initial themes across the sample. Themes were generated following analytic work over a series of discussions within the research team.

Results: Sixteen interviews were conducted. Four themes illustrating participants' perceptions of compassionate care were generated: (1) features of compassionate care include feeling valued, connected, and cared for by the health care provider; (2) threats to compassionate care in virtual rehabilitation; (3) facilitating compassion in virtual rehabilitation through preparation; and (4) benefits of virtual care.

Conclusions: Patient perceptions of compassionate care in a virtual rehabilitation setting may be impacted by the behaviors and communication of providers. Provider training and preparation and the personal connections formed with their patients may impact compassionate care experiences.

KEYWORDS

compassion; rehabilitation; virtual care; virtual rehabilitation; limb loss; chronic obstructive pulmonary disease; qualitative interviews

Introduction

Virtual care refers to health care services that are delivered remotely through the use of communication and digital technologies in order to benefit patients and maximize the quality of patient care. The COVID-19 pandemic resulted in an increased use of virtual care in Canada, with broad adoption across provider groups and types of chronic disease [1]. The increased demand for virtual care during the COVID-19 pandemic is expected to continue post pandemic [2], especially for individuals and subgroups that experience challenges attending in-person, for example, due to mobility challenges [3,4].

A growing body of literature about virtual care has described its numerous benefits, including convenient access to quality care, reduced time and cost of traveling to appointments, and improved access for rural or isolated communities [5]. Virtual care is also particularly beneficial for patient populations with a high disease burden [5]. Some benefits for providers include improved care efficiency (eg, seeing more patients and fewer missed appointments) and more frequent contact between patients and providers [5,6].

There are also limitations to virtual care, such as difficulty establishing a therapeutic connection between providers and patients [7], the absence of physical examination [5,8], limited availability of physical equipment, absent or inadequate cellular

XSL•FO
RenderX

services, and the costs associated with training personnel to implement virtual care [5,6,8].

Compassion is an important cornerstone of quality health care [9-11] and a critical element of person-centered care. Compassion has been defined in several ways, including recognizing suffering in others, understanding the humanity of this suffering, feeling emotionally connected with the suffering person, tolerating difficult feelings that arise, and acting or being motivated to act to help the person [12]. Compassion has been associated with improved patient satisfaction, compliance, and clinical outcomes [13-16]. According to Hodges et al [17], digital tools can shape individuals' expectations, actions, and behaviors; impact the patient-provider relationship; and shape the experience of compassion in health care. As we continue to use virtual care options, it is important to ensure that the care offered virtually is as compassionate and of high quality as the care offered in person.

In the rehabilitation setting, compassion is important for person-centered, empathetic care [18]. Although the importance of compassion in a rehabilitation setting is well recognized, there is very limited information on how compassion is communicated when the process is virtual. Individuals who experienced lower limb amputation (LLA) and individuals with chronic obstructive pulmonary disease (COPD) are examples of populations with chronic conditions who benefit from rehabilitation services to improve symptoms, function, mobility, and health-related quality of life. Exploring the experiences of individuals with LLA and COPD receiving virtual rehabilitation will provide valuable insights to inform the delivery of compassionate, person-centered care in practice. The 2-fold objectives of this study are (1) to explore what compassionate care means to patients living with limb loss and COPD who receive virtual rehabilitation consultations and (2) to explore patients' experiences of how the technology associated with virtual rehabilitation impacted their experience of care.

Method

Study Design

We adopted an interpretive descriptive approach [19]. Interpretive description is the investigation of a clinical phenomenon of interest for the purpose of capturing themes and patterns within subjective perceptions and generating an interpretive description to inform clinical understanding. We used the COREQ (Consolidated Criteria for Reporting Qualitative Research) guidelines.

Ethical Considerations

This study received research ethics approval from the Joint Research Ethics Board at West Park Healthcare Centre (REB number: 22 - 005-WP). Informed consent was obtained from all participants prior to study participation and all data was de-identified. Participants received an honorarium of CAD $25 (US $19.59) for completing the interview. The conversion rate during the study period ranged between US $0.7203 and $0.7835.

Recruitment

Participants were recruited from a rehabilitation hospital in Ontario, Canada. Individuals who were over age 18 years and had participated in at least one virtual care appointment at the rehabilitation center were eligible to take part in the study. Participants were required to be able to communicate in English and tolerate participating in a 45- to 60-minute interview.

For feasibility reasons, a convenience sampling strategy was used. Participants with limb loss or COPD were recruited, as these clinical populations represented the majority of individuals who were offered virtual care in the rehabilitation setting. Sampling from 2 subgroups was appropriate for this study because the research focus was on the experience of compassion during the virtual care interaction, rather than on any condition-specific issues. Where experiences or perceptions vary between subgroups, this is described in the Results section.

Individuals who consented to be contacted for the study and had completed a virtual visit were approached to participate in the study. Informed consent was collected prior to an interview taking place.

Data Collection

One-on-one interviews using a semistructured interview guide were conducted remotely via telephone or Zoom. Interviews were conducted by one researcher (BL). The interview guide was developed by the research team based on previous literature (see Textbox 1).

Textbox 1. Interview guide.

1. Can you first briefly tell me about yourself and what led to your need for rehabilitation?
2. I understand you had a virtual or remote consultation with a health care provider related to your condition or disability. Tell me about that experience.
3. Tell me about what it was like having your consultation with the team virtually.
4. What worked well about the virtual consultation?
5. What did not work well about the virtual consultation?
6. We often talk about the importance of compassion in health care. What do you understand about the word compassion when you hear it?

Interview questions were open-ended, exploring virtual care experiences, including what worked well and what did not work well, the meaning of compassion, and the experience of compassionate care. Probes were used to elicit more in-depth information and clarify participant responses. After each interview, the interviewer wrote supplementary field notes to

XSL•FO
RenderX

allow emerging insights to be incorporated in the ongoing data collection. Data collection and analysis were iterative. Demographic and clinical information was collected to describe the participants. Interviews ranged between 25 and 48 minutes.

Data were collected until researchers were satisfied that data were comprehensive enough with sufficient depth of data to identify recurrent thematic patterns in addition to having breadth of experiences in the context of the study setting. Interviews were recorded and transcribed verbatim. NVivo (Lumivero) qualitative software program was used to organize the data.

Analysis

A reflexive thematic analysis approach was used to generate domain summaries and initial themes, or patterns of shared meaning united by a core concept [20]. A coding framework was developed following data familiarization [20]. Two researchers familiarized themselves with the data by reading transcripts (BL and CM) before meeting to develop a preliminary codebook with codes and code descriptions. The codebook was used to code 2 additional transcripts, and revisions were made to the codebook. Subsequently, 2 researchers (BL and PF) coded each transcript. Incorporating 2 researchers allowed us to explore multiple assumptions or interpretations of the data. Memos were written as part of the analytic process to encourage reflexivity. Field notes were written after every interview, and notes were summarized and discussed.

Two reviewers (PF and AT) reviewed all codes and separately generated domain summaries before meeting approximately 5 times to discuss and record their interpretations of the data. Themes were generated inductively during this process. Following the generation of initial themes and domain summaries, 3 team meetings between researchers (PF, AT, and CM) were held to question one another, discuss and refine themes, clarify language, and interrogate the data to consider alternative interpretations.

Consistent with reflexive thematic analysis, the researchers played an active role in knowledge production and generation of themes [20] and considered the interpretation of the data. Themes were generated following analytic work over a series of discussions and were actively created through creative labor involving coding, discussion, questioning, and decision-making [20]. Memos and diagrams were generated to summarize and interpret the data. Demographic and clinical information was collected and summarized using descriptive statistics.

Results

Participants

Sixteen participants consented to take part in the study and completed the interview. The sample consisted of individuals with limb loss (n=7) and individuals with COPD (n=9). A description of the study sample is provided in Table 1.

XSL•FO
RenderX

Table . Demographic data.

Characteristic	LLA[a] (n=7), n	COPD[b] (n=9), n	Total (n=16), N (%)
Gender			
Female	1	4	5 (31)
Male	5	4	9 (56)
Employment status			
Full time	0	1	1 (6)
Retired	5	5	10 (63)
Unable to work	1	2	3 (19)
Education (highest)			
High school completed	1	3	4 (25)
Some college or university	3	2	5 (31)
College or university completed	2	3	5 (31)
Living arrangement			
Alone	0	2	2 (12.5)
Spouse or partner	3	3	6 (37.5)
Children	1	1	2 (12.5)
Spouse and children	1	1	2 (12.5)
Parents	1	0	1 (6)
Sibling	0	1	1 (6)
Age (years), mean (SD)	61.33 (15.77)	70 (10.54)	66.29 (13.24)

[a]LLA: lower limb amputation.

[b]COPD: chronic obstructive pulmonary disease.

[c]Responses to demographic questions were provided by 14 of 16 study participants. Two participants could not be reached following the interview to complete the demographic questionnaire; therefore, data for those participants are missing.

Four themes were generated to illustrate participants' perceptions of compassionate care based on their experiences with virtual care in a rehabilitation setting.

Theme 1: Features of Compassionate Care: Feeling Valued, Connected, and Cared for by the Health Care Provider

Overview

This theme characterizes participants' perceptions of the key features of compassionate care. While the features may not be unique to virtual care, they were seen as important components of compassion in the context of virtual rehabilitation. Several participants described compassion as a feeling of being taken care of, being heard, and being validated. Compassion was equated to caring, kindness, understanding, and warmth. They described compassion as positive, personal, and individualized, not judgmental or offensive. One participant indicated compassion made them feel valuable, like their life is worth something. Reflecting on their experience of compassionate care, one participant stated:

> *I feel good. I mean it's very, you know, it's you feel safe. You feel looked after. You feel heard. It's very helpful and I think it can - overall contributes to the healing process if you've got someone who cares.* [Participant 2]

The following subthemes further describe the core components of compassionate care from the participants' perspectives.

The Caring Health Care Provider

A health care provider's (HCP's) ability to offer empathy, reassurance, caring, and attentiveness influenced participants' experience of compassion. Being caring was most often associated with compassion. For example, one participant stated having a caring and empathetic HCP was more important than other aspects of bedside manner. Caring was described as the effort that HCPs made to show patients they are valued. This included caring actions such as remembering specific details about the patient and asking questions. When participants reflected on instances of genuine caring, their accounts highlighted the importance of authenticity in caring and the importance of an HCP being curious, observant, and attentive and having genuine concern about how their patients are doing. One participant shared this perspective about caring for HCPs and compassion:

> *To me compassion is authentically, authentic concern and care for an individual. You can put it on and pretend it, you can fake it, you could, but compassion is when it's authentic genuine care and concern for*

XSL•FO
RenderX

> *the wellbeing of someone else and you want the very best for them and the very best outcome for them.* [Participant 3]

Reassurance went hand in hand with caring and was also an important part of compassion. Many participants indicated they felt reassured when HCPs addressed their questions or concerns and went out of their way to be caring. Reassuring words and actions from the HCP helped establish comfort and trust, and made the patient feel like they could turn to and trust the HCP. Many participants shared stories about a difficult moment when an HCP was reassuring to them—participants valued this and interpreted that as compassion. One patient described that compassion involves the HCP understanding what is going on with the patient and advising and acting from that understanding.

Patient-Centered Behaviors: HCPs' Willingness to Help

Participants sensed compassion when HCPs seemed motivated to take action to care for them and were willing to help. Compassion was expressed as actions or words and involves "doing the little things" and "going the extra mile." Participants shared:

> *So, it can be actions. It can be words. It can be just making, you know, those, a lot of time it's words, just making sure like you know, if there's anything you need at all you just, please, please don't hesitate to call and let us know. We're here for you. That kind of extra bit.* [Participant 3]

> *I'm not very tech savvy, so yeah, the pictures I sent but I didn't send it to the right spot. So, then actually the doctor was on the phone with me and said, okay, this is how you do it and he started to help me, and we got it done…Yeah, so he was very, very…he's very helpful in all aspects…And anything that you need or anything – any concerns that you have, he addresses them…I mean usually they don't – doctors don't give you that kind of care, like, you know what, they brush you off and say okay, well you know what, you're gonna have to figure out – maybe get somebody to help you, no, he helped me…But yeah, step by step. Above and beyond.* [Participant 6]

> *And then with the virtual class now, one lady she does exercises with you and then there's another lady. I think she's just watching everyone to make sure everybody's okay. And if she sees that you look kind of distressed, she'll call you up and say…She'll say like I think you should just stop a minute, …they show compassion to everyone to make sure you're okay…You know, it's not just, okay, do this, do that and that, okay, next do this, do that. No. They make sure you're okay.* [Participant 14]

Willingness to help involved a genuine interest from an HCP for doing things to improve patients' well-being, including taking a step beyond traditional duties and building personal relationships. Many participants provided examples of HCPs exhibiting a willingness to help, which made participants feel cared for and motivated to get better. Participants consistently expressed that compassion felt like it was more than just doing a job and should not feel like it is a business. One participant stated:

> *To me, I never – I never really felt that, oh, you know, this is just – you're just a number and here we go. I find that they're very compassionate and they're very helpful to what you need. And I never felt brushed off, like, never rushed.* [Participant 6]

HCP Communication

Effective communication by the HCP helped participants feel compassion during virtual care appointments. Participants valued a HCP with good communication skills (eg, could "carry a conversation well"), who was personable, social, and attentive. Participants also felt better cared for when the HCP was organized, spoke clearly, and could be easily understood, and when the HCP made an effort to have a personal connection and to make patients feel comfortable (eg, by engaging in conversation outside of their medical condition). The attitudes, mannerisms, and tone of voice of the HCP conveyed compassion. Many participants interpreted clarity of information provided by the HCP as a component of compassion, as it enabled them to have a good understanding about their health condition. Several participants highlighted their preference that HCPs use language that could be easily understood and take the time to explain what is going to happen. One participant reported the following about HCP communication with patients and compassion even when they may not completely understand the experience:

> *…the doctors talk to you and explain things as if they were an amputee. Like they're not just saying do this, do that, you know, they kind of – I found it anyway that they really understood it and didn't make you feel like you were just some, you know, some guy with their leg cut off type thing. Like they understood, kind of understood what I was going through. And did their best to help me in that respect.* [Participant 5]

Participants indicated that not feeling rushed was an important part of making a connection with the HCP. In a virtual appointment, the conversation remained focused on the purpose of the appointment, and the duration of the appointment did not typically exceed what was scheduled. Compared to in-person care, where discussion could veer in many directions and many questions could be asked, some participants felt rushed during virtual appointments. One person shared their views on how feeling rushed may impact the experience of compassion:

> *That's just some of the things that was kind of like it just feels like the doctor doesn't really care or, you know, he's not compassionate about you. He's just more compassionate about getting his job done for the day type of thing.* [Participant 4]

Theme 2: Threats to Compassionate Care in Virtual Rehabilitation: Making a Connection

This theme illustrates the unique challenges of delivering compassionate care in a digital setting based on participants' experiences with virtual care. From the perspective of some participants, compassionate care was threatened when there was

XSL•FO
RenderX

an inability to see the HCP in a virtual appointment. When individuals struggled with technology and required a phone consultation rather than video, some participants suggested this impacted their ability to connect with the provider, as they could not see visual information such as the HCP's face, facial expressions, and mannerisms. One participant stated:

> *Well, I think that's more difficult because it's just – it's not on the same level. You know. When you're standing next to a person or you're standing next to you, you do have that personal observation, that personal connection and on a screen you don't.* [Participant 15]

The lack of body language and expressions could make the visit feel impersonal. As such, one participant recommended the importance of an in-person meeting prior to virtual meetings so they could become familiar with the HCP.

> *Well, I think it would be important that there is a physical meeting before. So, you go in and you visit the physician face-to-face. So, when somebody is talking to you on the phone, it's not a disembodied voice, you can actually have a picture in your head, what this person looks like, some of their mannerisms so you start to feel more comfortable of what is going to happen. I think if you were to do a virtual – it gets very clinical. It gets very – well, I shouldn't use the word clinical. But it gets to be very sterile. Here is the question. Answer it. Move on. Next. You know, conclusion, we're out of here. See you.* [Participant 1]

As a result, most participants strongly preferred video over phone connections, stating the visual information made them feel more comfortable, and several participants linked this to the experience of compassion in virtual care.

> *Well, you know the whole compassionate aspect, it's only words really. You can't see the person. Well, I guess it would be a visual thing. I mean you can't really see their reaction or, you know. Talking to someone on the phone, you can't tell if they're, you know, what their feelings are or whatever.* [Participant 7]

Other participants identified the lack of touch to be a limit to connection in virtual care. This not only limited the HCP's ability to assess the patient fully but also could limit the connection for some participants as described by one participant:

> *Like just listen. Listen to their -- listen to their pain. Be sad if they're sad. Be happy if they're happy. I'm -- like, you know, I don't know. I mean you can't hold them. Like you can't reach out and touch them. And touch is being the greatest compassion at all that there is. And so, you can't do that. So, you got to try to do it with your eyes, with your expressions, with your facial expressions, etc.* [Participant 9]

One participant's account showcased the challenge of delivering compassionate care in a digital setting. The participant shared:

> *Well, all of the video calls that I had with my doctors, the only one doctor I didn't like how he handled his was that he used to go by a window frame. As soon as that window's over, your time's up type of thing. So, if he gives you a fifteen minute video call or a call or virtual call or whatever you want to call it, and then in that fifteen minutes your time's up and you didn't get to say what you wanted to say or the help that you needed wasn't provided at the time, that's the only downfall I see in the system…That's just some of the things that was kind of like it just feels like the doctor doesn't really care or, you know, he's not compassionate about you. He's just more compassionate about getting his job done for the day type of thing…So, that's the only downfall I had with my virtual appointments.* [Participant 4]

To mitigate some of the innate challenges to providing compassion in virtual care, some participants suggested that prior to delivering virtual care, HCPs should receive training on communication skills about etiquette such as making eye contact, using an interesting background, and not taking calls in non–health care settings. Some participants also discussed the benefits of forming a personal connection to establish rapport with the HCP prior to starting virtual care, for example, via a one-on-one call.

Theme 3: Facilitating Compassion in Virtual Rehabilitation Through Preparation

In this theme, participants highlighted the impact of adequate preparation by the HCP in advance of the appointment on their experience of compassion. Participant descriptions about preparation for the appointment revolved around 2 aspects of the appointment: the behaviors and actions of the HCP and the logistics surrounding the appointment.

Behaviors and Actions of the HCP

Many participants indicated that when HCPs exhibited confidence in the technical skills required to run a virtual appointment or familiarized themselves with patient files and patient history, these actions heightened participants' feelings of compassion in virtual rehabilitation. One participant illustrated how this was linked to compassionate care:

> *…But the doctor, you know, he remembered specifically what had happened at last year's visit…And he remembered the condition of the stump and he specifically asked, you know, did that, you know, has that stayed in that condition and yeah. He just – I think he cares I suppose. I think that's the overwhelming impression that I get left with… and if he doesn't remember, he's at least taken two minutes before getting on the horn and he's looked through my file and he's realized what he's done before, and he can make a comment on it. He familiarized himself with me that's all. And so, and that, you know, I mean whether or not that's his actual memory or not, it doesn't matter. It comes across to me as, you know, as make me feel cared for and important and all that.* [Participant 2]

XSL•FO
RenderX

The experience was also described as more positive and pleasant when the HCP used a visually welcoming background during video calls.

HCP and Appointment Logistics

Participants indicated they perceived greater compassion in virtual care when they were clear in advance of their appointment on what to expect during their appointment. Participants felt better prepared when the purpose of the call was clarified, when they were informed about what would be happening during the appointment (eg, whether it will be telephone or video-based, which questions they might be asked, and which exercises they would be doing), and when they received instructions about how to join the call. When participants felt better prepared, they were more relaxed and confident about virtual care.

Some participants described the benefits of offering training to HCPs on the fundamentals of delivering virtual care, noting that such training could streamline HCP behaviors and appointment logistics. For example, one participant explained:

> *I mean take a Zoom 101 basics course or something like that (laughs) All those goofy mistakes that, you know, there's not a bright light behind him. All that sort of, you know, practical stuff. I think if you take all the technical stuff out of it and make it easy in that respect, you're just going to get better results trying to convey any kind of emotion through video.* [Participant 2]

Theme 4: Benefits of Virtual Care: Fitting Health Care Into Life

This theme describes how delivery of care virtually ensured that participants could fit their health care into their lives, enabling patient autonomy and control. The use of technology enabled participants to receive care while staying home, enabled them to be efficient with their time, and in some instances, offered additional autonomy and independence in their lives. Patients reported shorter wait times for virtual appointments; patients were seen sooner and had a greater number of touchpoints with the HCP, as it was much easier and faster to get to an appointment. Virtual appointments occurred on time as compared to in-person clinic visits, which often ran late. Through virtual care, patients avoided spending time on unnecessary tasks such as driving for long hours; finding parking; using a wheelchair, walker, or other assistive devices; and having someone else drive and attend the appointment, all of which were not required for virtual care. This was convenient for participants, and notably, it granted participants more autonomy and control in their lives since the call could be done independently and did not necessitate, for example, someone to drive them to the appointment. Participants shared the following views about attending appointments virtually:

> *And honestly, I think that that system is working much better, and it should be better for like I'm pretty sure any patient that's disabled. Like it would make your life so much easier and it's like you're in control. You don't have to go out of your house, get in a wheelchair or any assisted devices, get into a vehicle, have someone drive you or drive yourself, you know, it's more of a hassle, right, that you have to leave earlier. So, this is like more convenient for us I guess or not just us, but like for anybody, it's more convenient that you can do a virtual doctor's appointment and get the treatment that you need.* [Participant 4]

> *To me, that was great. I don't know about other people, but for me, it was great because I didn't have to try and get ready, try and get dressed. Put on the oxygen. Try and get in the car. Take the walker and trying, try and find where it is in the hospital. And then it's only like a half hour appointment, then you got to do all the things back home again. So, it was ten times easier for me.* [Participant 9]

While the option of virtual care often promoted autonomy, there were examples of participants still requiring assistance to partake in virtual care. A few participants noted they had the technology available but lacked the knowledge and confidence to use the technology to facilitate the call, especially to initiate the call. As such, they enlisted help from others, including family members and care staff, to facilitate the call or obtain the technology. One participant described:

> *Well, (laughs), if it wasn't for my grandchildren and my daughter, I wouldn't be able to do anything with technology because I'm one of them old farts that just – I can talk on the phone…* [Participant 5]

One participant suggested an approach by which the HCP and their team could assist patients with becoming oriented prior to the scheduled call, enable autonomy, and ensure a successful consultation:

> *So, it's just like there should be like an educational assistance, tutorial or a video of what apps or doctors if do use like virtual calls, have the person sit fifteen minutes earlier so they know how to flip the video over on the camera. So, there's a front camera and a back camera, right. So, like little things like that. I think that – if there was like a little tutorial on that just before your video call it would be fresh in your mind and I guess that'll help a lot of patients.* [Participant 4]

In most situations, virtual care enabled participants to fit their health care into their daily lives, allowing them to adjust to various circumstances (eg, patients' roles and responsibilities and weather conditions). For example, one participant highlighted that virtual appointments enabled them to sleep in, take calls in their pajamas, and even be home to receive packages and do other tasks. One participant reflected on the additional conveniences available to him; notably, attending virtually allowed him to continue being available to help his wife, who was also an amputee and to whom he was a caregiver.

In addition, the option of virtual care often enabled patient preferences to be incorporated into their health care. For example, HCPs often accommodated to the patient's schedule. Some participants noted scheduling an appointment seemed flexible and was not a hassle. One participant reflected on the flexibility:

XSL•FO
RenderX

> *And they're always very convenient. That's the nice thing about the doctors are very flexible with their times. If I'm not available, I found that they're available at a different time. I think their time is a little bit different schedule for sure. So that is, that is an advantage. That okay, if you can't talk between 10:00 and 10:15, can we talk to you between 1:00 and 1:15 and that kind of thing. So that's nice because that makes it feel like it's not all on you to have everything figure out according to their schedule. It's still that your personal situation still matters.* [Participant 3]

The option of virtual care also provided safety and comfort to some participants by offering relief from concerns about the COVID-19 pandemic. A few participants described their concerns about being exposed to COVID-19 while attending appointments in person and while waiting for appointments. Participants expressed that virtual appointments offered a sense of relief and comfort and were a safer alternative that allowed them avoid going in to hospitals during the pandemic. For example, one participant noted:

> *…with the virtual visits I, of course, and being scared of Covid like everybody was, it puts your mind at ease that I didn't have to take a chance of going down and because it was actually a visit to the hospital.* [Participant 5]

Discussion

Principal Findings

This study provides an understanding of the perceptions and experiences of compassion in virtual rehabilitation from the perspective of individuals with ongoing functional disabilities as exemplified by LLA or COPD. These findings extend our understanding of the meaning of compassion from a patient's perspective and shed light on key elements of compassionate care. By highlighting how compassion can be enacted in clinical encounters and the unique facilitators and threats to compassionate care in digital environments, these findings can be used to inform strategies to support HCPs to optimize the delivery of compassionate virtual care for people in rehabilitation settings.

First, our research provided insight on how participants perceived compassionate care. Our study reported that a feeling of connectedness with the HCP, an HCP's genuine concern and willingness to help, and patient-centered communication by the HCP are paramount for compassionate care. This is consistent with prior research in which previous definitions of compassion in both face-to-face and virtual health care settings focused on connection and concern for patients. Baguley et al [21] highlighted the importance of connection in a health care setting. They reported that 71% of participants in their sample felt compassion when the practitioner displayed listening and paid attention. A recent qualitative study by Wu and colleagues [22] examined patient-provider communication and compassion in a virtual setting and highlighted the important role of the patient-provider connection. The authors noted that feelings of autonomy and being prioritized were foundational for experiencing compassionate care in a virtual care setting.

Participants identified unique threats to compassion in a digital environment, including lack of connection with the HCP. We also identified new insights about the ways in which HCP actions navigating virtual care during appointments; appointment logistics and HCP preparedness for consultations enhance patient comfort and feelings of compassion during a virtual visit. Study findings are consistent with recent work by Desveaux and colleagues [23] in a primary care setting, which illustrates that a provider's behaviors are linked to how compassionate care is perceived by patients.

Wu and colleagues [22] suggest the importance of virtual training in offering clinicians the requisite technical, examination, and communication skills for positively impacting their comfort and preparedness for virtual interactions with patients. Such strategies may help to address some of the threats to compassionate care imposed by virtual care by enabling people to have successful virtual visits. Delivering compassionate care may call for structured preparation and training of HCPs to deliver virtual rehabilitation (eg, digital skills and communication skills in a digital environment). Future work is needed to explore best practices to facilitate compassionate behaviors in virtual care and the optimal models for training HCPs for compassionate virtual care.

Interestingly, participant perspectives reported in our study suggest an interplay between compassion and autonomy and comfort experienced in virtual rehabilitation. Participants identified several benefits of virtual care, including that wait times were shorter, they expended less time and energy to attend virtual appointments as compared to in-person care, and appointment times were more flexible. This is consistent with literature highlighting the convenience of virtual care [5,6]. However, our findings suggest that the benefits go beyond convenience for populations with complex health needs by enhancing a sense of control, autonomy, and independence, with less disruption to other aspects of daily life.

Study Limitations

For pragmatic reasons, we recruited a convenience sample of individuals who attended a virtual appointment. This method may not have captured those who faced major barriers and were unable to access virtual care. There was variation in the mode of virtual care and types of virtual appointments that participants had attended (eg, phone and video) and the nature of the activities that were being completed during the virtual appointment (eg, physiotherapy and consultation with a nurse or doctor). While participants received at least one virtual rehabilitation consultation, some participants had additional virtual interactions, for example, as a result of participating in virtual exercise in a group setting. We did not ask study participants about the total number of virtual appointments they attended, and thus, could not consider how their level of experience and comfort with tools and technology may impact their perspective about their virtual care interaction. Findings may not be transferable to other settings or populations due to the unique needs and experiences of the participants in this study. Moreover, participants who opted for virtual care may

XSL•FO
RenderX

have different characteristics than those individuals who did not or could not access virtual care.

Conclusion

Our study identified key aspects of the patients' perception of compassionate care in virtual rehabilitation settings. Ensuring that HCPs are prepared and adequately trained in forming personal connections with patients, communicating effectively in a virtual setting, and using the tools necessary to facilitate the connection prior to initiating a patient-provider relationship in a virtual setting will contribute to this being a positive patient experience. Future work could explore whether virtual care should be introduced only when extending an existing face-to-face patient-provider relationship and whether virtual care might be reserved to address only certain needs within the care journey. Potential changes to patients' attitudes and perceptions about virtual care as they progress through their care journey and develop rapport with their HCP could also be explored.

Abstract

Background: Web-based concussion self-management education programs for adolescents can improve functional outcomes, reduce concussion symptoms, and increase self-efficacy. However, there are a limited number of studies examining the perceptions and acceptance of these programs and the use of these tools in the adult concussion population.

Objective: This study aimed to investigate the perceptions and acceptance of clinicians and adults with concussions using MyGuide Concussion (Vancouver Coastal Health), a web-based concussion self-management tool.

Methods: Using a mixed methods sequential explanatory design, a convenience sample of 8 adults with concussions and 8 clinicians who used MyGuide Concussion over a 2-year period were interviewed, and their responses were analyzed.

Results: Participants reported two key benefits of using the web-based self-management tool: (1) the tool's emphasis on the interconnectedness of physical and psychological symptoms, and (2) the ability to provide reassurance that symptom being experienced were a normal part of the concussion experience. Clinicians described the tool as being useful as a supplementary source of information for clients in addition to clinical sessions and believed the content was useful for increasing clients' independence in managing their own recovery.

Conclusions: Overall, the evaluation of the MyGuide tool is an acceptable and well-perceived tool for adults with concussions who require a basic understanding of concussion recovery, particularly in the early stages of recovery. Future research may include optimizing MyGuide by targeting promotional strategies and addressing other barriers to use.

KEYWORDS

concussion; self-management; health information technology; perceptions; concussion recovery; concussion management; concussion rehabilitation; rehabilitation; self-management tool; perception; digital health; e-health; mobile app; mhealth; web-based tool

Introduction

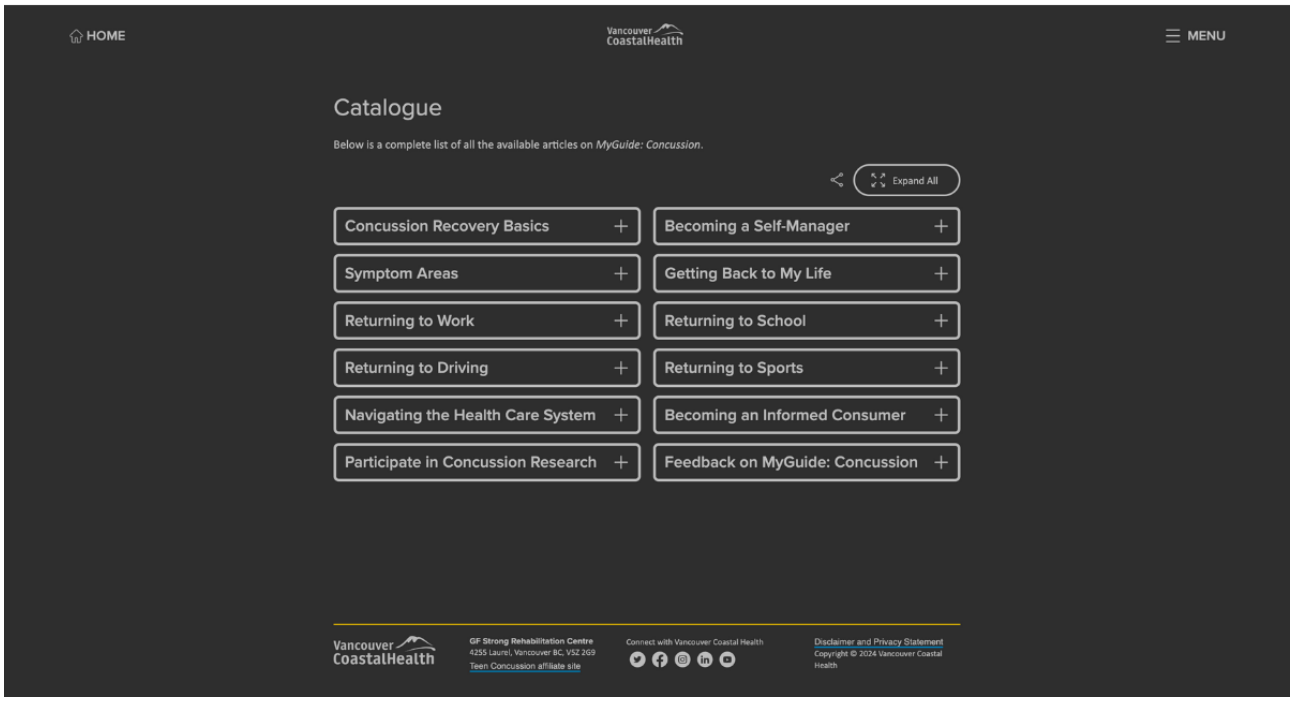
Lifetime concussion prevalence in adults has been estimated to be as high as 29% [1], with an annual incidence rate of approximately 1.2% in recent years being the highest it has ever been [2]. Concussion symptoms vary between people and across an individual's recovery process [3]. Symptoms can be experienced as physical (eg, nausea, headaches, and decreased

XSL•FO
RenderX

balance), psychological (eg, worsened anxiety, depression), or cognitive (eg, changes in concentration and memory) [4-6]. While most people recover within 2 weeks without intervention, some people experience persistent symptoms [7].

Self-management is a type of educational intervention that provides an individual with strategies and lifestyle behavior changes to manage the injury and improve overall recovery [8]. Concussion self-management (eg, information about concussion symptoms, prognosis, self-management behaviors, and resuming preinjury roles) can improve a person's understanding of their injury and related symptoms such as sleep and anxiety, reduce postconcussion symptoms [9-11] and facilitate recovery and return to preinjury activities and roles [12-18]. Furthermore, the timely provision of concussion education in the early stages of recovery has been found to lower the risk of developing prolonged postconcussion symptoms, especially for those with more severe traumatic brain injury (TBI), and when implemented within 3 months of injury [13,19]. Though there is no consensus on the optimum time for the introduction of concussion education, studies reporting improvements mainly focused on participants who were between 1 week to 6 months post injury [13,17].

-Technology-based education programs for individuals experiencing concussion symptoms show promise for improving recovery outcomes and self-management self-efficacy, given their accessibility and convenience, particularly for those living in rural and remote areas or areas that do not offer specialized health services [20]. For clinicians, the web-based delivery of health services and education can enhance clinician-client engagement and improve client-driven active participation in their own health [21]. For adults, a self-paced, web-based educational intervention for civilian, military service members, and veterans with postconcussion symptoms was found to increase self-management self-efficacy and improve concussion symptoms for individuals that had longer periods since injury (ie, 1 year) [22]. Overall, the evidence, though limited in amount, supports technology-based concussion education programs as a far-reaching and accessible approach to enable behavioral change, improve recovery outcomes, and help individuals return to their occupations before their injury.



The MyGuide Concussion tool (Vancouver Coastal Health) aims to provide current best practice knowledge to help individuals with a concussion manage their symptoms and empower them with the skills and confidence to take action in their recovery journey. While there are a number of websites that provide evidence-based concussion education, the MyGuide Concussion tool was designed to fill a gap by providing customized material and actionable ways to implement evidence-based self-management strategies into daily life. It will thus be referred to as a self-management tool. The tool was developed in 2019 by experienced clinicians working in the field of concussion, content experts, and through consultation with community stakeholders. The clinical material provided in the MyGuide Concussion tool was based on the Guideline for Concussion/Mild Traumatic Brain Injury & Persistent Symptoms developed by the Ontario Neurotrauma Foundation [23], and information is updated every 6 months. The MyGuide Concussion tool creates a personalized guide for each user, specifically targeting adults (ages 18 years and older) at any stage of recovery. Content is based on modules that include information, tools, and worksheets on relevant topics for people with concussions, as shown in Figure 1. The tool provides reminders to facilitate positive health behaviors and promote self-management while engaging with the tool (eg, taking regular breaks). Though intended to be used on a desktop computer, the MyGuide Concussion tool can be used on any device that can access the internet site.

Much of the literature on technology-based interventions involves randomized controlled trials examining postconcussion symptom improvement after interventions; however, in addition to quantitative measures, understanding the perceptions and acceptance of self-management tools is essential to identify barriers and facilitators to adherence and effectiveness of these tools. In a study on digital health interventions for concussion in adults, the perceptions of the intervention were positive, with high overall usability [24]. Another study implemented a web-based concussion education program and indicated that the concussion education program was easy to use and helpful for participants' recovery [25]. Overall, the perceptions and acceptance of web-based concussion education programs for adults is a relatively underexplored area, and it is important to continue to explore the design considerations that may be unique to this particular population. Importantly, the perceptions of the MyGuide Concussion tool have not yet been investigated.

The main purpose of this study was to evaluate the perceptions and acceptance of the MyGuide web-based customizable concussion self-management tool in the adult population. Perceptions will be determined based on usability, accessibility, and suitability of the site, and acceptance will be evaluated based on adherence to and impact and relevance of the site.

Methods

Study Design

This study used a mixed methods sequential explanatory design [26]. Integration of quantitative and qualitative data occurred at the level of sampling and analysis [27]. For sampling, we used a connecting approach in that participants who completed the quantitative surveys were invited to participate in the qualitative interviews. For the analysis, we used a merging approach, in that we compared responses from the surveys to comments from the interviews to identify any differences and gain a deeper understanding of the perceptions and acceptance of the MyGuide Concussion tool. Qualitative interview questions were developed based on responses provided in the quantitative surveys. The Design and Evaluation of Digital Health Interventions (DEDHI) framework was used to develop survey and interview questions in order to understand the perceptions and acceptance of using MyGuide. The DEDHI framework is a consolidation of various health promotion evaluation frameworks and life cycle models specific to digital health programs and can be used in all aspects of the technological life cycle, from early conceptual models to large-scale implementation in the health care sector [28].

Quantitative Recruitment

Recruitment occurred from December 11, 2020, to May 31, 2021, using convenience sampling. Recruitment for the survey was done through a pop-up window that appeared on the MyGuide Concussion tool. Individuals with concussion were included in the survey if they were 19 years or older, experienced a concussion within the last 2 years, and used the MyGuide tool. Individuals with any neurological health condition (eg, stroke, multiple sclerosis, Parkinson, and spinal cord injury) that may require services and resources beyond the scope of the tool were excluded from the study.

Quantitative Data Collection

A total of 8 participants with concussions completed a 10- to 15-minute survey conducted online or by telephone from January 24, 2021, to May 30, 2021. The survey included questions about general demographic information and an outcome measure of technology usability (Health Information Technology Usability Evaluation Scale (Health-ITUES)). This measure consists of 20 items with 4 subscales of impact, perceived usefulness, perceived ease of use, and user control, which have been used to assess the usability of web-based programs for adults living with a chronic health condition [29]. The measure has demonstrated high internal consistency reliability (Cronbach α=0.85-0.92).

Quantitative Data Analysis

The data are reported using the Good Reporting of a Mixed-Methods Study [30]. Quantitative data were analyzed using descriptive analysis to describe the demographics and Health-ITUES questionnaire.

Qualitative Recruitment

Recruitment occurred from February 7, 2021, to September 9, 2021. Participants with concussions were invited to participate in the qualitative interviews once they had reached the end of the quantitative survey. Recruitment for clinicians occurred through the use of the researchers' professional network. Clinicians were included if they were currently working in the concussion rehabilitation field for at least 2 years, had therapeutic roles (eg, occupational therapists, physiotherapists, doctors, and neurologists), were practicing in British Columbia, and were familiar with or used the content in the MyGuide tool.

Qualitative Data Collection

Participants (both clinicians and people with concussions) engaged in online semistructured interviews through Zoom [Zoom Video Communications] from February 7, 2021, to

XSL•FO
RenderX

September 9, 2021. The interview guides for participants with concussions are provided in Multimedia Appendix 1. The interview guides for clinician participants are provided in Multimedia Appendix 2. Interview questions for participants with concussions were adapted from a previous study that examined the user experiences of a self-management tool for individuals with spinal cord injury and their caregivers [31]. Qualitative analysis occurred alongside data collection to ensure data saturation was obtained.

Qualitative Data Analysis

The qualitative data were analyzed using conventional content analysis. This involves an inductive process of reviewing the data as a whole, then deriving codes from the individual responses themselves and categorizing these to identify connections and relatedness [32]. Conventional data analysis allows researchers to avoid imposing preconceived ideas or categories on participants and, instead, to focus on getting information directly from participants [32].

The qualitative data followed a 2-step analysis process**.** First, qualitative interview data were recorded and transcribed verbatim using a transcription program. Once transcribed, 2 researchers reviewed the transcripts and audio recordings for accuracy and removed any potential identifiers to protect participant identity. Each performed conventional qualitative content analysis separately and then compared to ensure accuracy and resolve any interpretive discrepancies. Both researchers performing the analysis were female undergraduate students, one with a background in behavioral neuroscience and the other in biology and psychology.

The research team used two main trustworthiness strategies. First, the authors were mindful of their positioning throughout data collection and analysis. A diverse range of perspectives was included to establish consensus in data analysis, including the remaining authors following the first round of coding. Complementary perspectives on the data were thus acknowledged, which allowed the authors to reflect on their biases [33]. Second, rich verbatim quotations from the interviews were included in the results to fully capture the voices of participants and increase the credibility of the findings [33,34].

Ethical Considerations

Ethics approval was completed by the University of British Columbia’s Behavioural Research Ethics Board (H20-02982).

Results

Quantitative Results

A total of 8 participants with concussions completed the surveys. Participants with concussion included 4 female and 4 male participants with an average age of 33.8 years (SD 12.3; Table 1). Health-ITUES scores are included in Table 2.

XSL•FO

Table 2. Health-ITUES (Health-Information Technology Usability Evaluation Scale) scores of participants with concussion.

Scale	Mean (SD)
Impact	4.41 (0.46)
Perceived usefulness	4.10 (0.57)
Perceived ease of use	4.42 (0.46)
User control	3.93 (0.45)

XSL•FO
RenderX

Perceptions: Usability

The Health-ITUES subscales Perceived Ease of Use and User Control were used as indicators of ease of navigation of the tool, with higher ratings indicating higher perceived ease of use and user control domains. Results showed relatively high scores by participants with concussion, with the perceived ease of use being 4.42 (SD 0.46) and user control being 3.93 (SD 0.45) on a 5-point scale. Most participants were using the MyGuide tool on the desktop platform.

Acceptance: Adherence

Both quantitative and qualitative data were used to understand adherence to using the tool. Survey data suggested that most participants had 1 to 5 visits to the tool in total. Furthermore, the survey data indicated that almost half of users completed 5 or more of the 11 modules.

Impact

Based on the Health-ITUES measure, where a rating of 5 on a Likert scale indicates strongly agree, Perceived Usefulness was 4.10 (SD 0.57), Impact was 4.41 (SD 0.46), and Overall Usability was 4.27 (SD 0.35). These high scores indicate that the tool had a positive impact on self-management and quality of life. Participants with concussion reported that they were looking for strategies to manage their concussion symptoms (8/8, 100%), more information about concussion symptoms (7/8, 88%), specific strategies for returning to normal day-to-day activities (7/8, 88%), and information on how to navigate the health care system (5/8, 63%). Overall, survey data suggested that people with concussions were either satisfied (4/8, 50%) or very satisfied (3/8, 38%) with the tool and generally described that the tool had met their needs (6/8, 75%). Respondents indicated that the tool provided background information about concussion, provided ways to manage concussion symptoms, and motivated recovery. All survey respondents indicated they would recommend the tool to other people with concussions, as they noted it was informative and provided people with reassurance and normalization of symptoms being experienced.

Qualitative Results

A total of 8 participants with concussions and 8 clinicians were included in the study. Participants with concussion included 4 females and 4 males with an average age of 33.8 years (SD 12.3; Table 1). Clinician participants included 7 occupational therapists and 1 physiotherapist, averaging 13.1 (SD 10.8) years in clinical practice with 8.5 (SD 4.7) years in concussion rehabilitation specifically (more details in Table 3).

Table 3. Demographics of clinician participants.

Characteristics	Participants, n (%)

Perceptions

Usability

Interview data provided context to the quantitative data. The majority of participants with concussions reported that the tool was simple and straightforward to use. One participant said, “[the website is] very linear... It shows you what you’ve done and, what you haven’t, and what you need to do next… It’s very, very well structured.” Participants also indicated that the clearly labeled topics, easy-to-understand section titles, and simple layout of the tool made it easy to find information. However, some participants reported confusion around use and navigation when initially using the tool independently, without the facilitation of clinicians.

Interview data from clinician participants indicated that the tool provided useful, curated, easy-to-understand, and credible information. One clinician explained:

> *Having one sort of a one-stop shop of information that's easy to go through is useful… [people with concussions] get lots of different information from different providers, and if they're symptomatic at the time, it's hard to take it all in…having somewhere just one source to go to is helpful. [The tool is] in an easy-to-read format, so it's not a lot of medical speak.*

Some clinician participants mentioned that some sections had a lot of information, which may have made clients feel overwhelmed.

Accessibility

Participants seemed to show a preference for different visuals than others (eg, dark mode vs light mode, and font sizes), and many described the value of the individualization and customization of the tool. Participants also reported that the concussion-specific accessibility features inherent in the tool (eg, clear, short sections of information) were helpful in creating

XSL•FO
RenderX

an accessible tool. One participant stated, "[The site] was very accessible…the sections were clear, they were short, you know, the content was good. You know, pretty hard to misunderstand." Furthermore, participants noted specific features that might enhance accessibility (eg, audio presentation of information and optimization of the tool on a mobile platform).

Suitability

Participants with a concussion indicated that the tool was suited for people who had had a recent concussion or were in the early stages of recovery and seeking basic information about their concussion. The suggested time for access to the tool was within the first 6 weeks of injury to receive the maximum benefit as knowledge and information were most needed at that point. As one participant described,

> *I think it would be used more as, like a stepping stone... I think it's something I'd go to for just the very basics, or I didn't know what was going on with my health or understand my situation, my condition.*

On the other hand, some clinician participants indicated that the MyGuide tool was appropriate for individuals with concussion at any stage of recovery. As one participant described their experience using the tool with different clients,

> *I've worked with people that are a week post-concussion to two years post-concussion, and I feel like it can work for everyone again, […] it's just kind of a foundation. I think I am comfortable referring every single one of my concussion clients.*

Clinician participants also noted that the tool could be suitable for individuals who were avoiding activities due to their concussion symptoms. These participants indicated that providing early education on topics like pacing was particularly important for these individuals, as the concept of pacing could be applied to various aspects of the person's recovery process or therapies (eg, physiotherapy). One clinician explained:

> *I would refer patients [to the site] who are probably struggling with pacing…I feel like getting their pacing under control is usually a higher priority than giving them, you know, some form of manual therapy, that's my perspective…because it's that art of figuring out what to address at what point in time, often when they are so significantly concussed.*

Clinician participants also indicated the different levels of suitability for some of their clients with chronic symptoms. As one clinician participant described:

> *Someone who's really chronic, let's say, post two years, oftentimes has built a pretty strong identity around their health... So I'm not sure that the impact would be the same per se, as someone earlier on in the experience. I think I'd still use it. It's really hard to know what somebody has been exposed to in terms of education and material… And maybe they haven't had any of that, or they have really low health literacy. So no, I still think it would be useful [but] in my experience, a lot of people have really built a disability identity by that point. And the concussion is something that has become part of who they are... if there's a tool like this might not be as impactful.*

Clinician participants indicated that the tool may not be appropriate for clients who are feeling overwhelmed and anxious, having difficulty processing information, and experiencing no screen tolerance, low computer literacy, and poor English comprehension.

Acceptance: Adherence

Based on the interview data, the primary reason people with concussions continued to actively engage in the tool was to seek out information to gain a better understanding of concussion recovery. Participants reported that they stopped using the tool when they acquired enough information or when they saw improvements in their recovery. One participant said of the tool, "It is sort of a learning tool, right?... But once I've learned how I can just focus on that myself, and I didn't really return to it, but I was using what it had taught me." Overall, the tool was often used over a short period of time and not used as a resource that participants with concussions were continuously referred to over a prolonged period.

Clinician participant perspectives gave further insight into other factors related to adherence. As most clinician participants noted they were actively referring their clients to the site, one factor that may have influenced their clients' adherence was based on how they were directing clients to the site. Participants mentioned they were either referring clients to the tool by working through the tool with their clients in sessions or by sending the link to their clients to have them go through the tool independently at home. For some participants, going through the tool was a good starting point for their clients, particularly when doing virtual sessions. One clinician said, "It's been really helpful for the clients when we do Zoom sessions... I can share my screen, and we can go through it together."

Clinician participants mentioned that most clients with concussions were only engaging with the MyGuide Concussion tool a few times independently but mostly accessed the tool when facilitated by the clinician. One participant stated,

> *I get the sense that, similar to most things I give them, [the client] needs to be directed and guided... I would say if I just gave the person that website, I would not anticipate that they're just going through it all themselves. If there are specific parts of it that I would want them to get out of it, I would definitely follow up and make sure that they really got what I wanted them to get out of it.*

As such, participants noted that the MyGuide Concussion tool was useful in therapy sessions but may not be as relevant if self-directed by participants.

Impact

Overview

During the interviews, participants reported value in the tool's information about various stages of concussion recovery. Participants with concussion noted that the tool was a trustworthy source of information, describing that affiliation with a predominant health care institute was helpful to increase

XSL•FO
RenderX

the credibility of the tool. In addition, participants with concussions expressed that referral from clinicians or other people with concussions increased their acceptance of this tool as a credible source of information. Many clinician participants indicated that the tool reinforced the basic information about concussion recovery and concussion self-management that they were teaching their clients and helped the clients connect concepts important for their recovery.

Several participants with concussions reported that the self-assessment strategies in the tool helped them assess and become more aware of their triggers and were beneficial in helping alleviate symptoms. One participant expressed that the tool reminded them how everything is connected, referring to how their physical and psychological symptoms impact their ability to meet their life demands. The tool helped them manage their symptoms of low mood and find ways to meet their life demands while also balancing their other physical and psychological concussion symptoms. Clinician participants shared that the application of the tool decreased the risk of complications and potentially reduced the overall length of recovery. One participant said:

> *I generally see people that are at least six weeks, but generally more like three months post-concussion. And I would say the majority of them have gotten to that point because they've been avoiding all activity. And I think the tool does a really good job of letting people know that's not what to do to get back and gives people a bit of a guide. So, I think that's kind of the reason that it could decrease the complications that we know happen once somebody is avoiding things for too long.*

Many participants with concussions explained that while physical symptoms may be more clearly linked to concussion, the psychological impacts were not as recognized as symptoms of a concussion. As one participant described,

> *It help[ed] me to realize that a lot of the symptoms I'm experiencing weren't from some other thing. It was from my concussion, even though it had happened quite a while ago. … so just being able to appreciate that these things are normal, and that... there's not something else wrong.*

Another participant described their frustration of not knowing the cause of their symptoms to the point of questioning the validity of their symptoms. They reported that the information on the tool not only normalized their symptoms but also provided them with validation that their symptoms were indeed related to their concussion. Clinician participants similarly expressed that the tool helped their clients normalize the symptoms they were experiencing and provided reassurance to their clients.

Participants with concussion indicated various changes they made to managing their concussion symptoms or overall health based on what they learned from the tool, some of which included gradually returning to physical activity and improving their ability to manage stress. In contrast, other participants indicated that they had not made any changes to how they managed their symptoms because they had already made the necessary changes before finding the tool.

In the cases where clients were receiving services from multiple providers, some clinician participants noted that the MyGuide tool validated and reinforced the information provided to clients by different clinicians. For some other participants, the tool helped prime their client on a particular topic, which helped enhance the subsequent treatment session. In particular, one participant noted that not only did the tool provide opportunities to learn about concussion recovery outside of treatment time and enhance the client's understanding of their condition, but it also allowed for the client to elicit social support from friends and family. Therefore, the tool both empowered clients to self-manage their concussions and encouraged reengagement with their social network and daily life activities.

Table 4 summarizes participants with concussion and clinician's perspectives on the tool's impact. Overall, data collected from the clinician participant interviews supported the perspectives of participants recovering from a concussion.

Table 4. Summary of perspectives on the impact of MyGuide on concussion recovery.

Participants with concussion	Clinician participants
Improved understanding of concussion symptoms and recovery process (from acute symptoms to returning to life after concussion).	Reinforced basic information about concussion recovery and self-management.
Improved awareness of and ability to self-manage triggers.	Decreased potential complications associated with concussion.
Provided reassurance and normalized symptoms.	Provided reassurance and normalized symptoms.
Changed overall approach to recovery.	Increased client empowerment.
Improved stress-management.	Provided opportunity to elicit support from family or friends.
Facilitated gradual return to activity.	Supported occupational reengagement.

Relevance

From the interviews, participants with concussions indicated that the tool was useful for gaining basic knowledge about concussion recovery and self-management strategies. However, many reported that they found the information on the tool to be repetitive to other information they had already read; as one participant described, "it was a lot of reiterating stuff I kind of already knew... it wasn't really telling me anything new." Other participants expressed that the tool lacked specific and detailed content on various topics, such as nutrition and differentiating an acute concussion from persistent postconcussion symptoms.

XSL•FO
RenderX

Another participant suggested that the tool would have been more useful if it included a self-monitoring tool, where individuals could track their symptoms and strategies used to manage their symptoms, which could be shared with their health care team.

Some participants with concussions expressed how they had only found out about the tool once they were further along in their concussion recovery and indicated that had they known about the tool earlier, it would have been much more useful to them then. One person highlighted this when describing their experiences after their injury, saying, "It took me months just to figure out what it was I was dealing with. So, if I had gotten [the tool] right away, it would have been extremely useful for me."

Another participant described why it would have been beneficial for them to have known about the tool earlier,

> *If I had had [the tool] immediately after having the concussion or shortly after [with]in the month... there would have been a lot less stress from having to deal with it, and not knowing what the cause of some symptoms were, and just being able to have a more well-developed understanding of what a concussion looks like.*

Participants with a concussion also indicated that the information on the tool may be outdated and perceived the tool to be less relevant as a result. Participants mentioned the importance of updating the tool regularly as new concussion research is published.

Clinician participants indicated that the tool supported and enhanced the services they provided to their clients. In particular, participants noted that the tool provided preliminary and important information for recovery in a timely manner, a mixture of information for different learning styles and needs, a reinforcement of information learned during in-person sessions, and an opportunity for remedial learning outside of treatment time. Learning outside of clinic time provided opportunities for clients to lead and participate more in their own recovery. One clinician said, "I tend not to refer, I tend to work through the concussion site with clients, I tend not to just […] sort of give it to them."

For some participants, it allowed them to focus on addressing more specific problems impacting recovery (eg, teaching the client about pacing). As one participant shared:

> *If it's a motivated person, and they are actually reading through [the tool]... I don't have to spend as much time necessarily providing some of that intro-level education. So, I think it can mean that we can move through treatment quicker. I like to give everyone the broad education, and then really more specific as we go to that person's individual barriers. But if a lot of the intro general stuff can be covered on that website, and the person's actually going through it… then I can get more specific quicker, which… for a clinician, that's great... it just means that I can do things faster.*

With the increase in demand for e-health services, many clinician participants expressed that the tool was compatible with this delivery method. In specific cases, the MyGuide tool could accommodate and provide access to important education on concussion recovery for individuals with limited or no insurance coverage. Other benefits of using the tool included improving overall workflow, providing consistent information across other clinicians or existing concussion rehabilitation programs, and enhancing other therapies (eg, physiotherapy).

Integration of Mixed Methods Results

Qualitative and quantitative results were integrated at the level of analysis. However, the accessibility, suitability, and relevance of the tool were only assessed using qualitative data. Multimedia Appendix 3 displays the integration of results using joint display.

Discussion

Principal Findings

Our study indicated that the MyGuide concussion self-management tool has good acceptance and perception by all participants (people with concussions and clinicians) using the tool.

Specific recommendations were provided by both participants with concussions and clinician participants to improve the ease of use of the MyGuide tool. Many clinicians requested that a downloadable PDF form be made for each module, as it would be beneficial to increase the accessibility of the tool for those with reduced screen tolerance. This format could also address the minor navigation issues that a handful of participants with concussions experienced when using the tool.

Participants also provided suggestions for increasing personalization and adherence to the tool. Participants with concussions reported that the use of the tool stopped when they acquired enough information or when they saw improvements in their recovery. Based on this, it would be beneficial to add more detail to modules, especially around nutrition, which one participant noted to be sparser. Clinician participants found that certain topics, such as return to sports, were irrelevant to the client's recovery, and some information was inaccessible to those with low or no screen tolerance or low computer proficiency. To address this, the tool should be recommended to clinicians as something that should be adopted into practice so they can support clients in refining the tool to be more relevant to their own recovery goals. Furthermore, adding audio or visual modes of delivery as opposed to text could increase accessibility for individuals with lower screen tolerance.

Comparison With Previous Work

Findings from our study indicated the benefits of the MyGuide Concussion tool; specifically, participants emphasized the importance of reassurance to people with concussions by normalizing their experiences. Previous research looking at brain injury found that reassurance was ranked as highly important when considering aspects of an intervention [35] and that normalization of emotions and behavior were important facilitators of self-acceptance and willingness to reach out for help when needed [36]. Furthermore, the MyGuide Concussion

XSL•FO
RenderX

tool was seen as beneficial for identifying symptoms, which, in turn, helped with finding ways to manage triggers. A study exploring barriers and facilitators of reintegration after concussion found that lack of concussion education was a major barrier to returning to learning, suggesting that the information provided in the MyGuide tool may be a facilitator in returning to everyday life following concussion [37]. Furthermore, education on symptoms following a brain injury has been tied to higher self-awareness and positive experiences during interventions [36], as well as better outcomes [35].

Findings in our study indicated satisfaction and benefit with using a web-based tool for self-management of symptoms and overall recovery after concussion. Similar web-based interventions designed for facilitating recovery in adolescents with mild TBI have also found that web-based interventions were effective in improving executive functioning and functional disability, although this was identified by parents instead of the adolescents themselves [38]. Other studies on mTBI have identified the active coping style involved in self-management as being linked to improved recovery after concussion and improved pacing of return to activity [39]. Participants with concussion and clinicians in this study both agreed that the MyGuide tool was best for individuals in the early stages of recovery who require basic information about concussion and self-management. In particular, participants with concussions suggested that providing the tool within one month of injury would be most beneficial as this is when concussion education is essential to reduce stress related to understanding concussions and what they look like. In line with our findings, other web-based interventions for mild TBI have identified time as a key factor affecting the effectiveness of the intervention, as individuals do not have the same need for more information later in recovery [35,38,39]. One study described that receiving information during an optimal time of exposure was more crucial to maximizing symptom improvement as opposed to the frequency of use of the tool [38]. Several other studies have highlighted providing timely services after a concussion as being a key factor in the effectiveness of self-management websites [13,19].

The ease of use of the MyGuide tool was reported to be relatively high for participants, and aspects such as the linearity of the modules, simple layout, and easy-to-understand information were described as effective by participants. The use of desktop computers seemed to be the preferred medium for the use of the tool, and those using a mobile device voiced the need for improvement of the mobile platform. Usability studies on web-based tools for people with TBI have similarly found that simple interfaces are favored [40]. However, in contrast to our findings, several studies on digital health have found that participants prefer using mobile devices over desktop computers as more people have mobile devices, and most people keep their mobile phones with them at all times compared with their computers [40,41]. This contributes to quick access to the digital tool whenever they need it, rather than just at home. Although participants in the present study all resided in urban areas, the use of digital platforms for health-related self-management programs has been noted as beneficial for use by people remote from treatment centers [42] and especially in rural areas [43], suggesting that the MyGuide tool has the potential to have more far-reaching benefits than was discussed in this study.

Limitations

There are 3 main limitations to this evaluation. First, this study had a small sample size, which may limit the ability to generalize the findings to the broader clinical population of those with concussion. However, data saturation was met during qualitative interviews, and the findings show preliminary support for the use of the MyGuide tool. Second, there may have been selection bias with participants with concussions as they required the ability to participate in an online survey and, as such, a higher capacity to engage with screens than other people with concussions. To mitigate this effect, participants had the option of completing the survey by telephone, but no participants requested a telephone survey option despite 75% (6/8) of participants indicating decreased screen tolerance in the questionnaires. This suggests further research may be required to understand whether decreased screen tolerance impacted module completion and to assess the interpretability of the results to the questionnaires that reported having enough information as a reason to stop completing the modules. Finally, occupational therapists were overrepresented as clinician participants, with no physicians involved in the study and the findings not necessarily representing all clinicians. However, these findings provide crucial information for later studies that aim to specifically understand other clinicians' perspectives.

Future Research

Future research should be done to assess whether the tool can be used in practice by clinicians other than occupational therapists and if the earlier introduction of the tool can provide increased benefits to people with TBI. The use of the MyGuide Concussion tool should also be examined in the senior population, considering the frequency of concussions due to falls in this age category and because this study may have limited generalizability as it focused exclusively on young and middle-aged adults. In addition, it would be beneficial to gauge to what degree screen tolerance impacts the completion of modules and the need for clinician involvement. Finally, as this study revealed a lower rating for User Control relative to other features, it would be beneficial to explore what contributes to this lower rating and what improvements can be made to mitigate any difficulties.

The MyGuide tool is a web-based customizable concussion self-management tool with good acceptability and perceptions by people with concussions and clinicians in concussion rehabilitation. MyGuide provides foundational information on concussion and self-management strategies, normalizes symptoms, and provides reassurance and support for occupational reengagement.

Abstract

Background: Hearing loss affects 20% of the global population, including 250 million experiencing chronic suppurative otitis media, which can present challenges for conventional hearing aids due to ear discharge. Although assistive technology for hearing is available in high-income settings, provision is poor in low-income settings due to high costs and low availability of audiology services, reaching approximately 3% of those who could benefit from it.

Objective: This study aimed to evaluate the performance of a low-cost self-fitted direct-to-consumer bone-conduction headset for individuals with conductive or mixed hearing loss.

Methods: We conducted a multiple methods study to test the efficacy and acceptability of this device using a purposive sample. Participants with a range of conductive and mixed hearing loss underwent speech-in-quiet speech audiometry with and without the device and took part in feedback interviews exploring their subjective impressions of the device.

Results: In 33 participants, the device improved speech recognition in those with bone conduction thresholds <50 dB by a median of 11%, with larger air-bone gap associated with larger improvement. Participants rated the device positively on weight, style, and ease of use.

Conclusions: This multiple methods study assessed the acceptability and efficacy of a low cost self-fitted bone-conduction device in adults. We found the device provides hearing benefit for those with conductive or mixed hearing loss (with bone conduction thresholds <50dB HL). Those with significant conductive hearing loss were measured to have their speech perception significantly improved. Participants had a mixed response to device aesthetics. Further studies should seek to establish if this type of device has effectiveness in real-world trials and which individuals are most likely to benefit. This low cost device could provide hearing benefits to millions of people without access to other devices. Product designers and clinical researchers should explore device optimization. Given the economic impacts of hearing loss across the globe, this style of self-fitted device could represent a paradigm shift in future assistive technology for hearing loss, in both high and low resource settings.

Introduction

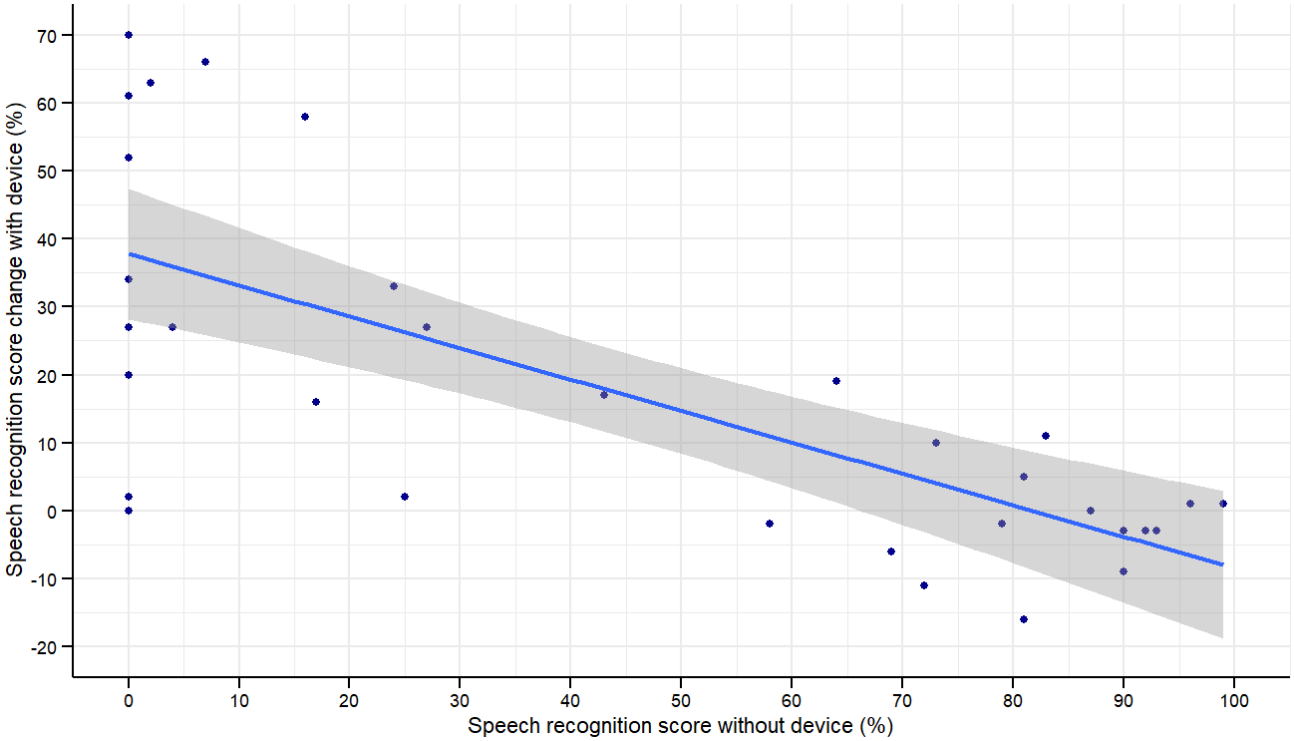
Hearing loss affects 1.5 billion people globally with an estimated 250 million people with chronic suppurative otitis media (CSOM) [1-3], which carries the additional stigmatizing burden of a discharging ear (otorrhea) and associated difficulty using conventional in-ear air conduction hearing aids [4]. In children, hearing loss impairs cognitive development, language, social-emotional skills [5] and other milestones [6]. In low-resource settings, the burden of hearing loss is further compounded by poor health provision and infrastructure to address the needs of its hearing-impaired population [7]. One estimate found >400 million people are “in need” of hearing aids and called for the development of innovative low-cost technologies and effective service delivery models [8].

In UK primary schools in 2019, only 43% of children with any level of hearing loss reached expected numeracy and literacy (vs 65% of typically hearing pupils), and by age 16 years, children are on average 17.5 months behind the attainment of their typically hearing peers [9]. This impacts throughout the life course, as adult employment rates for those with hearing loss are 65%, compared to 79% in people with no long-term health issue or disability [10]. In England, 48% of people aged 50 years and older have some degree of hearing loss [11], and this costs the United Kingdom £25 billion (US $33 billion) a year in lost productivity and unemployment [12]. Efforts to address hearing loss are necessary: medically, socially, and economically, across the world.

Hearing loss can be conductive, sensorineural, or mixed, and many mild, moderate, and severe types of hearing loss of all causes can be rehabilitated with conventional air conduction hearing aids (which transmit sound via the air to the tympanic membrane). However, for patients with conductive or mixed hearing loss (eg, due to CSOM), surgical intervention or bone conduction devices (BCDs), which transmit sound via the skull to the cochlea, are an alternative for rehabilitation [3]. In cases where the conductive component of hearing is large (air-bone gap>25 - 35 dB), some users demonstrate better [13,14] or comparable [15] word identification using a BCD compared to air conduction hearing aids. At present, bone conduction is used in only a minority of cases of hearing loss. For example, in the National Health Service (NHS) in England, around 350,000 new air-conduction hearing aids are provided each year (Prof K Munro, personal communication), in comparison to 1292 BCDs surgically implanted between 2022 and 2023 [16].

Clinically fitted BCDs may be external (nonimplanted, eg, attached via headbands) or implanted into the skull. If not implanted, their audiological function is suboptimal as the headband pressure and depth of skin overlying the skull will attenuate their performance [17]. Hence, the normal clinical pathway is that after successful trial of an external device, a BCD is surgically implanted into the skull and is usually highly effective [18,19]. Such devices are classed and regulated as a medical device and are costly, with recent low estimates of £3150 (US $10,000 to US $17,000; excluding costs of the surgical procedure) [20].

The high cost of implanted devices and the need for surgery means that BCDs are likely underused [21]. External BCDs could allow this technology to be expanded, for example, to treat the most common cause of pediatric hearing loss, glue ear (chronic otitis media with effusion), as this causes a conductive hearing loss that is temporary [22], where implantation would not be appropriate. It could also be used to aurally rehabilitate adults and children with CSOM, a disease most prevalent in low- and middle-income countries [2], where access to traditional in-ear air conduction aids is sparse and often inappropriate, as they are less effective in the presence of otorrhea and may exacerbate it [23]. However, medically certified external BCDs (typically fitted attached to a soft headband) are of comparable cost to implanted devices.



Previous pilot studies have shown benefit from a low-cost direct-to-consumer external bone conduction headset supplied by "Raspberry Pi Foundation” (Cambridge, United Kingdom) for rehabilitation of children with glue ear [24]. In 2 small trials, this device paired with a Bluetooth microphone (see Figure 1) improved word identification score by 23% in 20 children with hearing within normal limits [25] and reduced word discrimination threshold of distant speech in both quiet and in noise for 19 children with otitis media with effusion [26]. The majority of parents (22/26) opined that this device consistently helped their child to hear [24].

Figure 1. (A) Raspberry Pi Hear Glue Ear Headset (SKU: 105890) [24]. (B) Alead Nolan LiveMIC2 Bluetooth Wireless Microphone [27].

Figure 2. Plot of percentage (%) speech recognition score change with device and baseline percentage (%) score without device.

In this multiple methods study, we tested the efficacy of this device for speech recognition in quiet listening conditions in adults and to assess participant acceptance of the device. We purposively recruited adult patients with conductive and mixed hearing loss. The inclusion of mixed hearing loss allowed us to measure the effect of raised bone conduction hearing threshold on word identification, which is important for describing the fitting range of the device for future applications. We hypothesized that the device would markedly improve speech performance on average across participants. We further hypothesized that unaided speech performance (without the device) would predict the amount of benefit, with people who are high baseline performance benefiting less than those who are low baseline performance. We expected this effect to be most pronounced where the bone conduction thresholds tended towards normal limits and were combined with a large air-bone gap.

Methods

Ethical Considerations

Ethical approval and sponsorship for the study was obtained from the Liverpool School of Tropical Medicine (21-079) and the national NHS Health Research Authority Research Ethics Committee (IRAS 304976). The study was registered with the University Hospitals Sussex Clinical Research Department. All participants gave informed consent to participate.

Although patients and the public were not directly involved in the development of the research question, design and conduct

XSL•FO
RenderX

of this study, results will be disseminated to study participants either by post or email as per their expressed preference.

Participants

Purposive sampling sought eligible adults aged ≥18 years with documented conductive or mixed hearing loss regardless of etiology (unless otherwise indicated in exclusion criteria), including those previously fitted with hearing aids or BCDs (externally worn or surgically implanted). We excluded participants unable to converse in English (English did not need to be first language, but participant-determined fluency was the criterion), children, those with cognitive impairment that would limit word identification or device engagement, and those with medical conditions that would preclude wearing the device (such as severe eczema).

To recruit our sample, we interrogated our database of individuals who have previously attended outpatient ear, nose, and throat surgery or audiology clinic at University Hospitals Sussex NHS Foundation Trust, and recruited participants with a range of average bone conduction hearing levels. Details regarding previous aiding and rehabilitation are provided in Multimedia Appendix 1. We created *a* priori subgroups based on the World Health Organization (WHO) hearing-impairment grading system [7], but adapted to bone conduction thresholds only, to define mild (21 - 34 dB HL [decibels Hearing Level] mean bone conduction threshold), moderate (35 - 49 dB HL), and severe to profound (>50 dB HL) hearing loss [28,29].

Hearing threshold levels (HTLs) were measured using pure tone audiometry according to ISO [International Organization for Standardization]:8253 - 1 following the British Society of Audiology (BSA) recommended procedures (2018) in a soundproof booth (Eckel Audiology Suites, acoustic compliance HTM [UK Health Technical Memorandum] 2045/ISO 8253). Air conduction hearing thresholds were measured at 250, 500, 1000, 2000, 4000, and 8000 Hz for each ear independently. Bone conduction hearing thresholds were measured at 500, 1000, and 2000 Hz. Masking was applied where indicated, again as per BSA recommended procedures (2018). Hearing thresholds were measured using an audiometer (MedRx Avant A2D+ Audiometer, MedRx Inc) fitted with Telephonics TDH-39 supra-aural air-conduction transducers, 3M E-A-RTONE 5A insert earphone transducers, and Radioear B-81 bone-conduction transducer.

Measuring Speech Recognition Score

The BCD was a prototype (model G18) produced in collaboration by Hear Glue Ear and Raspberry Pi [24], paired via Bluetooth with an Alead LiveMIC2 Bluetooth Wireless Microphone (model A2DP; Alead Inc).

The efficacy of the BCD was measured by comparing word identification as a surrogate for speech recognition scores (SRS) from unaided (BCD inactive) and aided (BCD active) conditions. We used Arthur Boothroyd AB word lists comprising 15 lists of 10 monosyllabic, isophonemic consonant–vowel–consonant words [30]. We used AB testing because it is considered reliable (using phonemic rather than whole-word scoring), because normative data exist for adults and children [31], and because it is potentially superior in the assessment of speech audibility compared to Bamford, Kowal, Bench testing because context cues are not available and responses are less predictable [32].

The prerecorded English accent AB word lists were administered via a MOTU M4 Audio interface (MOTU, Inc) running a bespoke MATLAB program (MATLAB version R2022a) to present AB word lists in English (once with BCD active, once with BCD inactive). The air conduction dial level was set to give speech output level of 70 dBA root mean square through Etymotic ER3 insert earphones (Etymotic Research). Speech material presentation was diotic in all conditions (with both ears receiving the same signal). Insert earphones were calibrated using a Bruel and Kjaer ear simulator (Artificial Mastoid Type 4930 and Bruel & Kjaer Type 2250 sound level meter ISO 389 - 2). The bone conduction headset output level was set to give speech output level of 70 dB re 1 µN (with no frequency weighting), calibrated using a Bruel and Kjaer Type 4930 artificial mastoid. The air conduction speech stimulus was presented diotically at 70 dBA root-mean-square in both aided and unaided conditions.

For each condition, participants underwent a practice 10-word list followed by 5 test lists each formed of 10 consonant-vowel-consonant words presented in random order (uniform distribution). Responses were scored as the proportion of phonemes repeated correctly in each list of words (3 phonemes per word) [33].

We compared phoneme SRS from unaided and aided conditions. We recorded the number of participants in each hearing severity subgroup who attained a 50% aided word identification score (our definition of functional hearing) [34]. Statistical analysis was conducted in RStudio (Posit, 2020).

Questionnaire and Feedback on Device Performance and Acceptability

In total, 32 participants took part in semistructured feedback, of mean duration 8 (range 3 - 16) minutes. The feedback reported here focused on perceptions and impressions of the new device.

Each participant was invited to provide their opinion on device acceptability and performance using a 5-point Likert scale questionnaire. Extreme score anchors of heavy-light, ugly-stylish, and difficult-simple were used in the weight, style, and ease-of-use questions respectively.

Participants were then invited to provide verbal feedback to record more detail of their opinion. A pilot interview was used to adjust schedule prompts before finalizing, with an aim to interview for approximately 10 minutes. Interviews were undertaken in an audiology clinic room at the study site on the same day as the main experiment. An information sheet on the verbal feedback was provided via email before and offered again on the day. An audio recording of the interview was made (Philips 3200 SpeechMike Pro USB Microphone LFH3200) and anonymously mapped to study ID using Zoom software (Zoom Video Communications). Anonymized handwritten field notes were also taken.

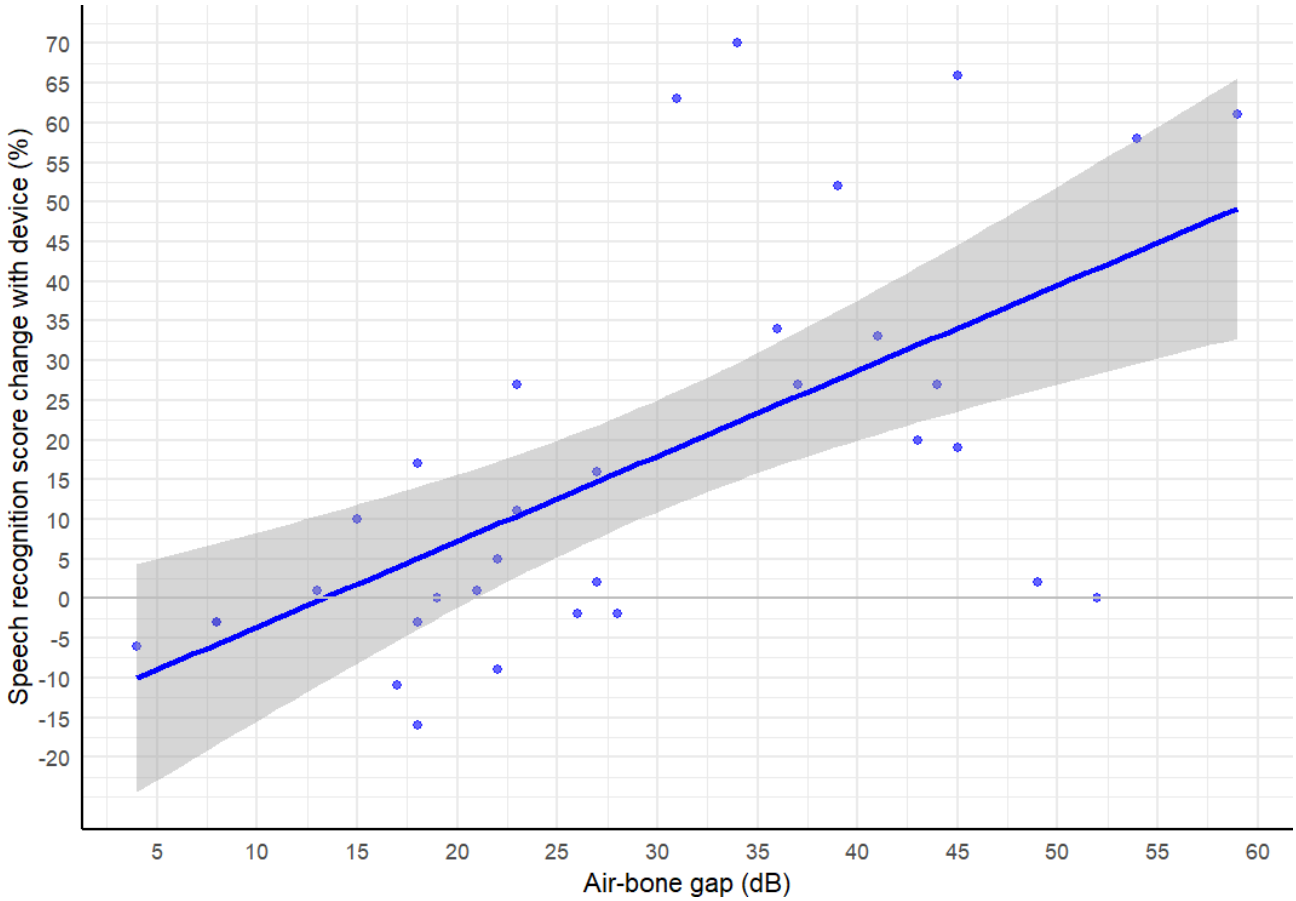
Audio recordings were transcribed [35], coded using NVivo V.12 Pro software (Lumivero), and content analyzed for

XSL•FO
RenderX

associations with audiometric and Likert scoring as well as for additional insights about design and acceptability. An inductive reflexive thematic analysis approach [36] was used to develop broader themes to illustrate participant experiences and selected excerpts used to summarize results. Due to the first author's epistemological standpoint about interview data, no frequentist attempts at triangulation, reproducibility, or mitigation of bias were made for the qualitative elements of this study.

Results

Participants



A total of 167 participants were contacted by letter, 36 expressed interest, and 33 attended and completed the study. Ages of participants ranged from 21 to 82 with a median of 70 (mean 66) years. Self-reported genders were male (n=15), female (n=16), and bigender or "any" (n=2). Participants were categorized according to average bone conduction HTL: 19 in mild (>20 - 34 dB HL), 10 in moderate (35 - 49 dB HL) and 4 in severe (>50 dB HL). The conductive element of hearing loss, the "air-bone gap," ranged from 4 dB to 59 dB (median 27 dB).

Audiometric Outcomes

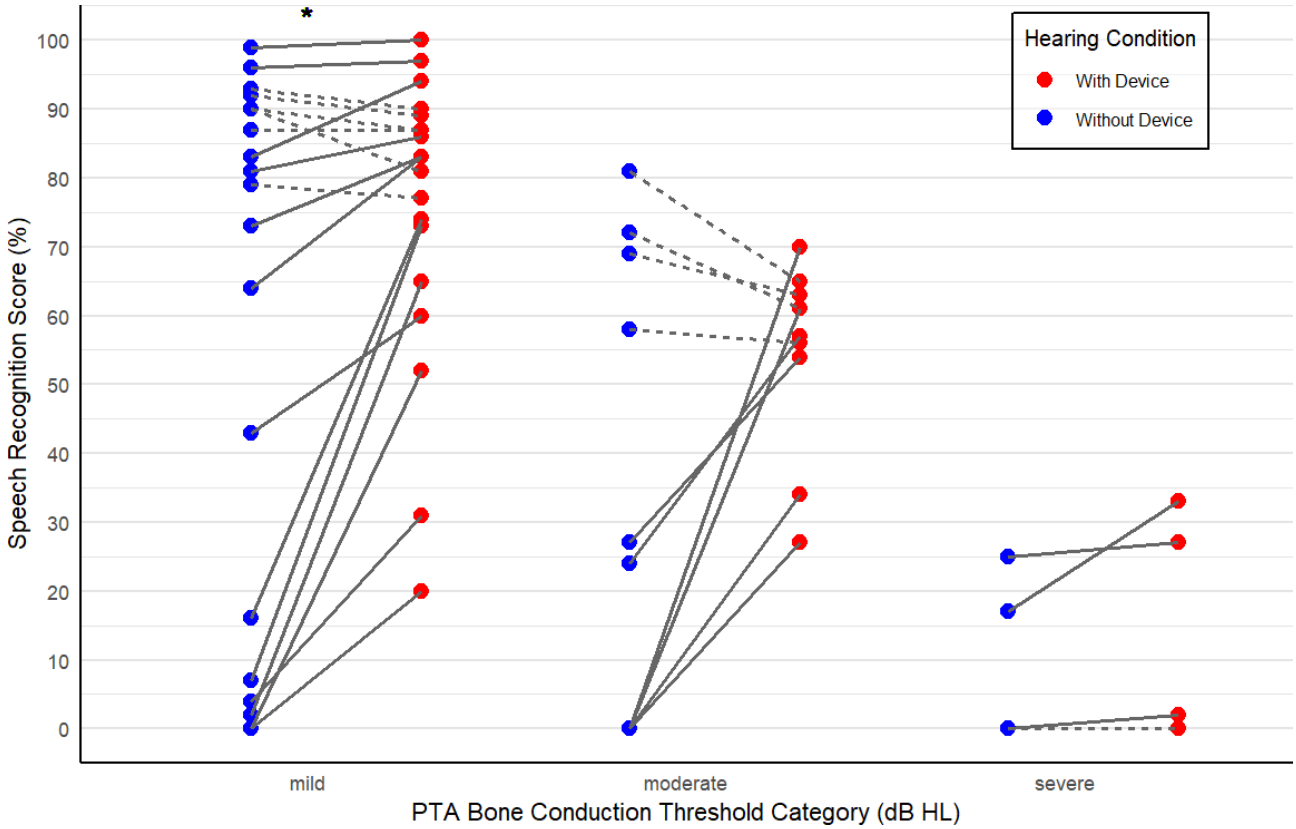
Median speech recognition score change with the device across all 33 participants was 10 (IQR 29). Figure 3 shows the relationship between unaided SRS, which represents baseline performance with no BCD benefit, nor lip reading, and SRS change between unaided and aided conditions. Participants in this cohort with lower unaided SRSs exhibit a positive trend toward greater aided score changes. The R^2 of the regression model is 0.52 (P<.01), regression coefficient (β) was −0.463 (SE 0.08), and t-statistic −5.74.

We next investigated possible mechanisms to explain the relationship between unaided and aided SRS. We used a hypothesis-driven approach with forward selection of variables in linear regression models for change in score, optimizing Akaike Information Criterion with each iteration [37]. In total, 9 regression models were fitted, and we found the model with the best Akaike Information Criterion (291) included only the variables of air-bone gap (Figure 4) and category of bone conduction HTL (Figure 5).

Figure 3. Improvement in % speech recognition score with device, depending on participant air bone gap in decibels (dB).

XSL•FO
RenderX

Figure 4. Scatterplot of speech recognition scores with (aided) and without device (unaided) for each participant. Solid line indicates an increase in score with device, and dashed line indicates no change or worse. The asterisk indicates statistically significant (P<.01) improvement with device for that group.



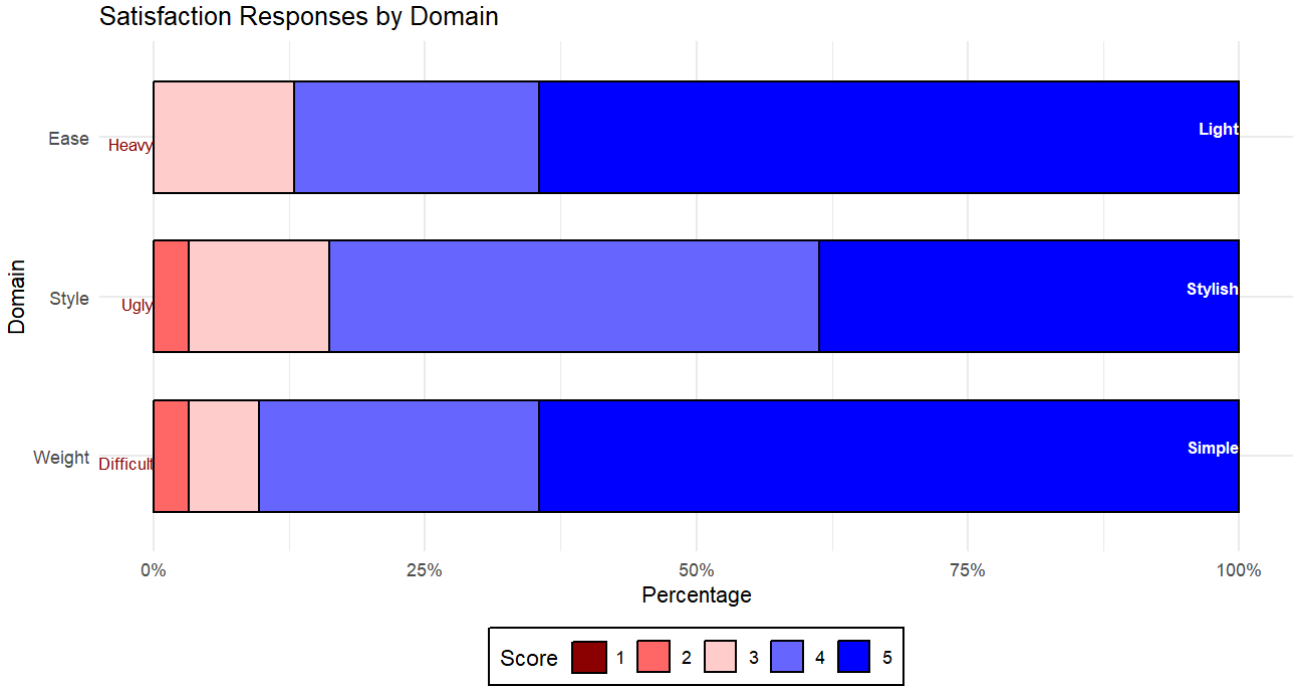


Figure 4 shows the relationship between air-bone gap, which represents the magnitude of hearing loss that is conductive, and the SRS change. Because the device provides sound transmission via bone conduction, we expected that greater magnitude of conductive hearing loss (air-bone gap) would be associated with greater aided SRS change. Regression analysis confirmed this prediction, with an adjusted R^2=0.459 (suggesting approximately 46% of variance in score could be explained by the model), and a coefficient of 1.2 (suggesting that for every 1 dB increased air bone gap, the AB score increased by >1 when using the device, P<.001).

Next, we investigated the effect of bone conduction HTL, which represents the magnitude of underlying sensorineural hearing loss (SNHL). Participants were categorized using the WHO hearing-impairment grading system according to their average bone conduction HTL. Figure 5 shows unaided (blue points) to aided (red points) SRS change for participants in the mild, moderate, and severe categories of bone conduction thresholds. Comparison of means between unaided and aided conditions across all conditions found a significant improvement in SRS (pooled Wilcoxon signed-rank test, V=409, Z=2.30, P<.01). Subgroup analysis showed a difference in SRS between unaided and aided conditions in the mild category (Figure 3, Wilcoxon signed-rank test, V=145, Z=2.01 P=.01, or P=.03 with Bonferroni correction for 3 comparisons), but differences in the other groups did not reach significance (z=1.78, uncorrected P=.08 for moderate and z=0.37, uncorrected P=.17 for severe).

XSL•FO
RenderX

Figure 5. Histogram of device satisfaction score responses from 31 participants. Higher scores were taken to be "positive" impressions of the device, based on discussion with participants to clarify directionality even with anchors.

The median change in SRS for each bone conduction hearing threshold category is presented in Table 1. Using pooled data, participants with hearing thresholds <50 dB (mild and moderate categories) showed median gain in SRS of 11%. Of 33 participants, 17 had worse than 50% unaided SRS, of which 9 participants improved to >50% (in these 9, median SRS went from 7 unaided to 61 with device).

Table . Change in AB speech recognition score (%) by pure-tone audiometry bone conduction threshold category.

Bone conduction threshold category	Median change in aided versus unaided SRS[a]	IQR of change
Mild	+10	−1.0 to 23.5
Moderate	+27	−5.0 to 33.8
Severe	+2	1.5 to 5.5

[a]SRS: speech recognition scores.

Feedback on Device Performance and Acceptability

Two participants did not fully complete the questionnaire, and for analysis, their scores were excluded. For the remaining 31 participants, mean scores (from 1 to 5) for weight, style, and ease of use were 4.5 (SD 0.74), 4.1 (SD 0.80), and 4.6 (SD 0.69), respectively. No individuals gave a score of 1 (worst score), and the ease of use and appearance was scored 2 for one participant respectively (refer to Figure 6). We found no clear relationship between SRS and verbal reported perceptions of the device. Although there was some negative feedback from participants with poor SRS about how well the device performed (particularly among the severe hearing loss group), some of the lowest (even negative scoring) SRS participants felt the device "worked," "worked well," or was "better than… (their current) device."

We also found no clear relationship between normalized Likert scale satisfaction scores and verbal reported perceptions of the device. Participants with maximum satisfaction scores still had recommendations for improvements or preferred a discrete device, and one said outright "I didn't like the look of it." Conversely, where participants gave poor satisfaction scores, occasionally weight, style, and ease of use were still described favorably, with one low-scoring participant reporting "a good design and a nice weight… you can't feel that you've got it on, really."

We asked participants if they would recommend the device to friends and family if they had a similar hearing impairment. In total, 79% (26/33) of participants said they would recommend.

Themes Developed From Verbal Feedback

Many participants described their adoption of new hearing technology or devices as "transforming their life" and their quality of life without the aids as significantly impaired.

> *If I didn't have my hearing aids then I'd be lost completely.* [Participant 12]

Regarding the new device specifically, participants were divided about aesthetics. There were no obvious respondent characteristics to identify who liked or did not like the appearance, but a larger sample size could reveal trends. Responses largely correlated to personal preference about the appearance of the device (namely whether aids should be obvious and celebrated or unobtrusive and remain discrete).

XSL•FO
RenderX

Some participants approved of the fact that the device (given its original purpose) looked like a music player or headphones.

> *People would wear them because they look like normal headphones… My cousin has some of these that he just uses for music!* [Participant 2]
>
> *They looked cool, and you wouldn't be embarrassed using them, because a lot of people go around with earphones anyway.* [Participant 4]

Several participants alluded to appearance, and perceptions of disability and attitudes in society. Some participants were happy the new device masked their disability, as it looked like a music device, but others liked that it proudly drew attention to their condition:

> *I mean if you're going to be deaf you're going to be deaf, so you might just as well flag it up.* [Participant 3]
>
> *If it was smaller, I could hide it under my hair…Because I'm quite vain. (Laughter).* [Participant 6]

For many participants, there were reflections on normality and disability, the hidden nature of deafness, and the difficulty experienced by participants coping with a hidden disability in an intolerant and ableist society. Many reflected on personal shame or stigma.

For some participants, having an obvious hearing aid of any description was something they found troubling given previous experiences. Many participants said they were more comfortable with devices as they grew older, reflecting perhaps that changes from their initial objections (which at the time, most put down to aesthetics) might represent growing personal acceptance of their hearing disability.

Discussion

Principal Findings

We investigated the efficacy of a low-cost direct-to-consumer BCD to improve SRS in participants with conductive and mixed hearing loss. The main findings were that (as would be anticipated) participants in this study with lower unaided SRS showed a trend toward the greatest improvement in aided SRS. Participants with larger air-bone gaps also showed a greater improvement in SRS (approximately 1% per dB of gap). The mean change in SRS for each category of bone conduction threshold severity was 17.4 for mild (SD 10), 21.7 for moderate (SD 27), and 5 for severe (SD 2), which was statistically significant only for the mild category group.

Our findings suggest that this low-cost device is likely to benefit individuals with a conductive hearing loss where underlying sensorineural thresholds are largely preserved, and, consistent with previous research [13,14], that benefit is more likely where air-bone gap is large.

Although statistical significance was not reached for the moderate bone conduction threshold group, 4 of 10 participants showed SRS change greater than 20%. This variability in outcome has several possible explanations. To categorize participants, we used average bone conduction HTLs, so it is possible that different shapes of bone conduction audiograms are better suited to the frequency response characteristics of the device. Interindividual variability in the moderate group could also be affected by characteristics other than bone conduction HTL, such as cognition [38,39] or capacity for speech recognition using additional information from lip cues and context [40]. In the severe bone conduction threshold group, there was no evidence of benefit (although this contained only four participants), which may be due to the reasons above, but more likely reflects the fact that this BCD is unable to rehabilitate when there is underlying severe SNHL.

Of 33 participants, 22 had an improved score, and nine had a worse score with the device. Of these, 5 participants with worse scores and 5 with better scores had scores equal to or within 5% of their original score. Concerns about test-retest within participant speech score variability are well documented [41]. Reassuringly, if all 10 participants with these small, potentially nonsignificant score changes were excluded from analysis, then the median score change remains significant to $P<.05$ for the mild but not the moderate threshold group, leaving our overall conclusions unchanged. Future studies should seek to predetermine minimally significant change levels. A score of 50% or greater on the Arthur Boothroyd word test has previously been defined as a marker of satisfactory rehabilitation with cochlear implants [42]. In our cohort, amongst the 16 participants where SRS was worse than 50% without the device, 9 achieved greater than 50% with the device, and mean SRS improvement in this group was 34 (SD 24).

Our qualitative investigation showed favorable opinions towards the size, weight, and ease of use of the BCD, with normalized mean satisfaction from these three variables of 0.8. Our interview data found that both word identification and questionnaire scores are imperfect surrogates of participant satisfaction. In the future, the satisfaction scores used for this questionnaire may benefit from correlation with an overarching construct of device satisfaction or a hearing-specific questionnaire.

Our findings suggest potential for the use of this kind of device. First, and perhaps foremost, the device could provide options for low-cost rehabilitation for those with conductive or mixed hearing loss in low-resource settings. In particular, many cases of hearing loss due to CSOM could be rehabilitated with a BCD [3]. A low-cost direct-to-consumer approach circumvents issues of conventional approaches to hearing aid provision in low-resource settings, including the need to travel to and attend a health facility, a lack of audiologists in such facilities (for example found to be 0.8 audiologists per million population in sub-Saharan Africa [43]), and the costs of a hearing device (an air conduction hearing aid can cost up to US $6000 in high-income settings [44], but commercially available BCDs for sports and recreation are available for £160 (US $149) [45], and the device used in this study was purchased for £18 (US $24.59) [24] (with the Bluetooth microphone an additional £79 [US $107.92]) [27]. These factors contribute to the fact that as few as 3% of people in low-income settings who would benefit from a conventional hearing aid currently have access [44], even though this is where an estimated 90% of people with

XSL•FO
RenderX

disabling hearing loss live [46]. A bone conduction externally worn device could be reused or redistributed as it would not need a personalized mold or programming and might have less likelihood of being a vector for microbial transmission compared to in ear air conduction hearing aids [47]. A low-cost device could be made available through conventional retail outlets or schools, demedicalizing hearing rehabilitation and aligning with the WHO promotion of community ear and hearing care [48].

Other causes of conductive or mixed hearing loss could also be rehabilitated by this device, both in low- and high-resource settings. Glue ear (otitis media with effusion) is the most common cause of childhood hearing loss, but usually resolves, making it highly appropriate for rehabilitation with a nonimplanted BCD, and potentially avoiding the need for surgery (with preliminary evidence to support use for this purpose from the studies by Holland Brown [24,25,49]). However, this needs further investigation as a previous datalogging study from the United States [50] found that as many as 73% of children using an external BCD had low use (mean of 1.25 h a day).

Research exploring the pathways for bone conduction sound transmission has been conducted by the Stenfelt laboratory, showing that cochlear excitation is produced through 5 different routes. This evidence shows the profile of transmission for mastoid transducer placement includes all 5 but is dominated by cochlear fluid inertia [51,52]. In contrast, a recently published study from the same group shows the route of transmission for the headset investigated here is dominated by ear canal sound pressure because of the preauricular transducer position [53]. This transmission route depends on the oscillation of the soft tissue of the external ear canal, which by being coupled to the air in the canal produces transmission like air conduction. Therefore, conductive hearing losses caused by outer- and/or middle-ear abnormality will reduce both air and bone conduction transmission from this headset. An extreme example such as aural atresia may significantly reduce the effectiveness of headsets with preauricular positioned transducers. The investigation presented here included a range of types and severity of conductive hearing loss. Although none had atresia or microtia, it is possible the anatomical variations could have different effects on the ear canal sound pressure route of transmission. This may have contributed to the heterogeneity observed in the word recognition scores.

Study Limitations

The aim of our study was to measure the effect of the BCD with a controlled input level speech stimulus via air conduction and bone conduction (aided) and air conduction only (unaided). This was a repeated measures within-subject design with randomized order of (aided or unaided) conditions, but it is possible that participants could feel the difference between conditions because of the vibrotactile sensation associated with bone conduction.

The device was evaluated in a quiet listening environment with microphone input speech clear and stable, which may not translate to less favorable listening environments.

Some of the variability in outcomes within bone conduction threshold groups may relate to asymmetry in hearing threshold between ears, which can decrease binaural summation [54], although SRS is usually best predicted by “better” ear performance on bone conduction thresholds [55]. Outcomes of cochlear implantation have been shown to better map to total auditory receptivity of the brain (what signal, if any, was received) as opposed to ear-specific events [56]. Future work and larger sample sizes may allow us to investigate at what threshold of bone conduction of the worse ear this device may improve SRS and whether this correlates to the worse ear gaining audibility, the effects of binaural summation, or (as it seems) predominantly air-bone gap.

The median age in our cohort was 70, and so a large proportion of our cohort will have presbycusis [57], with associated limitations to speech recognition performance [58]; a younger cohort may achieve greater benefit, and it may be that device performance would differ in those with SNHL versus from other etiology.

We did not assess previous rehabilitation (namely previous experience, duration, and quality with other assistive devices), which may correlate with capacity to benefit and word identification ability. Future studies could seek to record the duration of previous auditory deprivation in addition to prior device use, as this could impact participants’ baseline auditory processing, and cognitive ability may impact the capacity to benefit from the device.

We used bespoke approaches to qualitative assessment and are aware that other questionnaires to evaluate assistive hearing technology have been validated [59,60]. Participants did not adjust settings or handle the device during the word identification task, and so our qualitative findings are based on the participant having only a brief interaction with the device.

Future Work and Wider Applications

This multiple methods study demonstrates efficacy for a low-cost self-fitted, commercially available BCD to improve SRS in individuals with conductive or mixed hearing loss.

Objective measures of device output in laboratory conditions and normative head tension and performance of individuals with typical hearing would help interpret existing and future investigations of speech performance using the device. This could guide engineering optimizations of the device such as headband tension, signal processing, and transducer characteristics. Exploring opportunities to optimize costs versus performance could include potentially differentiated offerings for use in low and high-resource settings. Future studies should also explore the benefit of this BCD in different clinical scenarios, for example, for CSOM or glue ear.

In summary, this study shows that a low-cost direct-to-consumer BCD effectively improved word identification, had high user acceptability, and could support a shift toward self-fitted (nonmedical) rehabilitation for conductive or mixed hearing loss, in both high- and low-resource settings.

Abstract

Background: Pressure ulcers constitute a major health care burden, characterized by significant morbidity, diminished quality of life, and elevated treatment costs. Wheelchair users are predisposed to pressure ulcers due to sustained ischial and sacral interface pressures resulting from prolonged periods of sitting. Implementation of pressure-relieving interventions, including specialized seating systems engineered to redistribute load and augment the weight-bearing surface area, is critical for mitigating the risk of pressure ulcers.

Objective: This study aimed to evaluate a methodology for the custom fabrication of pressure relief cushions, through the user-cushion interface pressure mapping to reduce high-pressure areas and increase contact area in wheelchair users.

Methods: First, a validation study was carried out with 7 healthy volunteers. The pressure was determined with an FSA sensor (BodiTrak BT1510, Vista Medical Manufactures), and the cushion profile was obtained through a linear relation with pressure values. In the second phase, 10 cushions for wheelchair users were manufactured and tested. The resulting data from buttock pressure using a flat foam, Jay X2 (gel-foam), ROHO high profile (air), and customed-contoured cushions were analyzed and compared using the following 4 variables: peak pressure, peak pressure index, mean pressure, and contact area.

Results: In the validation study, the statistically significant difference between the flat and the custom-contoured cushion showed a better performance in pressure relief for the custom cushion (mean pressure 27.3, SD 4.5 mm Hg and 34.6, SD 3.5 mm Hg; $P<.001$). Regarding the study with wheelchair users, custom-contoured cushions had lower peak pressure (mean 91.3, SD 36 mm Hg), peak pressure index (mean 69.5, SD 33.7 mm Hg), and mean pressure (34.2, SD 17.4 mm Hg) against flat, Jay X2, and ROHO high profile cushions ($P<.005$). The contact area (mean 1457.6, SD 254.1 cm^2) was greater for the contoured cushion ($P<.001$) than for flat and ROHO high profile (Permobile) cushions; nevertheless, it was not significantly different from Jay X2 ($P=.59$).

Conclusions: The main finding is that the buttock pressure mapping method produces custom-contoured cushions that, compared with commercial cushions, have good pressure distribution and increased contact area. These results suggest that pressure mapping is a good alternative for manufacturing affordable custom-contoured cushions that can prevent the development of pressure ulcers.

KEYWORDS

pressure ulcers; pressure map; custom-contoured cushion; wheelchair; wheelchair user

Introduction

Wheelchairs are a critical assistive technology, enabling mobility and participation for individuals with physical disabilities worldwide. The World Health Organization (WHO) has estimated that 90 million people require a wheelchair to assist their mobility. Yet, only 18 million people can access an appropriate wheelchair [1]. Official statistics for Mexico in 2024 indicate that 8.3 million individuals live with a disability, with

XSL•FO
RenderX

3.3 million experiencing difficulty walking or rising from a seated position using their legs [2]. Furthermore, 4.1 million of this population lives in poverty [3]. The established correlation between poverty and disability in developing countries underscores the necessity for accessible, low-cost assistive technologies that are easily maintained and replaced.

Wheelchair users, who remain seated for prolonged periods, are considered a high-risk population for developing pressure injuries [4]. Pressure injuries, also known as pressure ulcers (term used in this work), decubitus ulcers, or bedsores, are localized lesions affecting the skin and soft tissues, resulting from sustained pressure and mechanical stress, typically over bony prominences or due to medical devices or personal items such as mobile phones [5]. These ulcers occur in 70% of cases at the sacrum, ischial tuberosity, and greater trochanter (pressure sites associated with the seated position). However, they may also develop on the occiput, scapula, elbow, heel, lateral malleolus, shoulder, and ear [6]. The etiology of pressure ulcers is multifactorial, involving a complex interplay of sensory deficits, alterations in skin moisture balance, and shear forces. The prevalence of pressure ulcers varies depending on underlying pathology, age, and comorbidities among wheelchair users. Notably, a systematic review and meta-analysis found that approximately one in 3 individuals with spinal cord injury develops pressure ulcers, highlighting the significant burden of this condition in this population [7].

One of the most widely used therapeutic strategies to mitigate the development of pressure ulcers is the use of pressure-relieving cushions for wheelchairs. These cushions are specifically designed to reduce focal pressure over bony prominences while increasing the contact area [8]. Various materials have been tested for fabrication, including foam, gel, air, and combinations [9-11]. In addition, dynamic cushions, which modify their shape through actuators such as pumps, have been developed to further alleviate pressure in high-risk areas [12,13].

While air and gel cushions have demonstrated efficacy in load distribution, they can be susceptible to damage, compromising their performance [14,15]. Consequently, the costs associated with repair and replacement can be prohibitive, limiting accessibility for many wheelchair users [9]. Custom foam cushions present a viable alternative for mitigating high-pressure areas [16]. However, inconsistencies in manufacturing processes and the complexity of mold generation can impede their widespread production. Furthermore, conventional fabrication techniques may pose risks to wheelchair users due to potential exposure to high-temperature chemicals that come into direct contact with the individual during the molding process. In addition, traditional molding is often time-consuming, and retaining information about the seat shape can be challenging due to the storage requirements for the molds [17].

The implementation of digital methodologies for shape capture and model generation in cushion fabrication facilitates the automation, acquisition, and storage of critical data, including cushion contour, pressure distribution profiles, and dimensional characteristics, streamlining and optimizing the manufacturing process. The pressure mapping of the user-cushion interface is a digital method for capturing the body shape, in which pressures are transformed into depth. The contoured cushion is produced through computer numerical control (CNC) foam carving. The main differences reported in the literature are the filters and smoothing of the pressure signals, as well as the relationship between the cutting depth and the interface pressure values, generally based on the deformation of the foam as a function of pressure [18]. Results have shown better pressure distribution performance in custom cushions than in flat cushions [19,20]. However, a comprehensive study has not been reported covering the design of the custom-contoured cushion through interface pressure, CNC manufacturing, and performance evaluation compared with the flat cushion and other cushions of different materials with the same pressure relief goal.

The objective of this study was to evaluate a methodology for the custom fabrication of pressure relief cushions, through the user-cushion interface pressure mapping to reduce high-pressure areas and increase contact area in wheelchair users.

Methods

Methodology

This work aimed to develop and validate a methodology for fabricating relief pressure custom cushions based on pressure maps of the user-cushion interface. Hence, the methodology is divided as follows: (1) pressure data collection, (2) surface model, (3) cushion fabrication, (4) validation study, and (5) cushion performance analysis and user satisfaction.

Pressure Data Collection

The pressure maps of the user-cushion interface were obtained using the commercial mat BodiTrak BT1510 with a 16x16 matrix of pressure sensors. The calibration kit of the mat (ACC16-Standard Small Calibration Jig) was used to calibrate regularly to ensure the accuracy of the measures. Before measuring a subject, initial tests with a constant known weight were performed; if the pressure data had atypical values, the calibration process was conducted.

The participants were asked to sit on the testing cushion: a commercial high-density polyurethane foam block (R-90) of 35 mm, covered with the pressure-mapping mat. Seat depth and footrest height were adjusted according to the anthropometrical dimensions of the subject to ensure a neutral seating position (hips, knees, and ankles at 90°). Pressure at the buttocks was recorded every minute for 10 minutes. If a located point reached the maximum value (200 mm Hg) during the test, the data set was discarded, and the mat and subject were repositioned, to conduct a new test.

The procedure explained above was used to generate the contoured profile of the manufactured cushions. However, the pressure maps obtained with the flat foam block and 2 commercial pressure relief cushions were also used to evaluate the performance of the manufactured cushion. For every participant, pressure maps were obtained with a flat R-90 foam block, a ROHO High Profile cushion (air), and a Jay X2 cushion (foam-gel). Finally, the same procedure was conducted with the custom-contoured cushion fabricated using the proposed methodology to compare the performance.

XSL•FO
RenderX

Surface Model

The pressure values obtained from the user-cushion interface with the testing cushion (pressure data collection section) were processed to generate the surface model of the contoured cushion. A linear relationship converts pressure values into cushion thickness values, establishing that the highest pressure, regardless of magnitude, corresponds to the lowest cushion thickness (40 mm). The areas where no pressure was recorded correspond to the points of the greatest foam thickness (75 mm). The surface was determined as follows:

(A) Pressure measurements taken every minute for 10 minutes are averaged.

$$(1) P=(\sum i=110pi)/10$$

where *i* is the number of the map taken every minute for ten minutes and pi are the pressure matrix

$$(2) Pi=(P1,1\ldots P1,16 \quad P16,1\ldots P16,16),$$

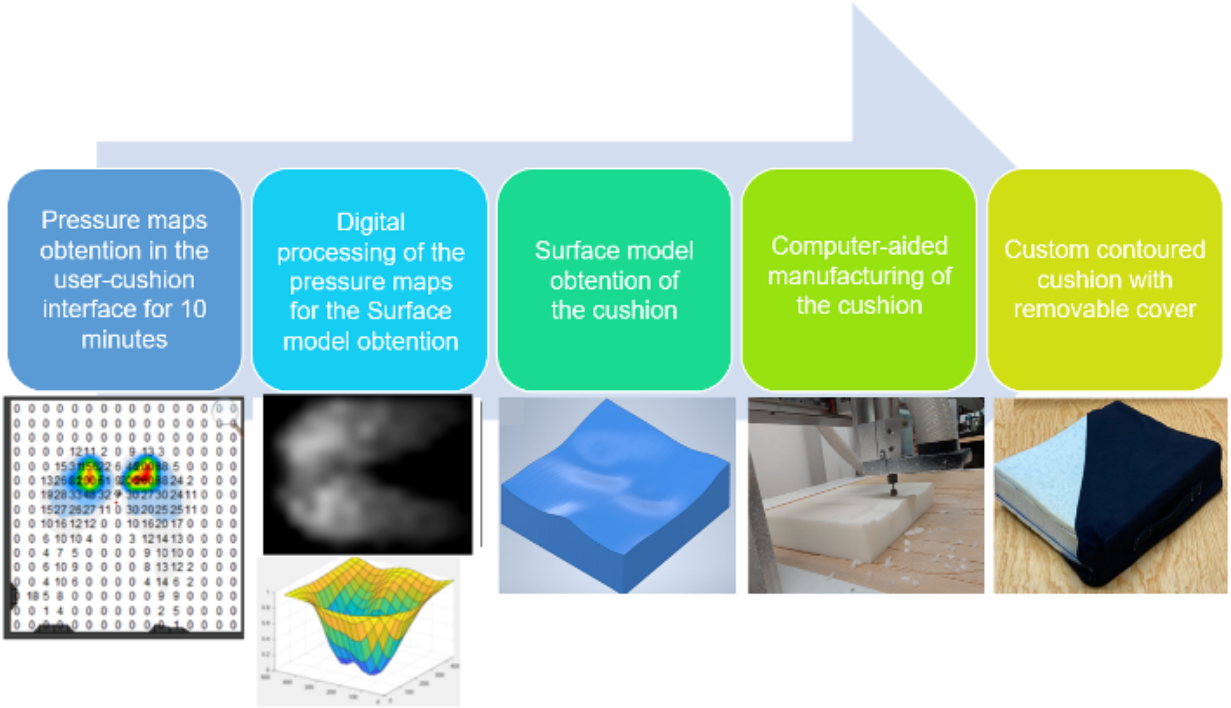
- (B) The average pressure (P) is converted to a grayscale image (Pg).
- (C) The contour of the seated person is defined through a threshold value to remove the pressure points out of the user-cushion contact area; then, a Gaussian filter is applied to obtain an offset (Of) to soften the final profile of the cushion
- (D) Two smoothing filters are applied to Pg to increase the user-cushion contact area. First, a Gaussian filter, then the values are normalized. Finally, an averaging filter is applied to the normalized data (PgN).
- (E) The cushion profile is obtained according to the following relationship:

$$(3) Z=(ZM-ZmPgm-PgM)PgN+zM,$$

where  is the cushion thickness for each value in the 16×16 matrix in millimeters. ZM and Zm are the maximum and minimum cushion thicknesses, set to 75 mm and 40 mm, respectively. PgM and Pgm are the maximum and minimum smoothed and normalized grayscale pressure.

The offset Of is applied to the obtained surface *Z* according to:

$$(4) S=Z-Of,$$



where *S* is the final profile of the cushion.

Cushion Fabrication

Once the surface model of the cushion was obtained ("Surface Model" section), the custom-contoured cushion was manufactured according to the following steps:

1. The values obtained with the procedure described in the section "Surface Model" were introduced into a computer-aided design (CAD) algorithm created in Inventor (Autodesk) to get the 3D model of the cushion.
2. The CAD model of the cushion was passed to a CNC milling machine (Shapeoko, Carbide 3D) to carve a commercial high-density polyurethane foam block (R-90) with dimensions of 45×45×7.5 cm to obtain the custom shape.
3. Once the foam has the desired shape, a sheet of 6.35 mm thick memory foam is added to each face of the foam.
4. A waterproof cover of a 1 mm layer of soft silicone (Smooth-On, Ecoflex 00 - 30) is cured onto the memory foam.
5. Finally, a custom removable cover was manufactured using a cloth of 94% cotton and 6% elastomer. The full procedure is represented in the schematic of Figure 1.

Figure 1. The schematic of the methodology developed to manufacture the custom-contoured cushion from the user-cushion interface pressure maps.

RenderX

Validation Study

The present study consists of two clinical phases.

Performance Validation of the Manufactured Cushion Using the Pressure Mapping Methodology

Seven nonwheelchair-using volunteers were included, with the following inclusion criteria: age between 18 and 60 years, absence of pain that would prevent them from remaining seated during pressure mapping data acquisition (10 min), and full range of motion in pelvic limbs, allowing for proper positioning (hip, knee, and ankle at 90°).

Assessment of the Performance of Custom-Contoured Cushions with Wheelchair Users

In addition, 10 wheelchair users were included, meeting the following inclusion criteria: age between 18 and 60 years, absence of pressure ulcers within the past year, absence of pain that would prevent them from remaining seated during pressure mapping data acquisition (10min), absence of joint limitations or postural abnormalities that would impede proper positioning during pressure mapping data acquisition, and absence of communication impairments or intellectual disability that would hinder informed consent.

For both groups of participants, anthropometric measurements and wheelchair dimensions were collected to evaluate their suitability. Then, the procedure explained in the "Pressure data collection" section was conducted: First, the pressure maps of the user-cushion interface with a polyurethane foam (R-90) of 35 mm thickness were recorded for 10 minutes. Then, the same procedure was repeated with the Jay X2 (gel-foam) and ROHO high profile (air) cushions. Finally, once the custom cushion was fabricated with the flat foam maps, 10 pressure maps were recorded using the custom-contoured cushion for performance evaluation.

Cushion Performance Analysis and User Satisfaction

The resulting data from buttock pressure using each cushion (flat foam, air, foam-gel, and contoured) was analyzed and compared using IBM SPSS software. The variables used to evaluate cushion performance were peak pressure (PP), peak pressure index (PPI), mean pressure (MP), and contact area. The pressure variables are reported in mm Hg and the contact area in cm^2.

Peak pressure is the highest-pressure value obtained in each measurement. Peak pressure index is the mean of the peak pressure with the pressures surrounding it; the PPI indicates the pressure under the ischial tuberosity area [21]. Mean pressure is the average value of the pressures distinct from zero. Contact area is the total area of the cells with a pressure value different from zero, reported in cm^2.

User satisfaction was evaluated using the Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST 2.0), which includes 12 items to assess satisfaction with a specific assistive device.

- Eight items assess the characteristics of the assistive device, including dimensions (size), weight, adjustments, safety, durability, simplicity of use, comfort, and effectiveness.
- Four items assess service aspects, including service delivery, repairs and maintenance of the device, professionalism of service, and follow-up service.

Participants were asked to rate their satisfaction with the device and service on a 5-point scale ranging from 1 ("not satisfied at all") to 5 ("very satisfied") [22].

Statistical Analysis

Descriptive statistics were performed for all variables, calculating means and SDs for quantitative variables, and frequencies and proportions for qualitative variables. Pearson correlation test was performed between anthropometric measurements and wheelchair dimensions of the users. Furthermore, medians were compared using Mann-Whitney *U* test to analyze pressure values and contact areas between the different cushions for all participants.

Ethical Considerations

This project was approved by the Institutional Review Board at Iberoamerican University (project number. 174/2022), and all participants signed the informed consent. The data of the participating subjects are found only in their clinical records and are protected by the current personal data protection laws in Mexico, to which the Universidad Iberoamericana adheres. For this study, the data of the subjects were anonymized, and their only compensation was their custom-contoured cushions.

Results

Performance Validation of the Manufactured Cushion Using the Pressure Mapping Methodology

A total of 7 nonwheelchair-using volunteers were included in the validation of the manufacturing process and performance of the custom-contoured cushions. Pressure measurements were initially taken on a flat foam surface, then cushions were manufactured according to these measurements. Pressures (PP, PPI, and MP) and contact area were compared. Statistically significant differences were found in all measurements, with lower pressures and larger contact areas observed in the cushions manufactured using the developed methodology (Table 1).

XSL•FO
RenderX

Table . Comparison of pressure and contact area variables between flat foam and the manufactured custom-contoured cushion in nonwheelchair-using volunteers. Data are presented as mean (SD).

Variable	Custom-contoured cushion, mean (SD)	Flat cushion, mean (SD)	*P* value
Peak pressure (mm Hg)	75.5 (12.3)	101.0 (13.4)	<.001
Peak pressure index (mm Hg)	53.9 (12.4)	73.6 (14.8)	.005
Mean pressure (mm Hg)	27.3 (4.5)	34.6 (3.5)	<.001
Contact area (cm^2)	1716.4 (128.8)	1509.5 (137.4)	<.001

Assessment of the Performance of Custom-Contoured Cushions With Wheelchair Users

Wheelchair Users

A total number of 10 wheelchair users were included in the study, with a mean age of 47 (SD 12) years, of whom 6 (60%) were female. The most common diagnosis was spinal cord injury (3/10, 30%), followed by poliomyelitis (2/10, 20%), cerebral palsy (2/10, 20%), amputation (2/10, 20%) and cerebrovascular disease (1/10, 10%). The mean wheelchair usage time was 10 (SD 5) hours per day. None of the participants used pressure-relief cushions. Only 2 had a history of pressure ulcers and the most common comorbidity was hypertension (2/10, 20%) and diabetes (2/10, 20%).

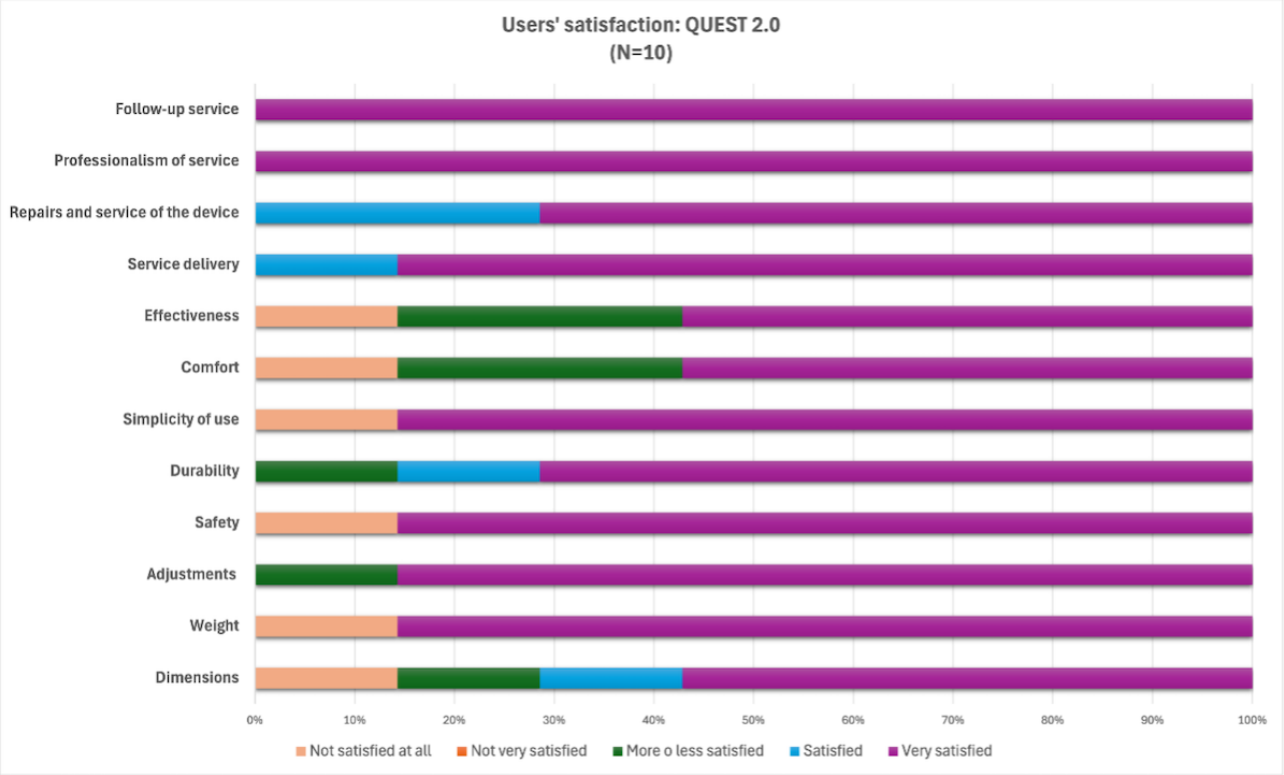
To explore the correlation between a proper wheelchair prescription and the user's wheelchair characteristics, the relationship between anthropometric measurements and chair dimensions was evaluated. This analysis revealed a statistically significant correlation only between pelvic width (mean 41.7, SD 6.5 cm) and chair seat width (mean 41.1, SD 4.7 cm*; r*=0.83; *P*=.005). Conversely, no correlation was found between seat height (mean 45.8, SD 7 cm) with leg length (mean 42.3, SD 4.4 cm*; r*=0.19; *P*=.67) or seat depth (mean 83.6, SD 9.6 cm) with buttock-popliteal fossa length (mean 43.1, SD 4.8 cm; *r*=0.42; *P*=.29).

Cushion Performance Analysis

The performance of the custom-contoured cushion was evaluated by comparing pressure distribution variables derived from pressure mapping data, including PP (mm Hg), PPI (mm Hg), MP (mm Hg), and contact area (cm^2). These variables were compared between the custom-contoured cushion and 3 commercial cushions: flat foam, Jay X2 (gel-foam), and ROHO high profile (air). Statistically significant differences were found in all variables when comparing the custom-contoured cushion to each commercial cushion; the custom-contoured cushion exhibited lower pressure values and a greater contact area. The only exception was contact area when comparing the custom-contoured cushion to the Jay X2 gel-foam cushion, where no statistically significant difference was observed (mean 1457.6, SD 254.1 cm^2 vs mean 1442.4, SD 187.7 cm^2; *P*=.595) (Table 2).

Table . Comparison of the custom-contoured cushion manufactured with the proposed methodology with a flat foam cushion and 2 commercial cushions, through the 4 evaluated metrics: peak pressure, peak pressure index, mean pressure, and contact area. Data are presented as mean (SD).

Variable	Manufactured cushion	Commercial cushion					
	Custom contoured	Flat foam		Jay X2		ROHO high profile	
	Mean (SD)	Mean (SD)	*P* value	Mean (SD)	*P* value	Mean (SD)	*P* value
Peak pressure, mm Hg	91.3 (36)	119.9 (37.5)	<.001	100.7 (42.6)	<.001	106.5 (51.8)	;<.001
Peak pressure index, mm Hg	69.5 (33.7)	96.3 (39.6)	<.001	79.5 (37.8)	<.005	83.9 (45.8)	<.001
Mean pressure, mmHg	34.2 (17.4)	41.2 (23)	<.001	40.7 (19.8)	<.001	41.2 (21.4)	<.001
Contact area, cm^2	1457.6 (254.1)	1250.2 (264.8)	<.001	1442.4 (187.7)	.59	1357.1 (221.7)	<.001



User Satisfaction With the Pressure Mapping–Based Custom-Contoured Cushion

User satisfaction was evaluated using the QUEST 2.0 questionnaire. The mean satisfaction rating for the assistive device was 4.2 (SD 1.07), while the service received a mean rating of 4.9 (SD 0.14). Among device aspects, adjustments and simplicity of use received the highest ratings (mean 4.7, SD 0.75). Furthermore, users reported a perfect score (very satisfied=5) for professionalism and follow-up service.

The distribution of user satisfaction related to the remaining eight items of the QUEST 2.0 questionnaire is presented in Figure 2.

Discussion

Principal Findings and Comparison With Previous Works

This work aims to develop and validate a methodology for fabricating relief pressure custom cushions based on pressure maps of the user-cushion interface. Two validation phases were conducted; first, 7 nonwheelchair-using volunteers were included to evaluate the performance of the contoured cushion versus a flat foam cushion. Then, 10 wheelchair users were included in the study to assess the performance of the custom-contoured cushion versus 3 commercial cushions by comparing pressure distribution variables, including peak pressure (mm Hg), peak pressure index (mm Hg), mean pressure (mm Hg), and contact area (cm^2).

According to the results presented in Table 1, the performance of the manufactured custom-contoured cushion was better than that obtained with the flat foam, which was similar to that reported in the literature. Li et al [19] developed a custom-contoured cushion by converting the interface pressure under the buttocks into the carving depth, reporting a decrease in mean and PP under the buttocks against a flat cushion. Regarding the performance of the custom-contoured cushion against the Jay X2 and ROHO high profile, evaluated in the second phase of the validation study, the cushion manufactured with the proposed methodology presents lower PP, PPI, and MP. In the case of the variable of contact area, in our study, the best contact area is provided for the gel-foam cushion.

According to the literature, several studies have compared commercial cushions using the interface pressure. Sy and Tam [18] reported similar pressure relief characteristics between a custom-contoured cushion and ROHO and Jay 2 cushions; however, the recording time is not reported. As part of a rapid review, He and Shi [15] reported 3 articles using a Jay 2 and a ROHO high profile, reporting the pressure at ischial tuberosities between 94 to 160 mm Hg and 102 to 196 mm Hg, respectively, which is consistent with our results, the gel-foam cushion performs better than the air cushion. In the study by Gil-Agudo et al [11], a ROHO air cushion had lower pressure values than a gel-foam Jay cushion; the MP maps were obtained by averaging the data from 1.5 minutes of recording. Mendes et al [9] reported that in the static position, Jay Fusion Air showed the best rates for average pressure and contact area, while the Roho had the lowest average for the PP. The data were collected for 5 minutes, recording 10 frames per second.

However, user-cushion interface pressures captured using a pressure mat entails several challenges: the constant requirement to recalibrate the mat; its correct positioning under the user avoiding wrinkles or folds; high sensitivity to the user position and movement, which impacts the resulting contour; the user must wear smooth clothing, free of pockets, prominent seams, buttons, or any objects that generate high-pressure points; and finally, the time and frequency of pressure data capture, because they are important factors for the variables analyzed (MP, PP, PPI, and contact area). Regarding this last point, in the aforementioned studies, the time ranges from 1.5 minutes (without sampling frequency) to 5 minutes with 10 frames per second; in our case, the measurement duration was 10 minutes with one map per minute. The optimal duration of pressure measurements is still unclear and deserves further investigation.

On the other hand, this technique automates the user shape capture, avoiding manual, time-consuming methods and waste material. In the proposed methodology, the pressure values are

XSL•FO
RenderX

converted into cushion thickness values by a linear relationship, in which it is established that the highest pressure, regardless of its magnitude, corresponds to the lowest thickness of the cushion (4 cm) and the lowest pressure corresponds to the highest thickness (7.5 cm), resulting in contours that have a thickness gradient that does not restrict the movement of the user.

Regarding to the relationship between anthropometric measurements and wheelchair dimensions, these parameters were intentionally examined, finding that only seat width and hip width had a statistically significant correlation. These results are unfortunate, as they reflect the limited access to custom-made wheelchairs in our country. These findings differ from the WHO's definition of an "appropriate wheelchair," which should meet the user's needs, offer a good fit, be safe and durable, be locally available, and include maintenance services [23].

At Iberoamerican University in Mexico, we aim to provide a personalized cushion designed for good pressure distribution at an affordable cost, as an alternative to commercial cushions. The university owns the necessary infrastructure for manufacturing the cushions, including the pressure mat, data processing software, and CNC equipment, and the institution covers its associated costs. The materials needed to manufacture the cushion are as follows: a block of polyurethane foam (R-90), a sheet of memory foam, a soft silicone layer (Smooth-On, Ecoflex 00 - 30), water-based contact adhesive (SILER), cotton cloth, and 2 zippers. The total cost for these materials amounts to US $50.

Conclusions

In this study, custom-contoured cushions were manufactured by mapping buttock pressure according to a linear relationship, establishing that the highest pressure, regardless of magnitude, corresponds to the lowest cushion thickness. Seven cushions were made for 7 healthy volunteers, showing better performance in pressure relief against flat foam. Ten contoured cushions were manufactured for wheelchair users, and the peak pressure, peak pressure index , mean pressure, and contact area were determined. The custom cushions showed better pressure relief characteristics than flat foam R90, Jay X2, and ROHO high profile cushions. This methodology presents an affordable option for wheelchair users to obtain a pressure relief cushion.

Abstract

Background: Wheelchairs are assistive mobility devices known to experience frequent part failures and breakdowns within 6 months of regular use. No tools or technologies exist to monitor the wheelchairs' condition or usage and inform stakeholders and users regarding when or how often they need to undergo servicing to avoid critical part failure.

Objective: We aimed to test the association between wheelchair usage and manual wheelchair damage, part failures, and consequences for older wheelchair users and evaluate their preferences for a new wheelchair servicing technology.

Methods: A cross-sectional study was performed with older manual wheelchair users atInstituto Nacional de Geriatría in Mexico. Demographic data, wheelchair information, failure counts, and preferences for new technology (sensor and smartphone app for servicing) were collected using surveys. Road shocks experienced by the wheelchair were collected for a week using a sensor.

Results: Ten participants (mean [SD] age, 78.8 [11.8] y; 8 female and 2 male) participated. Seven experienced an average (SD) of 2.86 (1.36) self-reported part failures. Road shocks correlated with self-reported loose brake failures ($r(8)$=0.58, P=.09), the damaged condition of tires ($r(8)$=0.61, P=.1), and the damaged condition of brakes ($r(8)$=0.58, P=.099). No consequences were reported. Part failures increased as self-maintenance occurrences increased ($r(9)$=0.67, P=.04). More than 8 participants responded that they would like to monitor the wheelchair's condition using the new technology and purchase it at an average (SD) price of US $28.95 (18.13).

Conclusions: In this study, the association between wheelchair usage and failures showed that data-driven wheelchair inspection schedules should be determined through a collaborative approach involving researchers and stakeholders in wheelchair repair provision and older adult users. Older adults are interested in using new technology to engage in wheelchair servicing.

KEYWORDS

maintenance; mobile app; mobility; older adults; repair; seating; telemonitoring; wheelchair; wheelchair breakdown; wheelchair failure

Introduction

Mobility is an essential element of an older person's physical capacity. The loss of muscle mass and muscle strength, decreased flexibility, and problems with balance can all impair mobility [1]. Mobility impairment is found in 39% of people over 65 years of age, more than three times higher than that among the working population [2]. Wheelchairs enable mobility; however, these assistive mobility devices have a longstanding issue, that is, their parts break with little use.

Cross-sectional studies evaluating wheelchair durability in the community have reported manual wheelchair part failures within 2 - 3 months of use [3]. They lead to physical, social, psychological, and economic consequences for the user [4] as well as device abandonment [5]. This problem is particularly severe in older adults; a higher incidence of failures was observed with elderly wheelchair users in a study conducted in El Salvador [6]. About 57% of the elderly experienced breakdowns in the past 3 months of wheelchair use due to high-risk failures of critical wheelchair parts such as casters and wheels. Around 75 - 95% of the elderly participants rated their wheelchairs as unsatisfactory with unsafe working conditions, contributing to failure, breakdown, loss of mobility, and consequences.

In an effort to improve quality, the World Health Organization (WHO) Guidelines have recommended device quality testing using standards and routine follow-up with users, including the maintenance and repair of wheelchair parts [7]. However, this crucial area has been largely neglected. The maintenance checklists and programs developed by the WHO and research groups have enhanced users' knowledge, performance, and compliance but have yet to prevent community failures [8].

XSL•FO
RenderX

Furthermore, a mixed-method study validating the user-led wheelchair servicing approach found that older adults using wheelchairs face numerous barriers to maintenance and repair, including health reasons, lack of tools, knowledge, and caregiver support [9]. This underscores the urgent need for novel strategies that can effectively prevent wheelchair failures and breakdowns in older adults.

For automobiles, advanced diagnostic technologies and odometer mileage direct maintenance and repair schemes. Similarly, low-cost sensors offer an opportunity. Using data loggers on community wheelchairs, studies have demonstrated a relationship between failure measures and wheelchair usage risk factors, such as wheelchair shocks and travel distance [10-12]. This study aims to validate this approach for older adult wheelchair users in Mexico. The study's primary objective was to evaluate the relationship between wheelchair shocks and failure measures and the secondary objective was to evaluate older adult's preferences for new servicing technology.

Methods

Study Location

The Ohio State University and Instituto Nacional de Geriatría (INGER) partnered to conduct a mixed-methods study with older adult wheelchair users in Mexico City.

Ethical Considerations

The study was conducted in accordance with the Declaration of Helsinki and approved by the Research and Research Ethics Committees of theDirección de Investigación, Departamento de Investigación en Epidemiología Clínica at INGER, under the number DI-PI-009/2021 (date of approval August 11, 2021). Deidentified data transfer and use were permitted under a clinical study agreement between the two institutes. Written informed consent was obtained from all participants before beginning any test. The participants were reimbursed for their first visit travel to INGER.

Study Participation and Recruitment

Participants who were full-time wheelchair users with manual wheelchair models and ≥60 years of age were screened and recruited. Sixty years of age is considered old age in international settings [13]. Flyers and word of mouth were approaches used to recruit older wheelchair users.

Study Procedures

Between August and November 2021, participants underwent two study visits to the INGER facility in Mexico City to collect data. Survey administration, weight measurement, damage condition inspection using a validated Wheelchair Maintenance Assessment tool (W-MAT) [14], and sensor installation were conducted during the first visit. The W-MAT manual includes instructions for inspecting wheelchair parts and scores the damaged condition of parts on a Likert scale of 0 - 2 with 0 indicating poor or damaged condition, 2 indicating good working condition, and NA indicating part not installed. Surveys included demographic information about the participants, part failures, maintenance, and consequences observed over the last 12 months. Participant's preferences for smart wheelchair servicing technology, including interest in self-maintenance and receiving maintenance reminders and willingness to buy the technology, were gathered using Yes/No/Maybe responses through the survey.

During the study visit, the COVID pandemic was ongoing. The wheelchair-user population was considered vulnerable during the pandemic. Hence, disinfection and distancing guidelines were followed. The clinical visit room was cleaned prior to the visit. Only essential staff needed for data collection attended the participant and their accompanying caregiver, if present.

Sensor Description

An inertial measurement unit sensor powered by three D-size alkaline batteries was installed on the side frame of the wheelchairs (Figure 1). The sensor is an upgrade to the sensor used in a previous study [15]; a tube clamp was attached for securing the sensor tightly on manual wheelchair tubular frames. The sensor stored the data on a micro-SD card. Participants collected sensor data for a week and returned for a second visit for sensor removal.

XSL•FO
RenderX

Figure 1. Wheelchair usage tracking sensor.

Data Analysis

Descriptive statistics (mean [SD]) were performed on survey data. The normality of the data was tested using the Shapiro-Wilk test. For normal data, counts, means, and SD were computed. For non-normal data, medians and IQRs were computed. Shocks greater than or equal to five times the root mean square of the resultant acceleration value [15] were computed from sensor data. Maintenance patterns were analyzed. The frequency of maintenance reported by participants was ordered with no/not possible=0, daily=5, weekly=4, monthly=3, quarterly=2, and yearly=1, and a cumulative total maintenance score for each participant was computed. Pearson correlation analysis was used to compare shocks, failures, part condition scores, and maintenance patterns. Since this was a pilot testing study with a smaller sample size, a less conservative α-level of 0.1 was selected.

Results

Participant Characteristics

Ten attendant-propelled older adults using standard folding wheelchairs participated in the study. Their demographic characteristics are reported in Table 1. Seven participants experienced an average (SD) of 2.86 (1.36) self-reported part failures with tires, axles, wheels, casters, nuts or bolts, brakes, brakes, seat, and back supports. No consequences were reported.

Table . Demographic characteristics (N=10).

Characteristic	Value
Age, years, mean (SD)	78.8 (11.8)
Gender, n (%)	
Male	2 (20)
Female	8 (80)
Length of previous wheelchair usage, months, mean (SD)	36.8 (31.5)
Number of falls in the last year, median (IQR)	1 (0–2)[a]
Total weight (user and wheelchair), kg, median (IQR)	73.1 (66.3–105.05)
Weight on casters, kg, median (IQR)	23.2 (21.4–27.8)
Wheelchair weight, kg, median (IQR)	13.4 (13.2–16.4)
Maintenance score, mean (SD)	18.5 (17.25)[b]
Maintenance personnel, n (%)	
None	5 (50)
Caregiver	3 (30)
Technician	2 (20)
Days spent outside of the home environment, n (%)	
None	6 (60)
1–2	3 (30)
>5	1 (10)

[a]Only n=6 patients reported falls.

[b]The maintenance score was out of 125.

Usage-Failure Relationships

Participants collected data for an average (SD) of 5.74 (4.34) days. One participant collected data for an hour and was omitted from the shock data analysis. Wheelchair shocks were on 40.38 (48.31) times/day with an average (SD) value of 7.89 (0.83) g. Shocks were correlated with self-reported loose brake failures ($r(8)$=0.58, P=.09) and tire damage condition ($r(8)$=0.61, P=.1). Brake damage assessed using the W-MAT was associated with shocks ($r(8)$=0.58, P=.099). Caster damage assessed using the W-MAT was moderately correlated with shocks but was not statistically significant ($r(8)$=0.52, P=.15). The user's age was correlated with seat failures ($r(7)$=0.58, P=.08). Failures increased as maintenance occurrences increased ($r(9)$=0.67, P=.04).

Servicing Technology Preferences

Six participants noted interest in self-maintenance, and 2 in collaboration with the caregiver. Seven participants said that they would like to receive reminders about wheelchair service. Nine participants said that they would like to monitor the wheelchair's condition using the sensor and an app, and 8 participants said that they would like to buy the technology or use a mobile phone at an average (SD) price of US $28.95 (18.13).

Discussion

Principal Findings and Comparison With Previous Works

The findings from this study support the latest evidence on wheelchair usage-failure relationships and help drive the research efforts toward improving wheelchair reliability [11,12]. This study correlates road shocks with wheelchair part damage and failure measures experienced by older adults in less-resourced settings. Even though differences exist in wheelchair design, settings, materials, and demographic characteristics compared to previous studies with adults under 60 years old, usage dictates failure phenomena. The greater the usage, the more frequently servicing must happen. While the proportion of 70% experiencing at least one failure in 12 months is similar to the literature, a lower failure count among older adults is justified, an observation found with older power wheelchair users [10].

XSL•FO
RenderX

Users whose chairs received maintenance more regularly witnessed more failures, similar to previous studies with adults [11,12]. Hence, it is essential to consider a collaborative approach to wheelchair servicing where users can take up simple maintenance tasks such as those listed in the WHO maintenance training, and clinicians and technicians can perform complex inspections since professional-led inspections reduce failures [16,17]. Collaborative approaches such as mobile clinics and the engagement of community-based rehabilitation workers in follow-up are promoted in the WHO Prosthetics and Orthotics Standards and can be applied to wheelchairs [18]. As several groups and stakeholders look forward to reforming wheelchair servicing, this research emphasizes considering performance data in decision-making and approach development.

Older adults' interest in using smart servicing technology coincides with a previous study in which 75% of participants upvoted new technology development, including smartphone apps [9]. This favorable outcome motivates the authors to continue developing new technologies while addressing barriers to wheelchair servicing reported by older adults. Following positive findings in this study, the authors aim to build a servicing intervention based on the usage-failure relationship and test its efficacy in preventing wheelchair failure.

Limitations

The small sample size and use of a significance level of 0.1 for this pilot study increases the chance of a type 1 error. Hence, the authors aim to validate the usage-failure correlations in a larger cohort in future studies.

Conflicts of Interest

Abstract

Background: In 2023, the National Clinical Guidelines for Stroke revised the recommended daily multidisciplinary therapy dose from 45 minutes per therapy to 3 hours of therapy overall. To monitor the achievement of these guidelines, there is a need for accurate measurement. This study introduces a novel co-designed digital dosage tracking system that uses Near Field Communication technology to log rehabilitation activities and demonstrates its feasibility and accuracy in a clinical setting through comparison with the current clinical method of manual recording.

Objective: This study aimed to assess the validity, feasibility, and usability of a novel co-designed digital tracker using Near Field Communication technology to automatically log rehabilitation dosage in people with stroke history, providing an objective and low-burden solution for clinical environments.

Methods: This pilot mixed methods study included 2 phases. Phase 1 involved a usability trial with 9 participants conducted at a university research center, assessing usability with the System Usability Scale (SUS) and Intrinsic Motivation Inventory (IMI). Phase 2 consisted of a clinical trial in a National Health Service stroke ward with 15 inpatients, comparing the digital tracker with manual therapist recordings for validity and feasibility using paired *t* tests, Cohen *d*, and Bland-Altman plots. An acceptable discrepancy range was set at ±5% - 10%.

Results: The digital tracker demonstrated high usability with a mean SUS score of 91.43 (SD 9.53) and strong user satisfaction (IMI score 6.29/7, SD 1.50). Clinical trial results showed a strong agreement between the digital and manual methods (t_{206}=−1.60; *P*=.11; Cohen *d*=−0.06), with a small mean time discrepancy of 1.23 (SD 11.01) minutes across 207 activities. The Bland-Altman plot indicated good accuracy and consistency between methods, with limits of agreement within the clinically acceptable range.

Conclusions: The co-designed digital tracker has been shown to agree with a manual method for recording rehabilitation dosage. This development presents the opportunity for objective, automated, and low-burden recording of rehabilitation dose to support prescription, monitoring, and research.

Introduction

Rehabilitation is crucial for regaining functions lost to stroke. The National Clinical Guidelines for Stroke in the United Kingdom and Ireland now recommend at least 3 hours of daily multidisciplinary therapy, a fourfold increase from the previous 45 minutes [1]. Yet, in practice, people often receive a total of 35.6 minutes per day of in patent stay therapy [2,3]. These shortfalls were attributed to highly varied nurse and therapy staffing levels exacerbated by understaffing issues, and

XSL•FO
RenderX

organizational factors such as the timing of therapy assessments and the presence of weekend therapy services. In addition, less than half of stroke teams provided an extended weekend therapy service.

Stroke rehabilitation activity in the United Kingdom is measured through manual tracking, typically based on therapists' notes. The Sentinel Stroke National Audit Programme (SSNAP) database is a national stroke register that audits care from approximately 250 stroke teams in England, Wales, and Northern Ireland through a combination of electronic data entry by the stroke team and manual data inputting to the SSNAP's online clinical database. Whilst SSNAP captures daily therapy duration and other key metrics, it lacks data on the structure, content, and timing of therapy sessions, and inconsistencies in therapist-reported durations have been noted with a tendency to overestimate the duration of treatment sessions [4]. This absence of standardized, automated, and objective methods for monitoring rehabilitation dosage and intensity hinders adherence to guidelines, personalized care, and research into innovative interventions.

Rehabilitation dosage refers to the total amount of therapy delivered, encompassing the intensity, frequency, and duration of rehabilitation activities [5]. Intensity, as defined by the United Kingdom's National Institute for Health and Care Excellence (NICE) guidelines, involves tailoring the amount of therapy each day to meet the individual's needs across various domains, such as physiotherapy, occupational therapy, and speech and language therapy [6]. In the National Health Service (NHS), the dosage of stroke rehabilitation a participant receives is typically recorded manually by health care professionals, who document the time spent undertaking their rehabilitation during a therapy session, the specific activities performed, and the intensity of these activities in relation to the amount of therapy each day to meet the individual's needs [7]. This manual recording process is regulated for auditing and developing stroke care pathways [8].

The use of Internet of Things (IoT) and mHealth devices for self-rehabilitation shows promise in improving post-stroke recovery and quality of life [9]. Near-Field Communication (NFC) has been proposed as a means of recording patient information [10], yet there remains limited evidence of its use for clinically tracking acute or subacute stroke rehabilitation dosage or intensity. One study measured stroke dosage through electronic counters that required participants to press a button after each repetition [11]. While a promising approach, this places the burden of measurement on the participant. Home-based rehabilitation tracking using computers and tablets have also been investigated, particularly in post-stroke aphasia, and been suggested as a potential solution to standardizing dose measurement [12-14]. However, studies proposing electronic or digital methods for dosage tracking often do not adopt a co-design approach that would accommodate the full range of stroke severities, including cognitive and aphasic impairments. According to Medical Research Council recommendations [15], the usability of rehabilitation tracking technology should be driven by a collaborative process involving both users and health care professionals, ensuring that design and functionality are optimized to address diverse user needs.

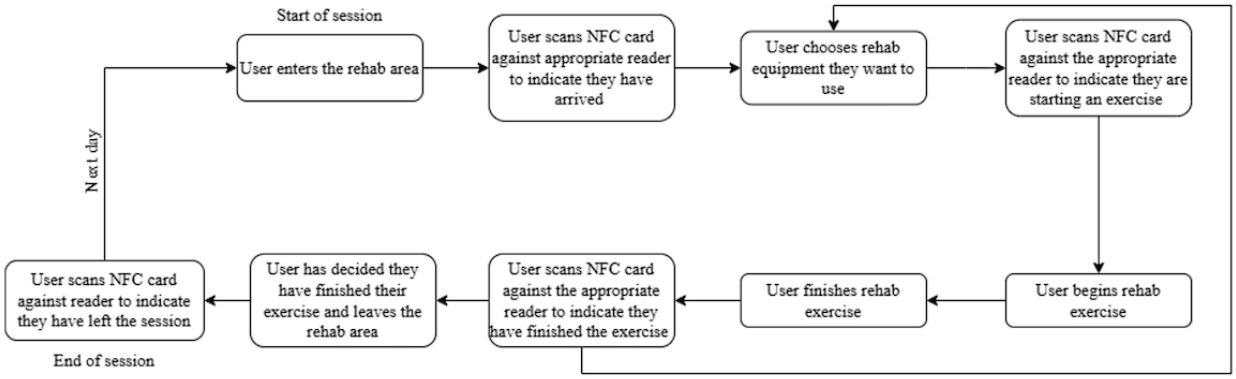
This study introduces a novel, co-designed tracker that uses NFC technology to track the dosage of rehabilitation across multiple domains (physical, cognitive, and communication). The tracker was designed with users (stroke survivors and stroke rehab professionals) to be accessible, clinically appropriate, and easy to implement, providing a comprehensive and user-friendly solution for monitoring compliance with stroke rehabilitation guidelines.

Methods

Overview

This pilot study, conducted in 2 phases, evaluated the digital dose tracker, co-designed by users, by assessing its feasibility, validity, and usability. Phase 1 focused on a usability study (n=9) conducted in a research setting. Phase 2 involved a clinical trial to assess the trackers' feasibility and validity (n=15). The primary outcome for Phase 1 was usability, measured by the System Usability Scale (SUS) and Intrinsic Motivation Inventory (IMI). The primary outcomes for Phase 2 were dose validity (comparison with the current method) and tracker feasibility [16]. Feasibility was defined as the ability of the digital dose tracker to be effectively used by all participants, including those with cognitive or physical impairments, without requiring significant modifications or support. It was assessed by the absence of user errors in Phase 2, withdrawals, and the successful capture of accurate rehabilitation data across various activities [17].

Co-Design of Digital Dose Tracker



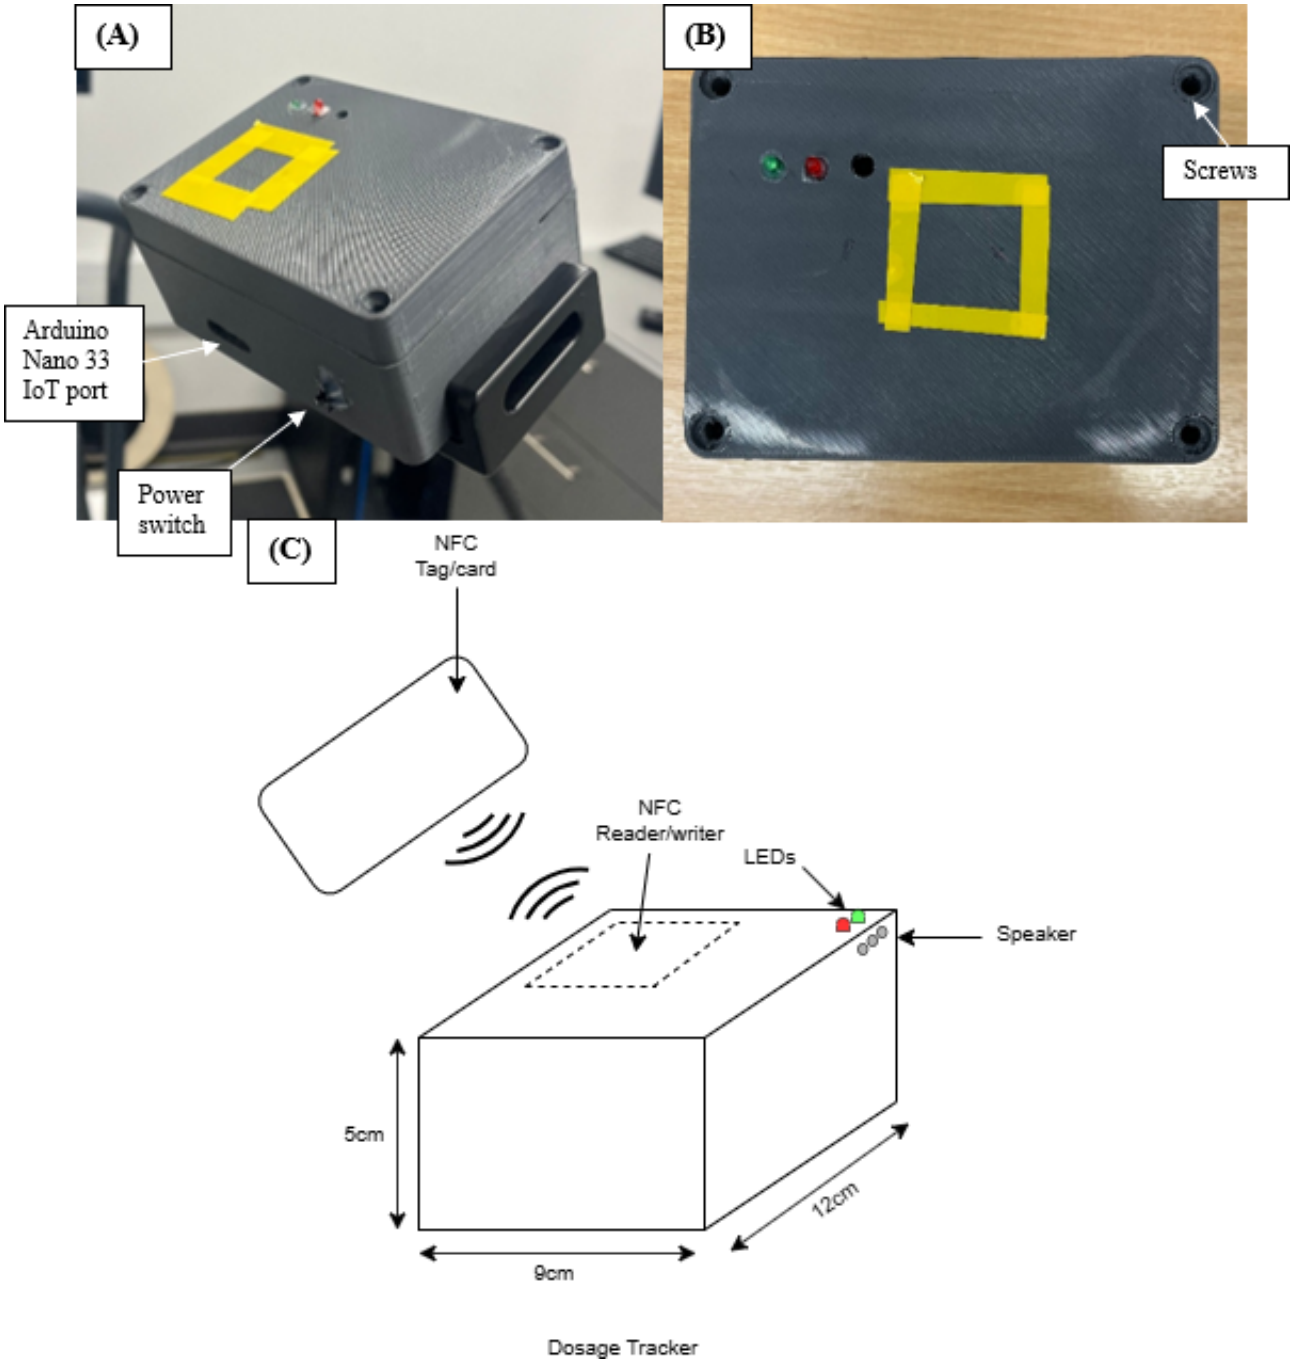
Two focus groups were conducted; first, to determine the need for a digital tracker and brainstorm ideas with the stroke rehabilitation community, second to create the product design criteria and user requirements for both hardware and software [16]. The same participants (6 stroke survivors and 1 physiotherapist) were involved in both focus groups. Design requirements were extracted through thematic analysis and ranked by priority which was determined by the frequency of mentions paired with the number of participants contributing. Once the design criteria were prioritized this was verified with the focus group participants. The key outcomes of these focus groups were the clear need to create a device that could track both dosage and intensity but was simple to use and could motivate engagement with rehabilitation [18].

Device Specifications

A recommendation from the cocreation process was to use a contactless ID card reader positioned at various rehabilitation workstations (Figure 1) [19,20], enabling users to tap their card and self-track their dosage in real time.

XSL•FO
RenderX

Figure 1. The user journey of the digital dose tracker. NFC: Near-Field Communication; rehab: rehabilitation.



The dosage trackers (Figure 2) consisted of an Arduino Nano 33 IoT (SAMD21, Arduino, Italy), a PN532 NFC module (NXP Semiconductors, Netherlands), green and red LEDs and an Adafruit mini speaker (Adafruit Industries; Figure 3) to provide visual and audio feedback. A rechargeable battery (5 volts, 1 amp) provided the power. Each tracker was programmed (C++) to register a participant's unique identifying number when they scanned their NFC card, allowing each rehabilitation activity and the corresponding time spent at each workstation, to be attributed to the correct user. Figure 2 highlights the positions of the light-emitting diodes, speaker openings, and the Near-Field Communication reader and writer. In addition, it depicts a Near-Field Communication card being brought into proximity with the device to facilitate communication between the card and the reader for logging participant dosage. The yellow markings in Figure 2A and 2B serve as visual guides to indicate the precise location of the Near-Field Communication reader, minimizing scanning errors.

When a user places their unique NFC card near a tracker for the first time, the green LED flashed once, and the speaker emitted a tone indicating a successful "scan in" to the equipment or room. Holding the card near the tracker a second time caused the green LED to flash twice, accompanied by another tone, confirming a correct "scan out." If a user then presented the same card to the tracker again, the system recognized that the same piece of equipment was being reused, or the same room was being re-entered. The card not being placed close enough to the tracker or being moved away too quickly could create registration errors. In these instances, the red LED flashed 3 times, and the speaker played an error sound, prompting the user to re-scan the card.

Phase 1: Usability

Participants

The usability of the digital dosage tracking system was tested with 9 participants recruited from an ongoing trial (ClinicalTrials.gov; NCT06787768) at the Sir Jules Thorn Centre for Co-Creation of Rehabilitation Technology, University of Strathclyde [17,18]. That trial was investigating the feasibility of a technology-enriched rehabilitation gym for people living with stroke, delivered entirely through technology (eg, virtual reality, treadmills, weight suspension, and power assistance equipment) over an 8-week program. Individuals in the trial were required to have experienced a stroke at least 12 months before, be in stable health, and be able to attend at least 2 of the 2-hour sessions per week, follow instructions in English, and offer verbal or written feedback. Within the technology-enriched rehabilitation gym, a physiotherapist designed, supervised, and reviewed each participant's program using principles of intensity, feedback, cognitive engagement, and aerobic activity, aligning it with the participant's goals and baseline outcome measures. Since all 9 participants met these criteria, they were also eligible to join our 8-week usability study, providing a controlled environment to evaluate the digital dosage tracking system.

Testing

Participants attended rehabilitation sessions in the research facility, where they used the trackers to log their rehabilitation activities. The activities and workstations used during this usability trial were matched to those in the subsequent clinical trial, maintaining consistency across both study phases. After completing the 8-week usability trial, participants filled out the SUS and IMI surveys to assess their experience with the system.

Analysis

The data gathered from the SUS and IMI surveys were analyzed to determine the usability of the digital dosage tracking system. The SUS provided a quantitative measure of usability, whilst the IMI offered insights into the participants' motivation and engagement with the system. The results were used to evaluate the trackers potential for integration into clinical practice

Phase 2: Feasibility and Validity

Participants

In-patients at a local NHS hospital, with a diagnosis of stroke and referred for rehabilitation, were invited to participate in the study, provided they met the following inclusion criteria: diagnosis of a new stroke by an NHS Lanarkshire physician, more than 48 hours since the stroke event, medically fit for rehabilitation as determined by medical staff, deemed to require rehabilitation, and able to provide informed consent. Individuals were excluded if they were acutely medically unwell, had active cardiac disease (such as unstable angina), active delirium or significant levels of confusion, had a seizure within the past 7 days, were being managed under the Adults with Incapacity Act, or were known to be pregnant. Those with aphasia and other cognitive or communicative difficulties resulting from their strokes were not excluded from participating. Given the nature of the stroke population, a significant proportion of participants were likely to have these impairments. In the United Kingdom, it is estimated that 50% of stroke survivors experience cognitive impairment, and approximately one-third have aphasia or other communication difficulties, particularly in the acute and sub-acute phases of recovery [21].

Testing

Participants attended as many sessions at a rehabilitation gym located on the stroke ward as able, with sessions lasting up to 2 hours. The tracker recorded the start and stop times when a participant scans their card at each activity, providing a log of the total time spent at each activity, the person who used it and exactly what the activity was to a local database based within the ward. At the same time, 2 supervising clinical staff members observed all participants and manually recorded the rehabilitation activities and durations. This manual logging was intended to simulate typical clinical practice, based on the advice of the local rehabilitation team, where therapists record the time spent at each station or device without tracking finer details such as repetitions or specific exercises.

Analysis

To assess the equivalence of the digital dosage tracking system with manual recording methods, paired sample *t* tests were used

XSL•FO
RenderX

to compare the mean times recorded by the 2 methods for each activity. Cohen *d* was calculated to quantify the effect sizes of any observed differences, with small effect sizes being indicative of negligible differences. Bland-Altman plots were used to visually explore the relationship between the 2 methods, and the limits of agreement (LOA) were calculated with a 95% CI to determine the range within which most differences would fall. Time recordings were standardized to minutes, and the average absolute time discrepancies and their variability are presented in the Results section. An acceptable range for discrepancies was decided to be within ±5%.

Ethical Considerations

This study received ethical approval from the Strathclyde University Ethics Committee under the protocol number UEC20/08: Kerr: Generic Framework Application: User experience of a technology-based rehabilitation program. All participants provided informed consent before their involvement in the study. Participants did not receive compensation, and all data were anonymized. The study was part of a clinical trial (ClinicalTrials.gov; NCT05981729) and received NHS Research & Development ethical approval from South East Scotland Research Ethics Committee 1 (IRAS ID No. 329156).

Results

Phase 1: Usability

A total of 9 people participated in phase 1 of this study (Table 1); however, 2 participants decided to withdraw from the trial in the final week, 1 due to other commitments and the second due to short-term illness. High usability was demonstrated with a mean IMI score of 6.29/7 (SD 1.5; Table 2), and a mean SUS score of 91.43/100 (SD 9.53); the total SUS score was calculated based on participants' responses to the 10-item questionnaire, with each item rated on a 5-point Likert scale. The scores were normalized and converted to a range of 0-100 (refer to Table 3 for further SUS results).

Question	P1	P2	P3	P4	P5	P6	P7	Mean (SD)
I would be willing to use this again because it has some value to me.	7	7	7	7	6	6	7	6.71 (0.49)
I am satisfied with my performance at using the system.	6	7	7	7	5	5	6	6.14 (0.90)
It was important to me to do well at using the system.	6	6	7	6	5	5	6	5.86 (0.69)
I used this system because I wanted to.	6	7	7	6	6	6	7	6.43 (0.53)
Using the system was an activity that I couldn't do very well. (R)	7	7	7	7	7	6	7	6.86 (0.38)
I felt pressured while doing this.	1	1	1	1	1	2	1	1.14 (0.38)
I think doing this activity could help me to motivate myself in continuing my rehabilitation.	7	7	7	7	7	6	7	6.86 (0.38)

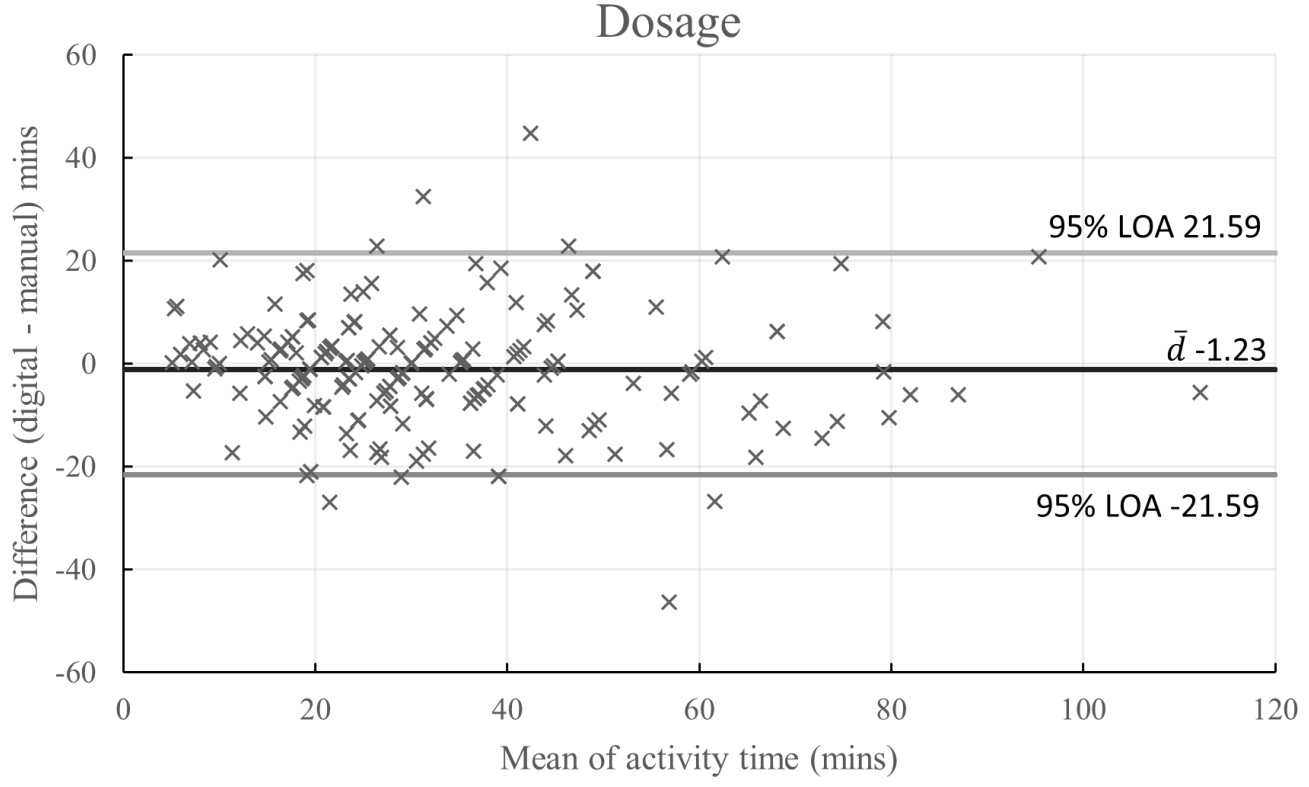
[a]R: reverse scored.

Table . System Usability Scale questions with average results; each item was rated on a 5-point Likert scale.

Question	Results, mean (SD)
I think I would like to use this system frequently in the cohort.	4 (0)
I found the system unnecessarily complex.	3.86 (0.35)
I thought the system was easy to use.	3.71 (0.45)
I think that I would need the support of a technical person to be able to use this system.	2.71 (1.75)
I found the various functions in this system were well integrated.	3.57 (0.49)
I thought there was too much inconsistency in this system.	3.57 (0.49)
I would imagine that most people would learn to use this system very quickly.	3.86 (0.35)
I found the tool very cumbersome to use.	3.57 (0.73)
I felt very confident using the system.	3.86 (0.35)
I needed to learn a lot of things before I could get going with this system.	3.86 (0.35)

XSL•FO
RenderX

Phase 2: Feasibility and Validity



Throughout the 6-month duration, 15 participants were recruited and completed the study (Table 4). Across the 15 participants, 207 activities were recorded by both digital and manual methods with an average number of sessions during inpatient stay of 9.1 (SD 7.4). There was a generally high agreement between the methods (t_{206}=−1.6; *P*=.11; Cohen *d*=−0.06), confirming the equivalence of the 2 tracking methods. The overall analysis, encompassing all recorded data from the various rehabilitation stations and gym attendance, revealed an average absolute mean time difference of 1.23 (SD 11.01) minutes across 207 total uses. This absolute mean time difference reflects a small 1 - 2-minute discrepancy between the digital and manual recorded times, indicating that whilst minor differences existed, they were not systematic and likely stemmed from normal variations in manual documentation.

Table . Participant characteristics of feasibility and validity trial.

Characteristics	All participants (n=15)
Age (years), mean (SD)	70.93 (13.31)
Sex, n	
Male	7
Female	8
Stroke type, n	
Ischemic	13
Hemorrhagic	2
Time since stroke (days), mean (SD)	19.5 (14.99)

The Bland-Altman plot (Figure 4) shows an even spread across the range of activity durations, indicating consistent agreement between the digital tracker and manual recordings. The plot reveals a bias of −1.23 minutes, suggesting good accuracy of the digital tracker relative to the manual method, with only a small systematic bias. The LOA were calculated to be from −21.59 to 21.59 minutes, which encompasses most of the observed discrepancies. Despite this range, the review of activity-specific durations revealed only minor differences, no greater than 6 minutes on average (Table 5), further supporting the reliability of the digital tracking system.

Figure 4. Bland-Altman plot comparing digital and manual dosage tracking methods. This plot shows the difference between the digital and manual dosage tracking methods for all recorded activities (n=207) at the stroke ward, plotted against the mean activity time. The plot includes the mean difference (bias, d-) and the upper and lower limits of agreement at a 95% CI. The bias value, closely aligned with the x=0 axis, indicates a high degree of validity between the 2 methods. LOA: limit of agreement.

Table . Summary of rehabilitation workstations and mean time discrepancies between digital and manual recordings. This table details the number of uses, the equipment involved, and the average time discrepancy (SD) in minutes between the digital tracker and manual recordings for each workstation. The "overall" row shows the combined data across all workstations and gym attendance.

Workstation category	Equipment	Number of uses, n	Time discrepancy (minutes), mean (SD)
Upper limb station	Graded Repetitive Arm Supplementary Programme (GRASP) kits, Gripable	24	5.23 12.8)
Cognitive applications	TinyTablet	24	2.73 (6.52)
Speech applications	TinyTablet	3	5.26 (21.08)
Power assist equipment	Three MOTOmed devices	67	3.23 (9.87)
All equipment uses	All above-listed equipment (excluding gym attendance)	118	0.27 (10.72)
Total time spent in rehabilitation gym	Attendance in gym	89	4.5 (14.55)
Overall	__[a]	207	1.23 (11.01)

[a] Not applicable.

Discussion

Principal Findings

The aim of this study was to evaluate a novel digital dose tracker against the standard manual recording method. Primary results showed a high level of agreement between the digital and manual methods, with Cohen *d* indicating a negligible effect size, which suggests that the differences between the 2 methods are minimal. This result confirms the digital tracker's consistent and complete data capture. Manual recording is currently the method used for auditing and developing stroke care pathways [8]. The digital tracker's ability to collect a broader range of activity data, as shown in Figure 4, highlights its potential to describe the intervention in greater detail, benefiting health care providers attempting to improve their services and researchers aiming to better understand response to rehabilitation interventions.

Phase 1 outcomes demonstrated the device's clear usability among users. The high scores for SUS and IMI were not surprising given the preceding co-creation process. Usability is a critical factor in health care and rehabilitation settings, as it directly influences the likelihood of a device being adopted in routine practice. The high usability demonstrated by this digital dose tracker ensures that both health care providers and people with stroke history can integrate the device into daily operations without significant disruptions or extensive training. This ease of use supports seamless implementation in clinical environments, enhancing the overall user experience and increasing the likelihood of widespread adoption [22]. In rehabilitation, where consistent and accurate use of technology can significantly impact patient outcomes and care efficiency, high usability is particularly important [23].

Whilst the mean time discrepancy between the digital and manual methods is relatively small (1.23 min), the larger SD 11.01 min indicates some variability in individual time recordings. This variability could be attributed to factors such as differences in manual recording practices among therapists, variations in task complexity, and individual participant behavior during rehabilitation sessions. Despite this variability, the overall agreement between the 2 methods remains strong, suggesting that the digital system is a valid tool for tracking rehabilitation dosage, especially when considering the average results across multiple sessions and participants.

The digital tracker accurately tracked rehabilitation activities by logging the unique identifiers of both participants and devices, ensuring precise data collection. Conducted under direct observation, therapists manually recorded the time spent at each station, reflecting standard clinical practice. Whilst a minor average discrepancy of about 1 minute was noted between the digital system and manual recordings, this difference was minimal and fell within an acceptable range.

In line with the definition of rehabilitation dosage, which includes the intensity, frequency, and duration of rehabilitation activities, the digital tracker successfully captures the essential elements of dosage as required by this definition. Although intensity refers to the individualized adjustment of daily therapy across various domains such as physiotherapy, occupational therapy, and speech therapy, this tracker is particularly adept at accurately recording the frequency and duration of therapy sessions. By logging the start and stop times of each session, the tracker provides a measure of the total duration of rehab, which is critical for ensuring that people with stroke history receive the appropriate amount of therapy prescribed to them and can be used to monitor achievement of guidelines.

The digital trackers approach to tracking rehabilitation dosage mirrors the standard clinical practice where therapists estimate the total time a patient spends at a therapy station. Therapists typically log this time without distinguishing between active therapy and brief pauses, which has been an accepted method in clinical practice for years. The 1-minute average discrepancy observed between the therapists' manual logs and the digital recordings reflects the minor variations inherent in manual estimation. Importantly, the fact that these times align so closely and fall within clinically acceptable margins of error

XSL•FO
RenderX

demonstrates that this method does not negatively affect the results. This small difference is within the clinically acceptable range, reinforcing the digital trackers reliability as a tool for tracking rehabilitation dosage.

The distribution of attendance across the different rehabilitation workstations also provides insight into the priorities and preferences of people with stroke history during their rehabilitation. Users at the stroke ward's rehabilitation gym had the autonomy to select the rehabilitation they preferred, with guidance and supervision, during their sessions. The Power Assisted Equipment station had the highest number of uses (n=67) which may reflect a common patient priority of focusing on motor recovery [24]. This preference is often driven by the desire to regain physical independence, which has been previously recognized as a priority for individuals with stroke over cognitive or speech rehabilitation.

The Bland-Altman plot, Figure 4, showed that the device was accurate in depicting a user's rehabilitation journey and the LOA were calculated with a 95% CI. There is currently no clinical documentation which specifies an acceptable LOA, but a margin of error within ±5% - 10% was deemed acceptable, given that manual recording in rehabilitation contexts could vary widely, affecting the reliability of data [25]. The LOA determined in this study was within this range.

Table 3 shows that 3 rehabilitation workstations had an average time difference of just under 6 minutes. This discrepancy is attributed to the need for hoist or transfer assistance for users with low to no mobility, resulting in waiting periods. This also applies to the time taken for participants to transfer in and out of the rehabilitation gym. Overall, wide differences were rare, and outliers were attributed to instances of human error in the manual recordings when the therapist was observing and recording multiple participants at once.

The feasibility of the digital dose tracker was further demonstrated by the fact that all users of the rehabilitation gym, regardless of their varying levels of cognitive or physical impairment, were able to effectively use the system. There were no withdrawals in Phase 2 or errors recorded by the tracker during the study, nor were any observed by the 2 clinical staff, demonstrating the trackers accessibility and functionality across a diverse stroke population.

Whilst the dosage tracker can operate on its own, it is a subcomponent of a more complex device with the intended purpose to measure both dosage and intensity of a person's rehabilitation. This device is a prototype and proof of concept, throughout the phase 1 usability trial participants were allowed to give feedback about the device to allow for adjustment and modifications, this included adjusting the brightness of the LEDs and increasing the volume of the speaker to improve audio and visual feedback. The device is limited in the quality of its components due to funding however if additional funding were to be obtained this would contribute to the refinement of the trackers to reduce the size and thus improve portability.

The study faced challenges related to the rate of participant uptake. A significant number of potential participants could not be included because they were only in the hospital for a few days, which did not allow sufficient time for the consent process. In addition, the rate of uptake in the study and the number of viable participants varied depending on the number of people admitted to the stroke ward during the study period. This limitation reduced the overall sample size, impacting the generalizability of the findings. Future studies could consider running for a longer duration to accommodate the consent process and variations inpatient admissions, thereby ensuring a more comprehensive assessment of rehabilitation dosage.

Conclusion

This study has evaluated a novel, co-designed, digital system for monitoring rehabilitation dose finding it largely agreed with traditional manual methods. It is one of the first studies to implement such a method of rehabilitation dosage tracking in a clinical rehabilitation setting. This promising system has the capacity to provide an accurate and automated method for measuring achievement of the new National Clinical Guidelines for Stroke recommendations and providing practical support for therapists and researchers.

Acknowledgments

We would like to thank all the participants for their participants for their engagement throughout the process. We would also like to thank Chest Heart and Stroke Scotland and the Engineering and Physical Sciences Research Council for their support.

This study was supported by a PhD studentship from the Department of Biomedical Engineering, University of Strathclyde, Glasgow, United Kingdom.

Abstract

Background: People with severe-to-profound intellectual disability and sensory-motor impairment tend to be passive and detached from their immediate context.

Objective: This study assessed a new technology system using a webcam to detect participants' responses (ie, hand contact with objects) and to trigger computer delivery of preferred environmental stimulation, such as music, contingent on (immediately after) the occurrence of those responses.

Methods: In total, 8 adults with severe to profound intellectual disability and extensive motor and visual impairments participated in the study. Each participant was exposed to an ABACB design. The technology system did not provide stimulation during the A (baseline) phases, provided stimulation contingent on the responses during the B (intervention) phases, and provided stimulation throughout the sessions during the C (control) phase. Sessions lasted 5 minutes.

Results: During the first baseline phase, the participants' mean frequency of responses per session was between about 3 and 6.5. During the first intervention phase, it increased to between about 10 and 18. It showed a clear decline during the second baseline phase, remained low during the control phase, and increased again during the second intervention phase. During this phase, it ranged from about 13 to 19.5.

Conclusions: The new technology system might be a useful tool to help people with intellectual and sensory-motor disabilities increase object contact and stimulation control.

Introduction

Background

People with severe-to-profound intellectual disability and sensory-motor impairment tend to be largely passive and detached from their immediate context [1-6]. Indeed, they may not have particular interest in the objects available to them, may lack speech and possess only minimal and inefficient forms of nonverbal communication, and may be unable to access environmental stimulation independently with the consequent risk of low and poor stimulation input [1-7].

This situation is largely unsatisfactory, and efforts have been reported to reduce its negative implications. Some of the efforts have been directed at increasing the level of interaction between

XSL•FO
RenderX

these people and their staff and caregivers to increase their stimulation input and the opportunity of practicing basic forms of communication [2,6-12]. Other efforts have been more specifically focused on enriching these people's daily conditions with increased levels of environmental stimulation [13-19]. These latter efforts presented a clear differentiation based on whether their scope was to (1) provide people with a rich stimulation context [18,20-22] or (2) enable people to exercise self-determination, thus seeking and controlling environmental stimulation through their own responses rather than relying on staff mediation [16,23,24]. Promoting self-determination can be considered a critically important goal within the rehabilitation process, that is, a goal that is instrumental to counter passivity (isolation) and foster independent contact with the immediate context and objects [25,26].

Studies aimed at enabling people to seek and control environmental stimulation independently (through their self-determination) have often relied on technology systems, including sensors (microswitches) linked to a computer, smartphone, or tablet [16,27-34]. Sensor activations via specific responses triggered the computer, smartphone, or tablet to deliver brief periods of preferred stimulation. In essence, the technology was arranged to ensure that even people with a limited response repertoire would always have 1 or 2 responses that they could use as tools (instruments) to seek and control environmental stimulation.

The results of those studies were largely encouraging. First, people were typically successful in using the responses selected for them to perform and thus enriched their stimulation input based on their own initiative (self-determination) and independent choice. Second, people seemed to enjoy such a situation. In fact, studies reported that they tended to show indices of happiness during sessions in which they were able to control their stimulation input through their responses [16,33,35-38]. Third, comparative evaluations seemed to indicate that indices of happiness tended to be higher (more frequent) in situations in which people controlled the stimulation through their responses than in situations in which the stimulation was automatically delivered (ie, independent of people's responses) [16,36].

The results mentioned earlier constitute an important basis for supporting the use of technology-based interventions aimed at enabling people to independently seek and control their environmental stimulation. Extending the use of those interventions poses questions about the responses the participants should be required to produce and the sensors that could be used to detect those responses. As to the responses, it would seem advantageous to select those that involve people's physical contact with objects (ie, to curb their isolation and detachment). As to the sensors, the main question is to ensure that they are suitable and dependable in detecting responses involving touching or exploring objects. The answer to this question is not always obvious. For example, one may argue that optic sensors placed in the proximity of the objects to be touched or explored could easily detect the responses. Yet, response detection might become inaccurate if the sensors' focus is altered during the sessions by people's erratic response movements. Pressure sensors under or to the side of the objects to be touched and explored could be effective. Yet, that would require that people apply some pressure on the objects.

Objectives

The purpose of this study was to assess (1) the suitability (applicability) of a sensor that did not need to be displayed in the proximity of the objects to be touched or explored but would detect the responses from a distance, thus bypassing the difficulties mentioned regarding optic and pressure sensors, and (2) the effectiveness of the sensor and related technology system in helping the participants increase contact with objects and control environmental stimulation. A positive answer regarding each of these 2 assessment points was thought to have relevant practical (clinical) implications for future work with people with multiple disabilities. The sensor consisted of a webcam. The technology system of which the sensor was part involved a portable computer fitted with specific software, a mini speaker, and a smart Wi-Fi plug. In total, 8 people with severe to profound intellectual disability and sensory-motor impairments were involved in the study, which was carried out using single-case research methodology.

Methods

Participants

The 8 participants represented a convenience sample [39] in that they were selected from rehabilitation and care centers of a single organization. All of them, however, shared a complex condition in terms of disabilities and limited engagement with the immediate context and were adults. Table 1 lists the 8 participants via their pseudonyms and reports their chronological age and their Vineland age equivalents for Daily Living Skills, personal subdomain (only this subdomain of the Vineland Adaptive Behavior Scales was used as it seemed the most representative of their general functioning). Their chronological age ranged from 27 to 48 years. Their Vineland age equivalents (obtained via the second edition of the Vineland Scales [40,41]) ranged from below 1 year to 2 years and 2 months, underlining the seriousness of their situation and their dependence on external support. All participants had congenital encephalopathy and presented with intellectual disability, motor impairments (ie, lack of ambulation or ambulation with support and arm-movement restrictions), absence of speech or any formal communication means, and minimal residual vision (Logan and Harper) or blindness (all others). No IQ scores were available for them as no formal testing was possible given their situation. The psychological services of the rehabilitation and care centers that they attended estimated their level of intellectual disability to fall in the profound or severe-to-profound range.

XSL•FO
RenderX

Table 1. Participants' chronological age and Vineland age equivalents for Daily Living Skills (personal subdomain).

Participants (pseudonyms)	Chronological age (years)	Vineland age equivalents[a] (years, months)
Liam	43	2, 2
Hallie	37	<1, 0
Logan	31	<1, 0
Kali	48	1, 3
Harper	43	2, 1
Jacob	33	1, 5
Millie	27	1, 1
Isabel	34	1, 2

[a]Age equivalents are based on the Italian standardization of the Vineland Scales [40].

The participants were included in the study based on a number of conditions, which had been verified through preliminary observations and staff interviews. First, they were generally passive with very limited contact with their immediate context but possessed the arm-hand motor schemes necessary to reach and touch objects on their desk. Second, they showed signs of interest in forms of environmental stimulation (eg, could display alerting and smiling in relation to music and songs). The assumption was that such stimulation could be used contingent on their object contact responses during the study. Third, they seemed to alert and sometimes to activate themselves (eg, producing a reaching response) in relation to the presentation of alerting stimuli such as verbal encouragements or noises. Fourth, rehabilitation personnel considered an increase in the participants' responses highly useful to break their withdrawal and to promote functional motor schemes. Fifth, the use of a technology system to help the participants acquire and consolidate their responses was viewed favorably within their daily contexts by regular staff and caregivers.

Setting, Sessions, Responses, Research Assistants, and Stimuli

Quiet rooms of the rehabilitation and care centers that the participants attended were used as the setting for the study sessions. In total, 3 types of sessions were available, that is, baseline, intervention, and control sessions. All sessions lasted 5 minutes. They were implemented on an individual basis, typically 2-3 times a day (nonconsecutively), 3-6 days a week. A response consisted of the participants making a new hand contact with (ie, touching or exploring) either one of the 2 objects available in front of them, that is, on the desk at which they sat. The objects included simple everyday materials such as sponges, small boxes, rings, and bottles, which were fixed on the desktop.

In total, 4 research assistants were responsible for implementing the sessions and checking their agreements and disagreements with the technology system regarding the responses it recorded and followed with stimulation delivery. They had university degrees in psychology and were familiar with the implementation of technology-aided programs with people with disabilities and with data recording procedures. Expert research assistants were involved in carrying out the study because they were expected to need only minimal practice (preparation) time and to be procedurally reliable given their experience. Moreover, contrary to staff personnel, they did not have care and rehabilitation duties that could interfere with the timing and implementation of the sessions.

The stimuli used during the intervention and control sessions included music, songs, noises, and voices or combinations of them with various types of lights (Logan) or mild airflows (Millie). The stimuli had been selected through a stimulus preference screening procedure carried out before the start of the study. The procedure consisted of presenting each of three 10-second segments of the songs and music pieces as well as clips of different lights, voices, and noises or brief airflows for at least 10 nonconsecutive times (ie, over different assessment periods). The stimuli were retained for the intervention and control sessions only when the research assistants and staff members involved in the screening agreed that at least 50% of their presentations were followed by positive reactions (eg, orienting and smiling) [26].

Technology System

The technology system was similar to that used by Lancioni et al [28] and included a webcam sensor linked to a portable computer, a Bluetooth mini speaker, and a smart Wi-Fi plug. The smart Wi-Fi plug was used only when the preferred stimuli following the responses included lights or airflows (see the *Setting, Sessions, Responses, Research Assistants, and Stimuli* section). The computer was fitted with Windows 11 and specific software. The webcam was mounted on a tripod to monitor the participants' responses from a distance. At the start of the study, the research assistants determined the best position of the webcam for each participant so that it could provide the computer and related software with a clear image of the participant's face and hands and of the objects to be touched. The software, which is freely available [42], was developed using the Python programming language and built on open-source libraries. These included OpenCV for image processing, MediaPipe Pose for detecting human body landmarks (specifically, hand landmarks) in 3D space, and python-kasa for controlling the smart Wi-Fi plug.

The software enabled the system to perform a number of essential functions. First, the system (1) monitored (via the webcam) the position of the participants' hands relative to the objects placed in fixed positions on the desk during all study

XSL•FO
RenderX

sessions, and thus (2) could determine whether the participants performed object contact responses by comparing the hand landmarks with the object positions. Second, the system provided participants with a 10-second period of preferred stimulation, such as music, contingent on (immediately after) each response performed during the intervention sessions. During the 10-second stimulation periods (and, for consistency, the 10-second period following each response in all other study sessions), the system halted its hand position monitoring so that no new response was recorded during that time. Third, the system controlled the presentation of alerting events during the different phases of the study (see the *Baseline I* section). Fourth, the system memorized the session setup parameters recorded for each participant at the start of the study (following the positioning of the webcam) so that the same parameters could be applied across all sessions. Fifth, the system assisted in recording the frequency of responses that occurred in the sessions. Preferred stimulation and alerting events were presented via the Bluetooth mini speaker, which served to increase their volume.

Measures and Data Recording

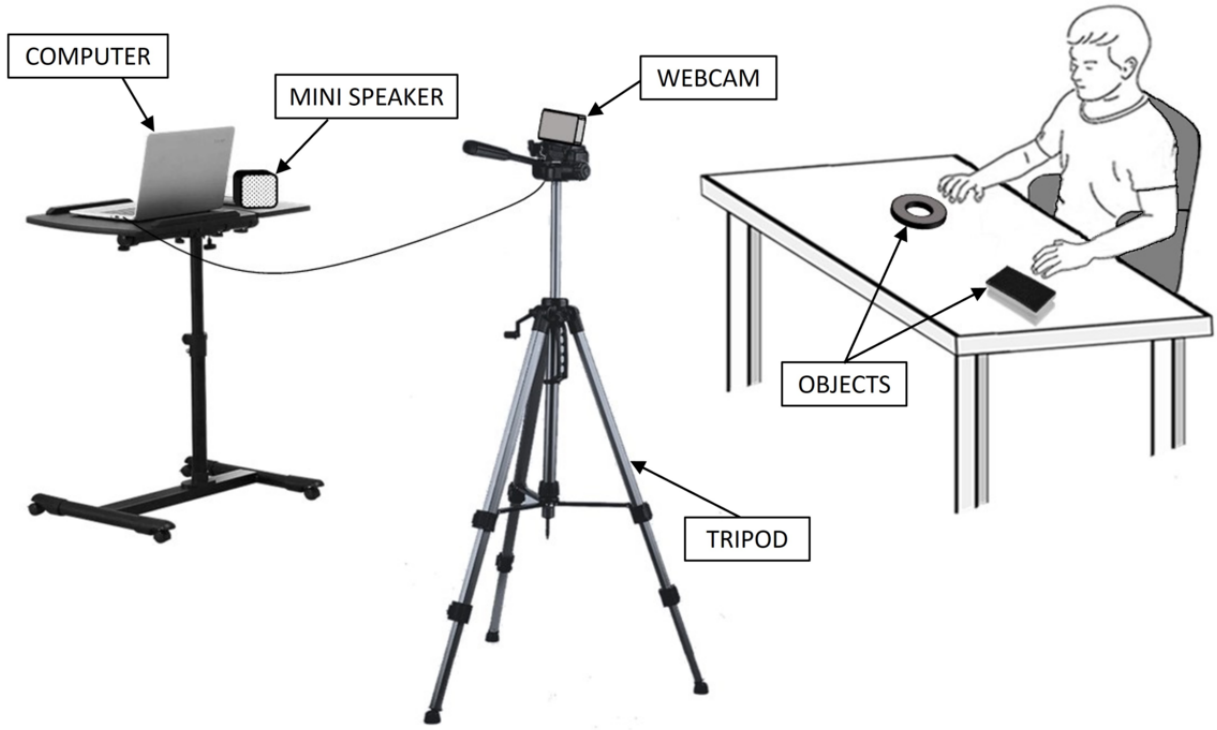
The first measure concerned the frequency of responses the participants performed during the baseline, intervention, and control sessions and was recorded via the technology system. The second measure concerned the level of research assistants' agreement with the system on the responses the system recorded and followed with stimulation during about 50% of the sessions of Intervention II. In connection with each of those responses, the research assistants were to note whether they did or did not agree with the system's recording. The percentage of agreement between research assistants and the system (computed on single sessions by dividing the agreements by the agreements plus disagreements and multiplying by 100%) ranged between 88% and 100%, with means for the single participants exceeding 96%.

Experimental Conditions and Data Analysis

Overview

Each participant was exposed to an ABACB design, in which A represented the baseline condition, B represented the intervention condition (with the system delivering stimulation contingent on the participants' responses), and C was a control condition [43]. The first baseline (A) phase included different numbers of sessions for the different participants according to a nonconcurrent, multiple baseline design across participants [43]. This single-case research design format was considered adequate to determine the strength and internal validity of the data gathered in the study [43].

To ensure a high level of accuracy from the research assistants (ie, a high level of procedural fidelity [44]) during the implementation of the 3 types of sessions, 2 strategies were adopted. The first strategy consisted of the research assistants practicing the use of the technology system prior to the start of the study. This was to enable them to determine the best position of the webcam and setup of the system with the participants. The second strategy consisted of the availability of regular feedback for the research assistants. Specifically, they were informed as to whether or not they were accurate in their implementation of the procedural conditions by a research supervisor who had access to video recordings of the sessions. This feedback was viewed as a precautionary measure more than a necessity given the research assistants' initial practice with the system and the fact that the system memorized the participants' session parameters and followed (enacted) those parameters automatically.



The participants' frequency of responses across the study phases was summarized in graphic form. The differences in response frequency between the (1) first baseline and first intervention phase, (2) second baseline and second intervention phase, and (3) control phase and second intervention phase were assessed using the percentage of data points exceeding the median (PEM) method [45,46]. This method, which is a basic and practical tool for the evaluation of within-subject research data, served to determine for each participant the percentage of intervention sessions with a frequency of responses higher than the median of the previous baseline or control phase.

Baseline I

Baseline I included 5-10 sessions. The participants sat at a desk that contained 2 easily reachable objects; that is, they were in a situation familiar to them (Figure 1). Before the start of a session, the research assistants guided the participants (through physical prompts, which could be accompanied by a verbal expression such as "Touch here") to touch the objects once or twice; that is, they provided 1 or 2 response practice trials. In an attempt to avoid the risk that the participants would remain passive throughout the sessions, alerting events were presented after periods of 30-40 seconds of no responding. These events (ie, 2-word verbal encouragements or brief sounds and noises triggered by the computer and delivered via the mini speaker) were to enhance the participants' vigilance and attention and eventually facilitate some responding (see the *Participants* section). The technology system was available (see Figure 1 for a schematic view of the webcam, computer, and mini speaker) but only served to present the alerting events and record the responses. In fact, no stimulation was scheduled for the responses.

XSL•FO
RenderX

Figure 1. Schematic representation of a participant sitting at a desk with objects and of the webcam, computer, and mini speaker.

Intervention I

Intervention I included 15-31 sessions. Conditions were as in Baseline I with the difference that the system provided the participants with 10 seconds of preferred stimulation (eg, music and song clips) after each response. The first session was preceded by 5-7 response practice trials with stimulation following each response. Intervention I continued until the participants had shown a clear response increase.

Baseline II

Baseline II included 5-9 sessions. Conditions were as in Baseline I.

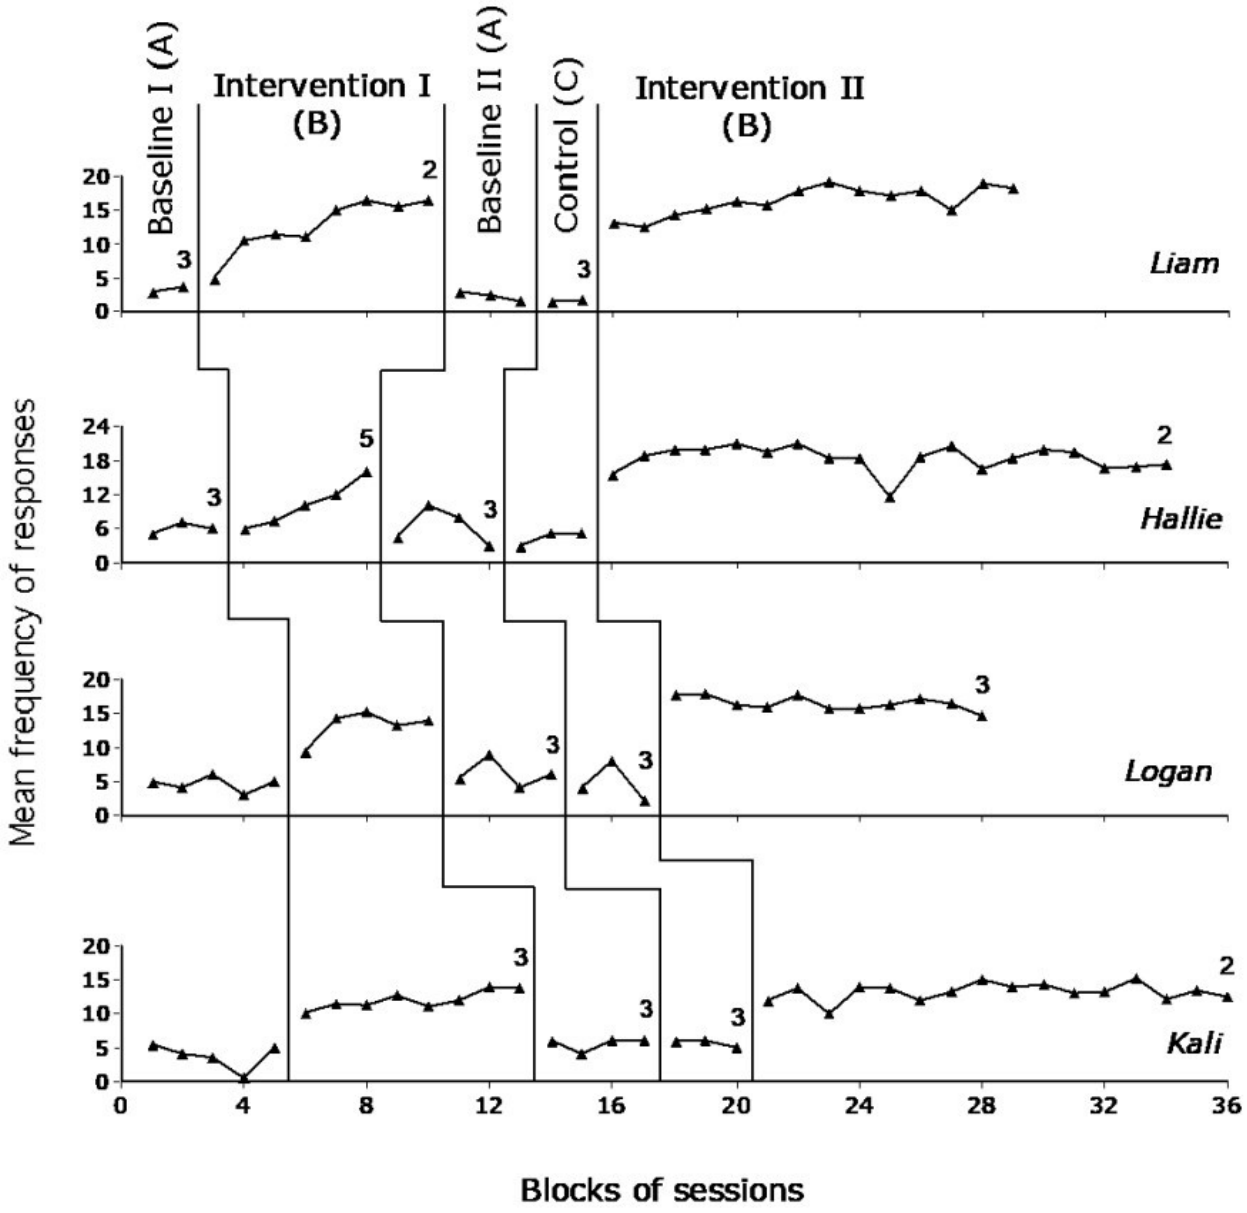
Control Phase

The control phase included 5-8 sessions. Conditions were as in Baseline II with regard to the availability of objects and alerting events. The difference was that the participants were provided with stimulation throughout the sessions. Stimulation changed several times during the session to minimize the risk of habituation effects [16]. The control phase was included to determine if stimulation availability per se was responsible for the participants' increased responding, that is, if responding was the result of general activation (excitation).

Intervention II

Intervention II included 43-74 sessions. Conditions were as in Intervention I. During about half of the sessions, research assistants were to note whether they did or did not agree with the system regarding each of the responses the system recorded and followed with stimulation delivery (see the *Measures and Data Recording* section).

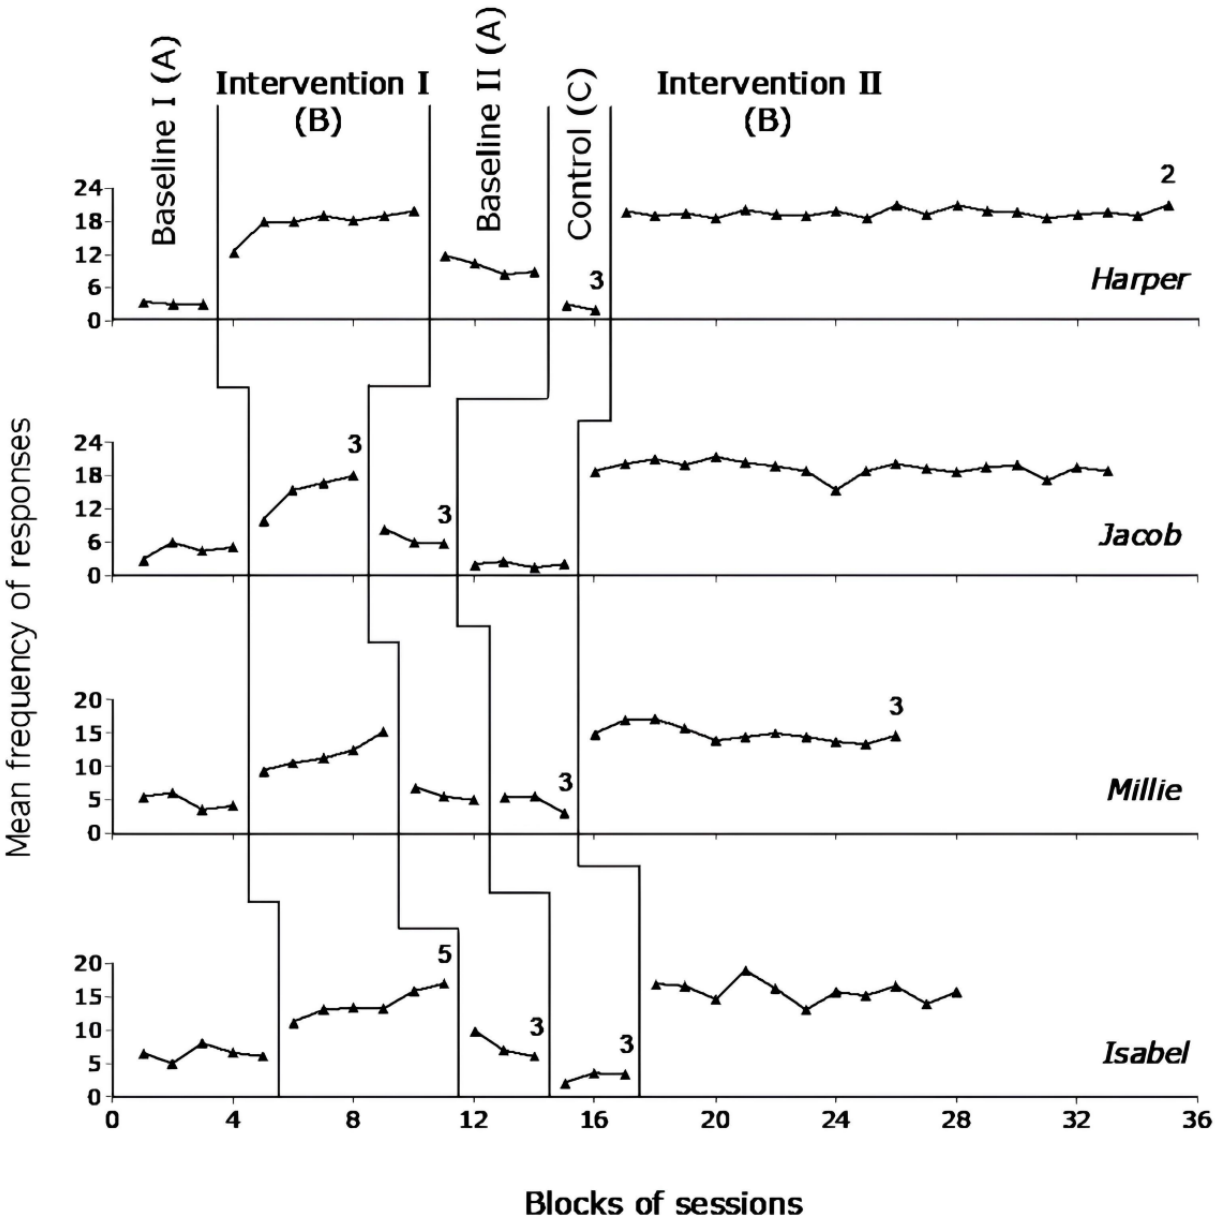
Ethical Considerations



Staff and caregivers considered the study a positive opportunity for the participants. In fact, the study was intended to help them acquire and practice functional motor responses and access preferred stimulation within a comfortable session arrangement that was free from any specific risk. The participants' legal representatives (who were contacted given the participants' inability to give their consent to the study) fully agreed with the staff and caregivers' view. They signed a consent form authorizing the participants to be involved in the study with (1) the possibility of ending such involvement at any time and (2) the guarantee of data deidentification. No participant compensation was available. The study complied with the 1964 Helsinki Declaration and its later amendments and was approved by the Ethics Committee of the Lega F. D'Oro, Osimo (AN), Italy (P030820241).

Results

Figures 2 reports the data for Liam, Hallie, Logan, and Kali and Figure 3 reports the data for Harper, Jacob, Millie, and Isabel over the different phases of the study. Each data point represents the mean frequency of responses per session over a block (group) of sessions. The blocks, which are used to simplify the graphic presentation of the data, include 2 sessions during the baseline and control phases and 4 sessions during the intervention phases. Blocks with numbers of sessions differing from those mentioned earlier are marked with a numeral, which indicates how many sessions those blocks include.



XSL•FO
RenderX

Figure 3. Data points for Harper, Jacob, Millie, and Isabel. Each data point represents the mean frequency of responses per session over a block of sessions. The blocks include 2 sessions during the baseline and control phases and 4 sessions during the intervention phases. Blocks with numbers of sessions differing from those mentioned earlier are marked with a numeral, which indicates how many sessions those blocks include.

During Baseline I, the participants' frequency of responses per session varied between 0 and 10, with means ranging from about 3 (Harper) to 6.5 (Isabel). During Intervention I, all participants showed a clear response increase. Their frequency of responses per session varied between 5 and 23, with means ranging from about 10 (Hallie) to 18 (Harper). The PEM method used to compare the data of Intervention I with those of Baseline I provided indices of 0.86 to 1. These indices pointed out that the response frequency of all or nearly all Intervention I sessions was above the median values of Baseline I, thus confirming the positive impact of the intervention conditions.

During Baseline II, the response frequency decreased for all participants. Their frequency per session varied between 1 and 14. Their means ranged from slightly above 2 (Liam) to about 10 (Harper). The response frequency did not seem to increase during the control phase. In fact, several participants tended to have a decline in responding. During Intervention II, the participants showed a response frequency similar to that observed toward the end of Intervention I. Their mean frequency ranged from about 13 (Kali) to 19.5 (Harper). The PEM method used to compare the data of Intervention II with the data of Baseline II and of the control phase provided indices of 0.98 to 1. These indices pointed out that the response frequency of all or nearly all Intervention II sessions was above the median values of Baseline II and of the control phase, thus confirming the strong impact of the intervention conditions. The difference between the intervention condition and the control phase indicates that the stimulation contingent on the participants' responses (and not the availability of stimulation per se) was responsible for the response increase.

The research assistants' level of agreement with the system on the responses that the system recorded and followed with

XSL•FO
RenderX

stimulation delivery was high. Indeed, the percentages of agreement (already reported as part of the data recording process; see the *Measures and Data Recording* section) ranged between 88% and 100%, with means for the single participants exceeding 96%. It may also be added here that no specific system dysfunctions were reported during the study and that the research assistants were successful in using it. In fact, they quickly managed to (1) determine the best position of the webcam for each participant (ie, the position that provided the system with a clear image of the participant's face and hands and of the objects to be touched), (2) save the related parameters in the system, and (3) apply those parameters at the start of all study sessions to ensure reliability across them.

Discussion

Principal Findings

The results indicate that the webcam-based sensor was adequate to ensure monitoring of the participants' responses, and the technology system in its entirety was effective in helping the participants increase the frequency of those responses [16,27]. The dependability of the sensor was confirmed by the high percentages of agreement that research assistants had with the system regarding the responses it recorded and followed with stimulation delivery. The effectiveness of the system in its entirety was underlined by the differences in participants' response performance between the intervention phases and the baseline and control phases. The fact that the study sessions were implemented by expert research assistants (see the *Setting, Sessions, Responses, Research Assistants, and Stimuli* section) does not imply that regular staff would not be as successful following a brief practice period with the technology.

Using a sensor that is largely unobtrusive (ie, that does not need to be connected to the participants' body or to the objects that the participants are to touch and explore) can be considered an important practical advantage compared to using conventional sensors such as touch and optic sensors [47-50]. The latter sensors, in fact, although profitably used in the past [3,27,34], need to be arranged in contact with or proximity to the objects targeted for the participants' responses, with the risk that those responses may alter their position and make their functioning inaccurate. Accessibility to the sensor and technology system reported may be facilitated by the fact that (1) the webcam, portable computer, Bluetooth mini speaker, and smart Wi-Fi plug are commercial devices, and (2) the software is freely available. The cost of the system in its entirety is about US $850. This cost might be viewed as relevant for a single user and quite reasonable for a rehabilitation center in which several participants could benefit from the system. One might also expect that cheaper and simpler versions of the system will be developed in the near future, given the great demand for technology support in this area [29,30,51].

The existence of a reliable sensor, applicable in situations in which other (conventional) sensors such as touch, pressure, and optic sensors may be difficult to use, can be considered an important step forward in the development of technology-aided programs for people with extensive multiple disabilities (ie, people who tend to be passive and largely dependent on staff and caregivers for accessing environmental stimulation). Indeed, a reliable and suitable sensor can enable care and rehabilitation staff to help participants strengthen a developmentally relevant behavior, such as contact with the immediate environment, in a substantially independent (self-determined) manner [52-55].

Pursuing participants' independent contact with their immediate context and control of environmental stimulation may be viewed as a significant clinical and rehabilitation objective within any intervention program for people with extensive disabilities [27,56-58]. In fact, people who make contact with and explore objects in their immediate proximity (1) exercise useful motor responses that curb their tendency to be passive and detached, and (2) discover the power of their responses through the stimulation following those responses [54,59-61]. This discovery can then help them maintain their responses over time (strengthening their self-determination) and contribute to improving their appearance, mood, and quality of life [16,55,61-64].

While no direct data were collected regarding the participants' mood during the intervention sessions of this study, evidence from other studies in the area suggests that intervention conditions may have a positive impact on mood [16,33,37,38,65,66]. As to the discovery of the power of one's own responses, the data of this study add useful information. The participants' consistent responding during the intervention phases and the low responding during the control phase indicate that responding was not simply the consequence of stimulation availability. Rather, it appeared to be linked to the participants' discovery of the stimulation contingency value or, in other words, of their responses' power to control stimulation occurrence [60,61,63]. Such a discovery could be taken as a clear sign of clinical and rehabilitation progress [58,62].

Intervention approaches based on the use of a technology system like that used in this study or a new version of it may have relevant implications also for staff personnel. In fact, the system would allow them to offer participants extra opportunities for positive engagement with relatively limited time investment. This could be viewed as an extension and enrichment of the intervention protocol with affordable extra costs in contexts where staff resources are typically limited.

Limitations and Future Research

The study presents 2 main limitations, that is, the absence of maintenance and generalization data, and the lack of a social validation check. The first limitation prevents one from making statements as to whether the system can be effectively used over time and across different contexts. To amend this limitation, future studies will have to extend the data collection to longer periods of time using a variety of objects as well as different settings [60,61,67,68]. Positive maintenance and generalization data would provide a strong basis for considering the system a profitable tool within an intervention protocol designed for people with extensive disabilities. Support for the system might be further strengthened by the recognized need for technological assistance within programs directed at people with extensive and multiple disabilities [27,29,30,49,51].

XSL•FO
RenderX

The second limitation prevents one from making statements as to how the system may be viewed by staff, caregivers, and other service providers working within daily contexts for people with extensive disabilities. One way to address this limitation is to arrange surveys with care and rehabilitation personnel about the system's effectiveness, acceptability, and applicability in daily contexts. Surveys could be carried out by having the personnel (1) view video clips of intervention sessions carried out with different participants, and (2) rate the content of those clips in terms of system effectiveness, acceptability, and applicability [66,69,70].

One might also find the relatively small number of participants and the use of short (5-min) sessions to be additional limitations of the study. As to the first of these 2 potential limitations, one may argue that the single-case experimental methodology used with the 8 participants to evaluate the impact of the system was adequate to confirm the internal validity of the data reported [42,71,72]. Single-case replication studies and studies using group designs could provide new important evidence to determine the external validity of the present findings [71-73].

Regarding the short sessions, 2 views may be expressed. On the one hand, it may be argued that the use of short sessions represents a limitation of the study that does not allow one to determine for how long people like our participants can remain positively engaged with objects. On the other hand, it can be stated that, given the typically limited attention of these people [74,75], using short sessions may be a largely justified choice.

Conclusions

The results indicate that the technology system used in the study was adequate to ensure monitoring of the participants' responses (ie, touching and exploring objects) and to control the automatic delivery of preferred environmental stimulation contingent on those responses. A sensor that is largely unobtrusive and does not need to be near or physically connected to the objects to be reached (1) can be considered advantageous compared to conventional sensors such as touch and optic sensors, and thus (2) can allow new intervention opportunities for people with extensive disabilities. While highly encouraging, these results are to be taken with caution until new research evidence is available, and the limitations of this study have been addressed.

Acknowledgments

This research received no external funding.

Data Availability

The datasets generated during this study are available from the corresponding author on reasonable request. The software the authors developed to control the experimental conditions is available at no cost [41].

Authors' Contributions

GL was responsible for setting up the study, acquiring and analyzing the data, and writing the manuscript. GA and CF collaborated in setting up the study and the technology system, in acquiring and analyzing the data, and in editing the manuscript. NS, MOR, JS, VC, and OT collaborated in setting up the study, analyzing the data, and writing or editing the manuscript.

Abstract

Background: Mainstream smart home technologies (MSHTs), such as home automation devices and smart speakers, are becoming more powerful, affordable, and integrated into daily life. While not designed for individuals with disabilities, MSHT has the potential to serve as assistive technology to enhance their independence and participation.

Objective: The study aims to describe a comprehensive MSHT-based intervention named ASSIST (Autonomy, Safety, and Social Integration via Smart Technologies) and evaluate its feasibility in enhancing the functional independence of individuals with complex physical disabilities.

Methods: ASSIST is a time-limited intervention with a design based on the human activity assistive technology model, emphasizing client-centered goals and prioritizing individual needs. The intervention follows a structured assistive technology service delivery process that includes 2 assessment sessions to determine technology recommendations, installation and setup of the recommended technology, and up to 8 training sessions. An occupational therapist led the intervention, supported by a contractor and a technologist. Feasibility was evaluated through several measures: (1) the ASSIST Functional Performance Index, which quantifies the number of tasks transitioned from requiring assistance to independent completion and from higher levels of assistance or effort to lower levels; (2) pre- and postintervention measures of perceived task performance and satisfaction using a 10-point scale; (3) the number and types of tasks successfully addressed, along with the costs of devices and installation services; and (4) training effectiveness using the Goal Attainment Scale (GAS).

Results: In total, 17 powered wheelchair users with complex physical disabilities completed the study with 100% session attendance. Across participants, 127 tasks were addressed, with 2 to 10 tasks at an average cost of US $3308 (SD US $1192) per participant. Of these tasks, 95 (74.8%) transitioned from requiring partial or complete assistance to independent completion, while 24 (18.9%) either improved from requiring complete to partial assistance or, if originally performed independently, required reduced effort. Only 8 (6.3%) tasks showed no changes. All training goals, except for 2, were achieved at or above the expected level, with a baseline average GAS score of 22.6 (SD 3.5) and a posttraining average GAS score of 77.2 (SD 4.5). Perceived task performance and satisfaction showed significant improvement, with performance score increasing from a baseline mean of 2.6 (SD 1.2) to 8.8 (SD 1.0; $P<.001$) and satisfaction score rising from an average of 2.9 (SD 1.3) to 9.0 (SD 0.9; $P<.001$).

Conclusions: The ASSIST intervention demonstrated the immediate benefits of enhancing functional independence and satisfaction with MSHT among individuals with complex physical disabilities. While MSHT shows promise in addressing daily living needs at lower costs, barriers such as digital literacy, device setup, and caregiver involvement remain. Future work should focus on scalable models, caregiver engagement, and sustainable solutions for real-world implementation.

Introduction

Background

Assistive technology (AT) is federally defined as "any item, piece of equipment, or product system, whether acquired commercially, modified, or customized, that is used to increase, maintain, or improve functional capabilities of individuals with disabilities" [1]. Traditionally, AT refers to specialized devices designed for individuals with disabilities, such as wheelchairs, environmental control units (ECUs), and augmentative and alternative communication devices. Recent advancements in digital consumer electronics have expanded the scope of AT. Mainstream smart home technologies (MSHTs), such as home automation devices and smart speakers, have emerged as a viable alternative to traditional ECUs [2,3]. These technologies, while not explicitly designed for individuals with disabilities, can perform similar functions by promoting autonomy, reducing caregiver reliance, and enhancing quality of life [4-6]. Their affordability, accessibility, and integration of cutting-edge technologies, such as artificial intelligence (AI) and the Internet of Things (IoT), further underscore their potential. However, individuals with disabilities, particularly those who are not technology savvy, may struggle to envision how these technologies can meet their needs without proper guidance [2,4,5,7]. The wide variety of available options can also create confusion, especially when sales representatives lack training in addressing disability-specific needs or AT principles. Integration issues, such as ensuring MSHT devices work seamlessly with each other and existing AT while being compatible with the physical environment, further complicate their implementation. These challenges highlight the need for structured support to maximize the potential of MSHT as AT.

A scoping review by Cleland et al [8] identified 11 studies (up to July 2022) that examined the outcomes of home automation for individuals with disabilities. In total, 4 of these studies were noninterventional, focusing on exploring user experiences with their existing home automation technologies [4,9-11]. The remaining interventional studies primarily investigated specialized devices and applications or interventions using a room equipped with home automation technologies [12-17]. Notably, only 1 study specifically provided MSHT for individuals with amyotrophic lateral sclerosis, but it focused on a limited set of devices, including a smart speaker, light bulbs, and smart plugs [18]. Furthermore, only 4 studies were published after 2020 [4,13,14,18], emphasizing the need for updated research to reflect the rapid evolution of MSHT. A few recent studies after this scoping review have further explored the role of MSHT in supporting individuals with disabilities, highlighting both the potential and challenges associated with their implementation. Ripat et al [19] presented a case series of 3 individuals with high-level tetraplegia, emphasizing the benefits of low-cost, readily available technologies over stand-alone, dedicated devices. However, their effective use depends on appropriate access or interface methods, integration with current and future technologies, and the availability of training and maintenance support. Arthanat et al [7] developed an interventional protocol based on the human activity AT model for individuals with Alzheimer disease and their care partners, focusing on using MSHT to support personalized goals, such as safety, activity engagement, and caregiver connectivity [7]. While all 5 dyads reported positive goal attainment, challenges included unfamiliarity with MSHT, misconceptions about its use, and technological complexities that sometimes outweighed its benefits. These findings emphasize the need for comprehensive systems and support to optimize MSHT as AT solutions.

As MSHT continues to proliferate and integrate into everyday life, it is crucial to examine how these technologies can be effectively delivered to individuals with disabilities. While MSHT is readily available off the shelf, a structured AT service delivery process, commonly emphasized for traditional AT, may also be considered for MSHT [20]. AT services are defined as "any service that directly assists an individual with a disability in the selection, acquisition, or use of an assistive technology device" [1]. Research has shown that both the quality of AT and a robust service delivery process are vital to ensuring effective and tailored solutions for individuals with disabilities [21]. Our group conducted a qualitative interview study with 15 practitioners experienced in providing MSHT as AT. One of the key themes that emerged was the critical role of thorough needs and ability assessments before selecting devices. Practitioners noted that commercial technologies, despite their availability, still require specialized evaluation to ensure they meet the unique needs and abilities of clients with disabilities. Participants also highlighted the importance of demonstrating or trialing MSHT not only to aid in device selection but also to educate clients about its potential and secure their buy-in [3]. These insights align with the findings by Larsson Ranada and Lidström [22] that a structured service delivery process significantly contributes to the usability and satisfaction of AT devices.

Despite the growing availability of MSHT, limited research has systematically explored how these technologies can be effectively implemented as AT. Ripat et al [19] and Arthanat et al [7] briefly introduced their client-centered intervention protocols that addressed technology selection, customization, and training. The Delphi survey by Mun and Kim [23] identified 59 key features of a smart home modification program for individuals with physical disabilities, spanning 4 domains: user tasks, physical functions, environmental factors, and smart home characteristics. These features provide valuable guidance for implementing MSHT interventions, but further work is needed to explore how structured processes and individualized

XSL•FO
RenderX

approaches can optimize MSHT's role in supporting individuals with disabilities.

Objectives

In this study, we developed and evaluated the feasibility of ASSIST (Autonomy, Safety, and Social Integration via Smart Technologies), a comprehensive MSHT-based intervention designed to enhance functional independence and participation among individuals with complex physical disabilities. Grounded in the principles of AT service delivery, ASSIST used a structured process to assess users' needs, abilities, and contexts; select and acquire suitable devices; assist with installation and setup; and deliver targeted training. The intervention used a range of commercially available MSHT devices and mobile apps to address critical areas, including environmental control, activities of daily living (ADL), instrumental activities of daily living (IADL), communication, leisure, and emergency management.

Methods

ASSIST Intervention

Conceptual Framework

ASSIST was designed to enhance independent living and participation for individuals with complex physical disabilities through the use of MSHT. The intervention is guided by the human activity AT model [24], which comprises 4 key components: human, activity, AT, and context.

The activity component focuses on key activities that can be supported by MSHT based on user needs and priorities. Due to the dynamic and rapidly evolving nature of MSHT, there is often limited awareness among people with disabilities about the available technologies and their potential applications to meet diverse needs [2,3,5,7,20]. To address this gap, we developed and validated an ASSIST Functional Performance Index (AFPI) [2]. The AFPI features an item bank comprising 46 everyday tasks that can be addressed using off-the-shelf MSHT. These tasks span several areas, including environmental control, ADL, IADL, communication, leisure, and emergency management. The AFPI serves 2 primary purposes: helping clients identify and prioritize tasks most relevant to their needs and assessing task performance both before and after the intervention to measure the impact of MSHT.

The human component is considered an intrinsic enabler, emphasizing the importance of aligning individual abilities with the functional requirements of MSHT [25]. For the ASSIST intervention, a comprehensive assessment of human abilities is conducted to ensure an appropriate match. This includes evaluating motor, cognitive, visual, hearing, speech, and tactile abilities, as well as activity tolerance. In addition, factors critical for effective MSHT use, such as proficiency with mobile devices, existing technology use, and comfort and attitude toward technology, are assessed.

The context component encompasses cultural, physical, institutional, and social dimensions, all of which play a critical role in the selection and effective use of MSHT. Facilitators and barriers within these contexts are key considerations. For the ASSIST intervention, contextual factors, such as the home environment, type of caregiver support, and personal beliefs and values, are assessed.

The AT component is considered an extrinsic enabler. For ASSIST, this includes not only the MSHT itself but also access methods (eg, voice control, switches, and accessibility features), the integration of various technologies, and customization tailored to the client's abilities and needs. In addition, "soft technologies," such as training clients in the use of MSHT, are incorporated to ensure successful adoption and use.

Intervention Protocol

Overview

ASSIST uses a structured AT service delivery process, consisting of up to 10 in-person sessions (each 60-90 min) conducted in clients' homes over a period of 3 to 6 months. A licensed occupational therapist (OT) leads the intervention and is supported by a technologist who assists in identifying and customizing technology solutions and a contractor who handles technology installation. The process includes 2 assessment sessions to identify technology solutions, followed by technology installation and up to 8 sessions for setup and training. The detailed components of ASSIST are outlined in the subsequent sections.

Intake

Before the assessment, clients were asked to provide background information on their health, functional status, insurance coverage, living conditions, caregiver support, and technology use, including their experience with traditional AT and MSHT, mobile device proficiency via the short-form Mobile Device Proficiency Questionnaire (MDPQ) [26], and their comfort and attitude toward technology.

Assessment 1

During this session, the OT introduced the ASSIST program and conducted a brief interview to clarify intake information as needed. The OT then worked with the client to sort and rank tasks using the AFPI, identifying the top 10 priorities. For each of these tasks, the OT collected self-reported baseline performance using the AFPI's independence scale and had the client rate their perceived performance and satisfaction on a 10-point scale. In addition, the OT conducted functional assessments relevant to the identified tasks in areas such as upper extremity motor function, cognitive function, visual function, auditory function, tactile function, speech and language function, and activity tolerance. A mobile device assessment was also conducted, where the OT observed the client perform 5 smartphone tasks: making a phone call; sending an SMS text message; checking the local temperature using a weather application; using the internet to find the best local pizza place (with a distracting phone call); and downloading, moving, and deleting an application. Performance was documented regarding phone stabilization and positioning, manual access and control, speech and voice access, and cognitive considerations.

Assessment 2

This session aimed to help the client select smart home ecosystems and input methods that matched their functional

XSL•FO
RenderX

abilities, comfort level, and use context to support task performance. The OT guided the client in trialing devices, input methods, and ecosystems using a custom smart home demo station and conducted an environmental assessment to ensure compatibility with the home's physical characteristics and power sources. Others in the home were also consulted to understand their needs and preferences. The OT then collaborated with the technologist to identify technology solutions and shared the recommendations along with a training plan with the client.

Technology Installation

Once the client approved the technology selection and training plan, the OT coordinated the device acquisition and any necessary installation requiring hardwiring or significant physical labor by an affiliated contractor.

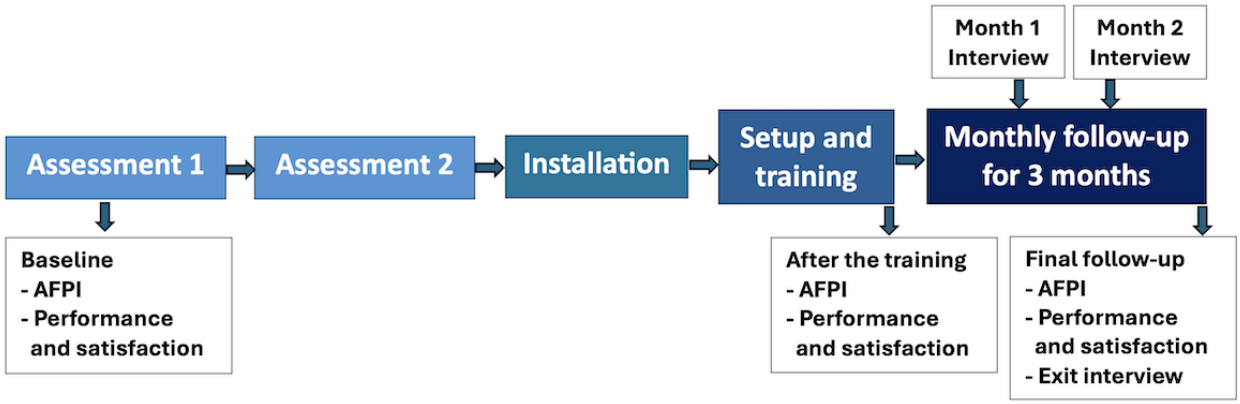
Training Sessions

Up to 8 training sessions were scheduled for each client. During each session, the OT began by assisting with pairing the devices and integrating them into the selected smart home ecosystems, if applicable. The OT then provided training on foundational digital skills, if needed, and familiarized clients with the MSHT devices designed to support the identified tasks. The Goal Attainment Scale (GAS) [27] was used to monitor progress throughout the training, which prioritized cognitive strategy training over traditional instruction-based methods. This approach taught clients to systematically plan, execute, and evaluate tasks, fostering critical thinking, adaptability, and self-reliance [28]. By emphasizing problem-solving, the training aimed to promote skill generalization and long-term use of MSHT, even in situations where devices malfunctioned, enhancing clients' confidence and independence. In addition, clients were provided with a device manual in their preferred format (digital, print, or both). The manual included comprehensive information about the products, such as maintenance requirements and manufacturer contact details for troubleshooting and support. At the conclusion of the final training session, the OT collected self-reported posttraining performance using the AFPI's independence scale and had the client rate their perceived performance and satisfaction on a 10-point scale.

Follow-Up

The OT conducted phone follow-ups at the end of the first and second months after the training to address any client questions, assist with troubleshooting, and provide additional training if needed. During the final in-person follow-up at 3 months, the OT collected self-reported performance using the AFPI's independence scale, gathered client ratings of perceived performance and satisfaction on a 10-point scale, and conducted an exit interview.

Feasibility Evaluation



Participants

Participants were eligible for inclusion if they met the following criteria: (1) aged ≥21 years; (2) had a physical disability that prevented independent control or access to their environment; (3) used a powered wheelchair as their primary means of mobility for ≥40 hours per week; (4) had been living in their own residence for at least 6 months; (5) scored 12 or higher on the Mini Montreal Cognitive Assessment 5-Minute Brief Version or 18 or higher on the traditional Montreal Cognitive Assessment (using modified scoring for individuals with physical disabilities and omitting written tasks), indicating no more than mild cognitive impairment [29]; (6) used a smartphone, tablet, or augmentative and alternative communication device; (7) were receptive to using MSHT in their residence; and (8) had internet service in their residence. Exclusion criteria included (1) being medically unstable, defined as having been hospitalized >3 times in the previous 12 months and (2) planning to change residence within 1 year.

Study Design

The study used a mixed methods pre-post design, following the ASSIST protocol as previously described (Figure 1). After providing informed consent, participants completed demographic and intake questionnaires via REDCap (Research Electronic Data Capture; Vanderbilt University). Eligible participants collaborated with study OTs to identify up to 10 tasks to address. Each participant was allocated up to US $5000 to cover the costs of devices and installation services required for these tasks.

Data Collection

Technology Comfort and Attitude

Participants were asked to rate their technology comfort on a 4-point Likert scale with the following options: very comfortable, comfortable, uncomfortable, and very uncomfortable. They were also asked to select all descriptors they felt applied to their attitudes toward technology from a list, including satisfied, dissatisfied, enjoyment, frustration, confident, uncertain, simple, challenging, hesitant, excitement, fear, and overwhelming.

MDPQ-16 Tool

The 16-item short-form MDPQ is a validated tool designed to assess an individual's proficiency with mobile devices across 8 key domains: mobile device basics, communication, data and file storage, internet, calendar, entertainment, privacy, and troubleshooting and software management [26]. Each item is rated on a 5-point scale with the following options: never tried (1), not at all (2), not very easily (3), somewhat easily (4), and very easily (5). Scores are averaged across the domains and summed to calculate a total proficiency measure, ranging from 8 (lowest proficiency) to 40 (highest proficiency).

AFPI Tool

The AFPI is a validated tool designed to evaluate an individual's ability to perform everyday tasks that can be facilitated by MSHT to enhance performance and participation [2]. The AFPI comprises a 46-item task bank categorized into 6 domains: environmental control (9 tasks), ADL (5 tasks), IADL (20 tasks), communication and planning (6 tasks), leisure activities (4 tasks), and emergency management (2 tasks). Participants respond to a series of questions indicating how they typically complete each task and the level of assistance or effort required.

Their responses are coded on a scale from 1 to 11, as detailed in Table 1. While higher codes generally indicate greater independence, it is important to note that certain paired codes (ie, 2 and 3, 4 and 5, 6 and 7, 8 and 9, and 10 and 11) distinguish whether the individual uses technology for support or not, without implying a difference in overall independence.

Table 1. Autonomy, Safety, and Social Integration via Smart Technologies Functional Performance Index codes.

Code	Responses
1	Task not completed (due to lack of ability or resources) but has the desire to complete it
2	With complete assistance from another person and technology
3	With complete assistance from another person
4	With partial assistance from another person and technology
5	With partial assistance from another person
6	On my own with support from technology—hard
7	On my own without support from technology—hard
8	On my own with support from technology—some effort
9	On my own without support from technology—some effort
10	On my own with support from technology—easy
11	On my own without support from technology—easy

Self-Perceived Task Performance and Satisfaction

Participants were asked to rate their self-perceived task performance and satisfaction using a 10-point scale. For task performance, they were instructed to rate how well they currently complete the task, with 1 indicating "not able to do it at all" and 10 indicating "able to do it extremely well." Similarly, for satisfaction, they were asked to rate their level of satisfaction with how they currently complete the task, with 1 indicating "not satisfied at all" and 10 indicating "very satisfied."

Intervention Feasibility

The feasibility of the ASSIST intervention was evaluated across several key areas.

Participation and Attendance

This area evaluated the proportion of participants who completed the intervention and attended all scheduled sessions.

Tasks, Technology Solutions, and Costs

Tasks addressed covered the number of tasks successfully addressed compared with those that could not be addressed.

Categories of tasks included a detailed breakdown of the types of tasks addressed by the intervention (eg, environmental control, ADL, and IADL) and the specific tasks commonly addressed within each category.

Technology solutions included a classification of the types of technology solutions implemented to support the identified tasks.

Costs included the total costs incurred, including both technology costs and installation expenses.

Training Effectiveness

Participants' progress in achieving their identified goals during the training sessions was assessed using GAS [27]. Participants collaborated with the study OTs to develop personalized goals based on the identified tasks. The OTs ensured that all goals

XSL•FO
RenderX

adhered to the specific, measurable, achievable, relevant, and time-bound criteria [30]. For each goal, 5 levels of attainment were defined to measure progress. Level 0 indicated that the participant achieved the goal at the expected level. Positive levels, +1 and +2, reflected that the participant exceeded expectations, with +2 representing significant improvement beyond what was anticipated. Conversely, negative levels, –1 and –2, indicated outcomes that fell short of expectations, with –2 representing a much worse result than anticipated. At the beginning of the training, participants' baseline levels were established, typically at –2 or –1. Progress was then reassessed periodically throughout the training sessions. The overall GAS score was computed at baseline and after the training using the following formula:

where w represents the weight assigned to each goal and X is the level achieved for each goal. In this study, as the goals were based on prioritized tasks, they were considered equally important, and equal weights were assigned.

Intervention Outcomes

Of the tasks addressed, the percentage that resulted in a shift from requiring assistance to achieving independence, the percentage that resulted in a change from complete to partial assistance or reduced effort if originally performed independently, and the percentage that resulted in no measurable change were covered in task outcomes.

Participant feedback included changes in self-perceived task performance and satisfaction between baseline and posttraining assessments.

Data Preparation and Analysis

All study data were retrieved from the study REDCap site. Descriptive analyses were conducted to summarize participant characteristics, tasks addressed, costs, GAS, AFPI performance, and self-perceived task performance and satisfaction. Changes in GAS, self-perceived task performance, and satisfaction before and after the intervention were analyzed using a paired sample 2-tailed t test or its nonparametric equivalent if assumptions were violated. All statistical analyses were performed using SPSS (version 28; IBM Corp).

Ethical Considerations

This study was approved by the Institutional Review Board at the University of Pittsburgh (STUDY19100361). All participants provided written informed consent before enrollment. All data were anonymized for analysis. Participants did not receive monetary compensation; instead, they were allowed to keep the technology devices recommended to them as part of the study.

Results

Overview

The study began in October 2021 with the enrollment of the first participant. From October 2021 to October 2022, the ASSIST protocol was trialed with 2 (11%) of the 18 participants to refine and streamline the process. Key adjustments included the addition of the MDPQ-16, self-perceived task performance and satisfaction measures on a 10-point scale, and finalizing the administration of the AFPI. Participants were asked to review the AFPI item bank to identify tasks they could not perform independently but wished to or tasks they found challenging or required assistance with. Then, they collaborated with the OT to prioritize tasks for intervention.

The remaining 16 (89%) of the 18 participants were enrolled starting in November 2022. One participant from this group withdrew after the first assessment session due to resistance to changes in their apartment or daily routine and a lack of readiness for the intervention. The remaining 15 participants completed the posttraining evaluation in December 2024. In total, 18 participants enrolled in the study. Of these, 17 (94%) completing the full study protocol and attending all scheduled sessions. As follow-up data collection is still ongoing, this study only reported results from baseline to posttraining evaluation. Results from follow-ups, monthly interviews, and exit interviews will be included in a future manuscript.

Participant Characteristics

Demographic details for the 17 participants who completed the study are presented in Table 2. The participants in this study were aged between 23 and 80 years, with an average of 47.9 (SD 15.6) years. In total, 14 (82%) of the participants received paid assistance, either from professionals, family members, friends, or a combination of these, while 3 (18%) of them relied solely on unpaid caregivers. Weekly caregiving hours varied widely, ranging from 10 to 168 hours, with an average of 74.7 (SD 43.7) hours per week, highlighting the participants' diverse support needs. All (n=17, 100%) participants had upper extremity motor deficits, and additional functional challenges were common. Some (n=7, 41%) participants reported visual challenges, with 6 (35%) retaining functional vision and 1 (6%) being legally blind. Some (n=7, 41%) participants experienced speech difficulties, and 1 (6%) reported auditory challenges. Moreover, some (n=8, 47%) participants faced sensory limitations.

All (17/17, 100%) participants used powered wheelchairs for mobility. Most controlled their wheelchairs using joysticks (15/17, 88%), while 12% (2/17) of the participants used alternative methods: chin control and head array. Smartphones were widely used among participants. In addition, 59% (10/17) of the participants owned iPhones, while 18% (3/17) of the participants used Google Pixel phones, and another 18% (3/17) used Samsung phones. Moreover, 6% (1/17) of the participants did not own a smartphone and used a family member's phone when needed. For smartphone interaction, 47% (8/17) of the participants used a combination of touch, joystick, switch, or voice control; 35% (6/17) relied solely on touch or joystick; and 18% (3/17) exclusively used voice control. Beyond smartphones, 65% (11/17) of the participants had adopted at least 3 types of MSHT, 12% (2/17) had 1 or 2 pieces of MSHT, and 24% (4/17) participants did not own any MSHT products but possessed a tablet, a computer, or both.

[a]One participant reported both races.
[b]AA: associate of arts.
[c]AS: associate of science.
[d]BA: bachelor of arts.
[e]BS: bachelor of science.
[f]MA: master of arts.
[g]MS: master of science.
[h]PhD: doctor of philosophy.
[i]EdD: doctor of education.
[j]C2: the second cervical vertebra.
[k]C4: the fourth cervical vertebra.
[l]AIS: American Spinal Injury Association Impairment Scale.
[m]C6: the sixth cervical vertebra.

Participants reported varying levels of comfort with technology. Of the 17 participants, 1 (6%) described feeling very uncomfortable, while most felt more at ease, with 7 (41%) participants identifying as being very comfortable and 9 (53%) as being comfortable. In terms of attitudes toward technology, the most commonly chosen descriptors used by the participants included satisfied (n=10, 59%), frustration (n=9, 53%), confident (n=8, 47%), and enjoyment (n=7, 41%). Some participants described their experiences as challenging (n=6, 35%), uncertain (n=6, 35%), or overwhelming (n=4, 26%). Fewer participants chose terms such as dissatisfied (n=2, 12%) or fear (n=1, 6%). Some (n=5, 29%) participants selected only positive descriptors, 2 (12%) selected only negative descriptors, and 10 (59%) described a mix of positive and negative experiences.

Mobile device proficiency, as measured by the MDPQ-16, showed a wide range of abilities. The average score (excluding the first 2, 12% of the 17 participants whose data were not collected) was 29.8 (SD 9.5), with 3 participants scoring below 20, indicating significant challenges; 3 scoring between 20 and 30, reflecting moderate proficiency; and the remainder (n=9) scoring between 30 and 40, representing higher proficiency.

Tasks, Technology Solutions, and Costs

Overview

Each participant was asked to identify up to 10 tasks, resulting in 155 tasks being identified (mean 9.1, SD 1.4 tasks per participant). Of these, 127 (81.9%) tasks were addressed (mean 7.5, SD 2.0 tasks per participant). Table 3 provides a detailed breakdown of the 127 tasks addressed across domains, including 64 (50.4%) for environmental control, 8 (6.3%) for ADLs, 37 (29.1%) for IADLs, 12 (9.4%) for emergency management, 3 (2.4%) for communication, and 3 (2.4%) for leisure.

In total, 28 (18.1%) of the 155 tasks were not addressed due to various factors, such as the absence of appropriate technology solutions, insufficient infrastructure, and the need to prioritize tasks for digital literacy training.

Some tasks could not be addressed due to the absence of appropriate technology solutions. For example, a smart shower controller was not implemented because the available products override manual controls, potentially leaving users unable to adjust the shower manually if the device malfunctions. Similarly, no suitable smart or standard scale was available for home weight monitoring for individuals who use powered wheelchairs. Side-to-side bed position adjustments were not possible with the smart bed frames currently on the market. In addition, while medication dispensers could help organize and dispense medications, they were not suitable for individuals with upper extremity motor impairments who could not reach and retrieve the medications independently.

Environmental constraints further posed challenges. For instance, the lack of nearby outlets prevented the installation of devices, such as bidets and air conditioners, in participants' homes.

In other cases, tasks had to be reduced to allow participants sufficient time to improve their digital literacy and prevent them from feeling overwhelmed.

In terms of technology solutions, participants were first guided to select at least one smart home ecosystem to integrate their MSHT devices. A total of 6 (35%) of the 17 participants opted to use 2 smart home ecosystems, and the rest (11/17, 65%) chose a single ecosystem, as shown in Table 4.

A variety of MSHT devices were provided to address participants' identified tasks. Products were selected based on compatibility with the participants' chosen smart home ecosystems, the desired features, and environmental compatibility. These devices leveraged AI and IoT capabilities to enhance automation, remote control, and accessibility. An overview of the provided technologies and their functionalities is given in the subsequent sections.

Lighting Control

Participants required flexible solutions for diverse lighting conditions, including ceiling lights, lamps with either standard or atypical bulbs, multiway switch configurations, and motion sensor controlled lights with extended illumination. The provided devices integrated IoT connectivity and AI-driven automation, allowing for application and voice control as well as automation tailored to user preferences and routines.

Smart in-wall dimmers and switches provided remote and automated lighting control while allowing manual operation without disrupting application or voice control. Companion switches for multiway installations maintained smart lighting functionality across multiple switch locations. Retrofit smart switches and button actuators provided remote control for nonsmart lighting fixtures without replacing existing wiring. Smart bulbs and plugs enhanced flexibility by enabling customizable lighting scenes and automation without modifying existing fixtures. Smart dimmer switches that were attached to existing light switches prevented accidental switch offs that would disable the functionality of smart light bulbs while allowing for local manual control.

Home Access

Participants received automated door and lock solutions that integrated with smart home ecosystems for enhanced safety and security. These devices leveraged AI-based access control, object recognition, and IoT-enabled remote operation, allowing for hands-free entry and real-time monitoring.

Automatic door openers with voice control modules or smart garage door openers enabled hands-free operation through voice assistants, allowing individuals with mobility limitations to open doors effortlessly.

Smart locks (retrofit and permanent solutions) provided keyless entry via mobile apps, biometric authentication, or voice commands, offering secure and customizable access.

Video doorbells (wired or battery-powered video doorbells with solar options) provided real-time video streaming, 2-way communication, and motion-triggered or object recognition–based notifications, with some models offering facial recognition to identify known visitors. When integrated with other smart home devices, video doorbells could trigger automated routines, such as turning on lights to enhance accessibility.

Window Treatment Control

AI-enhanced motorized solutions were provided to automate curtain and blind adjustments for improved accessibility. They could also automate adjustments based on time of day, room temperature, or sunlight exposure.

Retrofit curtain bots motorized existing curtain rods for voice and mobile app control. Retrofit options for tilt wand control adjusted blind slats via voice and mobile app control. Retrofit options for horizontal or vertical blinds or shades with continuous loop controls adjusted the blind tilt or lift or lowered the blind or shade via voice and mobile app control. Smart blinds (roller, cellular, and top down or bottom up) adjusted blinds via voice and mobile app control.

Climate Control

AI-enabled thermostats and fans automated temperature regulation, with some models featuring adaptive learning to adjust based on user routines.

Smart thermostats enabled temperature control via mobile apps or voice commands, with some models featuring occupancy sensors and learning algorithms for adaptive adjustments. Smart ceiling fans and standing fans provided scheduled automation and IoT integration to adjust airflow based on temperature sensors and voice or mobile app control. Smart bridges for existing fans converted nonsmart fans into IoT-compatible devices, enabling voice or mobile app control and automated control.

Surveillance and Inventory Management

Smart cameras, designed for indoor and outdoor use, provided surveillance and security, with some models featuring voice-controlled pan, tilt, and zoom functions and object recognition features. In addition, when paired with mobile apps such as Sortly (Sortly Inc), they helped participants manage health care supplies. When placed inside a refrigerator, they also facilitated the tracking of stored items.

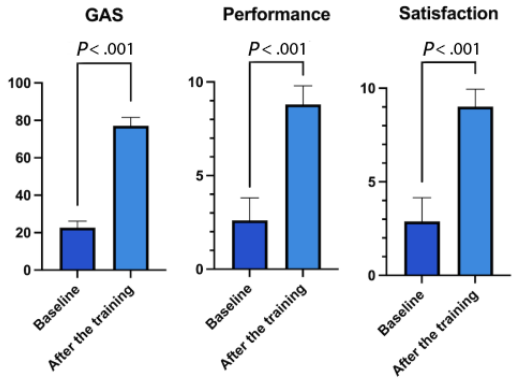
Wearables for Emergency Support and Daily Assistance

Smartwatches, including Apple Watch (Apple Inc) and Google Pixel Watch (Google LLC), supported multiple tasks, such as accessing emergency services or contacts, making in-store payments, and managing personal health.

In addition, a variety of AI-driven and IoT-enabled solutions further supported participants' independence and home automation. Textbox 1 provides a list of such solutions.

In terms of costs, all participants stayed within the US $5000 allowance. The overall cost of devices and installation services by the contractor averaged US $3308 (SD US $1192) per participant. Notably, 8 (47%) of the 17 participants selected "open or close door" as a desired task, which required relatively expensive automatic door openers that are not typically classified as MSHT. Excluding the cost of automatic door openers, the average cost per participant decreased to US $2234 (SD US $984).

XSL•FO
RenderX



Textbox 1. Solutions that supported participants' independence and home automation.

- Robotic vacuums: used artificial intelligence–powered navigation to optimize cleaning paths, avoid obstacles, and automatically lift mops based on floor type; features such as autoemptying bins and self-washing mop systems reduced maintenance needs
- Smart home hubs: centralized control for all Internet of Things–enabled devices, allowing seamless automation
- Smart button actuators: converted standard appliances into smart-enabled devices by automating button presses
- Smart power strips: enabled remote control of multiple devices with artificial intelligence–driven energy consumption tracking
- Smart smoke and CO detectors: provided real-time alerts and remote monitoring for safety
- Smart bed frames and voice-controlled bed systems: allowed users to adjust positions via voice commands or mobile apps
- Smart faucets and bidets: touchless control enhanced hygiene and accessibility
- Smart pet feeders and water fountains: enabled individuals to independently manage their pets' feeding and hydration through automated schedules, with mobile app or voice control for portion adjustments and monitoring
- Streaming devices: provided access to digital media, enabling voice and mobile app control for seamless navigation of entertainment and news
- Smart Sensors (water leak sensors, contact sensors, etc): enhanced independence by providing real-time alerts for leaks, open doors or windows, or unauthorized access; these Internet of Things–enabled sensors could integrate with smart home systems for automated responses
- Essential Accessories: enhanced independent use of smart devices, including smartphone mounting systems for beds and wheelchairs, charging solutions for independent device charging, and mesh Wi-Fi systems to improve connectivity

Training Effectiveness

Participants completed an average of 5.6 (SD 1.7) training sessions. Working with the study OTs, they collaboratively established 117 goals, averaging 6.9 (SD 2.3) goals per participant. This number is slightly smaller than the total number of tasks identified, as some tasks were combined for efficiency, for example, combining "open or close doors" with "lock or unlock doors." Nearly all goals (114/117, 97.4%) achieved at least level 0 (met expectations) on the GAS, and most (99/117, 84.6%) reached level 2 (significantly exceeded expectations). The average baseline GAS score of 22.6 (SD 3.5) increased to 77.2 (SD 4.5) after training (Figure 2), indicating substantial progress across participants. Paired sample *t* tests showed statistically significant improvements in GAS scores after training (t_{16}=37.6; *P*<.001; Cohen *d*=6.0).

Figure 2. Baseline and posttraining comparisons. GAS: Goal Attainment Scale.

Intervention Outcomes

On the basis of the AFPI results, 74.8% (95/127) of the tasks showed a shift from requiring assistance to achieving independence. An additional 18.9% (24/127) of the tasks demonstrated a transition, either from requiring complete assistance to partial assistance or, for tasks performed independently, a reduction in the effort required. Only 6.3% (8/127) of the tasks showed no measurable change.

Self-perceived task performance (excluding the first 2 participants whose data were not collected) improved significantly from a baseline mean of 2.6 (SD 1.2) to 8.8 (SD 1.0) after training, while satisfaction with task performance increased from an average of 2.9 (SD 1.3) to 9.0 (SD 0.9; Figure 2). Paired sample *t* tests indicated statistically significant improvements in both self-perceived performance (t_{14}=13.8; *P*<.001; Cohen *d*=1.7) and satisfaction (t_{14}=13.8, *P*<.001; Cohen *d*=1.7) after the intervention.

Discussion

Principal Findings

This study introduced ASSIST, a comprehensive intervention that leverages off-the-shelf MSHT to support individuals with complex physical disabilities. The findings demonstrated the intervention's feasibility in improving functional performance and supporting independent living. Participants reported transitioning from relying on caregiver assistance to independently completing 74.8% (95/127) of their identified tasks, reducing the level of assistance or effort required for

XSL•FO
RenderX

18.9% (24/127) of the tasks, and significantly improving perceived task performance and satisfaction.

ASSIST uses a client-centered approach through 2 comprehensive assessment sessions aimed at identifying each individual's unique needs, abilities, and context. This approach is essential not only because of the wide range of MSHT available and its potential to address numerous daily tasks but also because selecting the appropriate devices requires careful consideration of multiple factors, such as the user's functional abilities, preferences, technology experience and comfort, and home environments. For example, we prioritized retrofit options for renters, provided mesh Wi-Fi systems to resolve connectivity issues, and selected devices with mobile apps that ensure accessibility for participants relying solely on voice control. We also addressed the concerns of others in the home. For example, parents of a participant were hesitant about installations in shared spaces, such as the living room and kitchen, fearing they would look "obvious." After the OT showed them permanent solutions that matched their wall color, they approved. We also developed an environment checklist for different types of MSHT to streamline the selection process, ensuring compatibility and efficiency. Many of the factors addressed in ASSIST align with the 59 key features of a smart home modification program for individuals with physical disabilities identified in the Delphi survey by Mun and Kim [23]. This client-centered approach is further supported by the findings of Ripat et al [19], who emphasized the importance of addressing unique goals, circumstances, and contexts in their case series on the identification and assessment of electronic aids for daily living among individuals with high-level tetraplegia. Their work stressed the necessity of tailoring interventions to meet the distinct needs of each individual, even among those with similar injury levels.

The client-centered approach in ASSIST extends to its training sessions, where individualized plans are developed based on participants' technology experience, comfort, attitudes, and mobile device proficiency. For example, 2 (12%) of the 17 participants with similar functional profiles, both relying exclusively on voice control for smartphones, had different technology attitudes and MDPQ-16 scores (16.5 vs 36). One described their attitude as "dissatisfied, frustrated, uncertain, and excited," while the other chose "simple." As a result, the study OT designed tailored plans, with the first participant starting with basic voice control training and the second covering advanced skills, such as creating routines. This approach aligns with Arthanat et al [7], who emphasized using GAS for individualized training in their MSHT intervention for individuals with Alzheimer disease and their care partners.

Notably, our client-centered approach was supported by several tools. First, many individuals are not familiar with or do not keep up with technological advancements. This issue was highlighted in our previous work on developing and validating the AFPI tool [2] and by Arthanat et al [7], who found that participants' unfamiliarity with the technology was a major challenge in their MSHT intervention. Similarly, a UK policy report based on roundtable discussions and interviews highlighted low awareness of MSHT as a significant barrier, affecting both individuals with disabilities and professionals [5]. To address this gap, we used the AFPI tool to identify performance challenges clients were interested in addressing, which could be facilitated by MSHT, even if they had no previous knowledge of these technologies. This tool streamlined the task prioritization process. Although participants were informed that they could suggest tasks beyond the AFPI task bank, only a few additional tasks were proposed. Second, we used a demo station to facilitate device trials, focusing on selecting a suitable smart home ecosystem. Trialing mainstream smart home ecosystems is crucial, as they offer limited customization compared with traditional AT products. The hands-on experience provided participants with new information and helped them make more informed choices. For example, 2 participants, despite owning Amazon Echo devices, preferred Google Home after testing both systems. They found Google Home's simple interface and well-spaced control buttons easier to navigate and use for selecting smart home device controls. In addition, they appreciated the seamless integration with the hands-free Google Assistant on their Android (Google LLC) phones. Similarly, another 2 participants who owned Amazon Echo devices expressed interest in also using Apple Home, as they were already using Siri (Apple Inc) for other tasks on their iPhones.

It was encouraging to find that 76% (13/17) of the participants in this study already owned at least 1 MSHT device. However, their attitudes toward technology, as reflected in the descriptors they selected, revealed mixed experiences. While 5 (29%) participants selected only positive descriptors, such as "satisfied," "confident," or "enjoyment," most (n=12, 71%) participants chose either negative or a mix of descriptors. "Frustration" emerged as the most frequently selected negative descriptor, chosen by 9 (53%) participants. This aligns with our observation that, despite owning MSHT devices, some (3/17, 18%) participants had stored them away due to difficulties during setup, and most (10/17, 59%) were unsure how to integrate their devices into a smart home ecosystem. These findings suggest a need for targeted support to bridge the gap between ownership and effective use of MSHT, especially among populations with diverse abilities and needs.

It is also worth noting that more than half (10/17, 59%) of the participants in the study were enrolled in the US Medicaid home- and community-based services (HCBSs). Although the HCBS waiver definitions in the state of Pennsylvania include provisions for MSHT, such as electronic communication aids; mobile apps; hubs; software; and devices that control appliances, lights, telephones, and security systems, none of the participants were aware that they could request MSHT through their service providers. Furthermore, our investigation revealed a lack of clear processes for the provision of such technologies under the AT services in HCBS waiver programs.

This finding emphasized the need for better education and guidance for both service providers and participants to ensure these technologies are effectively integrated into care plans.

Barriers to Implementation

The intervention faced several challenges, including factors related to participants, technology, training, and context.

XSL•FO
RenderX

Lack of Digital Literacy and Accessibility Knowledge

Some (7/17, 41%) participants faced challenges with digital literacy and accessibility, which created significant barriers to implementing MSHT effectively. These limitations impacted participants' ability to interact with the technology, requiring study OTs to address these issues as part of the training. For example, 12% (2/17) of the participants were taught to use Amazon Alexa by clearing clutter around the Amazon Echo speaker, enabling audio cues, and pausing after the wake word to confirm the device's responsiveness. OTs also provided guidance on password management, application organization, and accessibility features, such as voice control settings and voice assistants for participants relying on voice commands, as well as assistive touch settings for those needing improved touch interaction. While the MDPQ-16 assessed mobile device proficiency, it did not account for physical abilities or appropriate phone mounting on wheelchairs or bedside setups, which are critical factors for successful MSHT implementation for individuals with complex physical disabilities.

Technology Selection, Installation, and Customization

Selecting, installing, and customizing MSHT presented various challenges and often required significant time and effort. In some cases, it was difficult to find technology that fully met participants' needs, as noted in the Results section, and in other instances, the technology only partially addressed their requirements. Device installation posed additional barriers. While Best Buy Geek Squad provided valuable services, it did not carry all the products provided to participants, necessitating the involvement of a general contractor. However, finding contractors knowledgeable about MSHT proved challenging. Beyond installation, pairing and integrating devices required substantial effort and often took longer than anticipated due to pairing complexities. Customizing solutions to meet participants' unique needs added another layer of complexity. For example, one participant with both motor and visual impairments required a solution to respond to visitor calls and grant building access. To address this, we adapted a smart control button, linking it with the Tasker application (Crafty Apps Ltd) on his Android device. The button was configured for easier activation using his elbow and programmed via Tasker to simulate pressing "6" on his phone, enabling him to independently let visitors into the building. Another participant with a weaker voice experienced difficulties using a Fire TV Cube (Amazon.com, Inc) to control the television. This issue was resolved by adding a high-definition multimedia interface extension cable and an infrared blaster, positioning the device closer to the client to enhance speech recognition for voice commands.

Training

A significant barrier to implementation was the overlap between device setup and participant training during training sessions. The study OTs were tasked with pairing, configuring, and customizing devices to meet participants' needs during the training sessions. The complexities of pairing for some devices and the time required for troubleshooting sometimes extended these sessions beyond 90 minutes. Ideally, all devices should be fully installed and configured before training begins to allow sessions to focus solely on skill development and effective use of the technology. This challenge highlights the need for a clear separation between device setup and training phases to streamline the implementation process.

Contextual Factors

Environmental and contextual limitations posed significant barriers to implementing MSHT. As noted in the Results section, environmental issues, such as missing electrical outlets, prevented the installation of devices needed to address participant needs. For 2 (12%) of the 17 participants living in subsidized housing, obtaining permission to install technology added delays and required additional effort, including writing justification letters and educating building contractors on MSHT installation. Caregivers also play a crucial role in sustaining the use of MSHT, particularly for devices requiring maintenance or caregiver collaboration. While caregivers were encouraged to participate in training sessions, their presence was not mandatory, which sometimes hindered effective implementation. For instance, 2 (12%) participants were provided similar technological solutions to manage their health care supplies, requiring caregivers to use a recommended tracking application; one participant found the solution effective for accurate tracking and timely ordering, while the other found it ineffective due to the caregiver not using the application to update supply information, highlighting caregiver engagement as a barrier.

In general, the findings of this study highlight significant opportunities to use MSHT to support a wide range of activities at a cost substantially lower than traditional AT, such as ECUs. MSHT offers versatility and affordability, making it a promising option for enhancing the independence and participation of individuals with complex physical disabilities. However, MSHT alone is not a complete solution. These individuals and their families often require ongoing support, including education on the available options, assistance with device selection, proper installation and setup, and training to ensure users feel confident and empowered. As emphasized in the Global Accessibility Reporting Initiative report [31], the concept of AT in the digital world must evolve to integrate mainstream technology into AT provision and include training on how to use these devices, their features, and associated services for professionals, caregivers, and end users with disabilities. Without the support, barriers such as lack of digital literacy, difficulty with setup, and underuse of features can limit the effectiveness of MSHT. Addressing these gaps is essential to ensuring that MSHT fulfills its promise of providing cost-effective, inclusive solutions for individuals with disabilities.

Limitations

The study had several limitations. First, it reported only the quantitative results from the ASSIST intervention and excluded the 3-month follow-up data intended to evaluate continued use, performance, and satisfaction with MSHT after 3 months of independent use. As the study is ongoing, we chose to focus this paper on the immediate outcomes of the intervention due to the substantial volume of information collected, with plans to publish a subsequent paper addressing sustained use, qualitative feedback, and caregiver perspectives.

XSL•FO
RenderX

Second, the study primarily focused on participants with disabilities, with limited emphasis on caregiver involvement. While MSHT has the potential to significantly support caregivers, this aspect was not fully explored. Only 2 caregivers were enrolled in the study, and their experiences will be detailed in the follow-up paper. Future research should prioritize caregiver recruitment to comprehensively examine the dual impact of MSHT on individuals with disabilities and their caregivers.

Third, the study focused on participants with complex physical disabilities and had a small sample size. Future research should include a larger, more diverse sample to better assess the broader applicability of MSHT interventions.

Fourth, this study focused on commercial smart home technologies and did not evaluate open-source options for free alternatives. Further research should explore cost-effective options to enhance accessibility for individuals with disabilities.

Fifth, the intervention provided funding for MSHT devices and installation services to ensure a focus on evaluating their impact. However, this approach does not reflect real-world practices, where financial and logistical barriers can significantly affect access and use. Future studies should explore strategies for addressing funding and installation barriers in practical, real-world settings. In addition, the cost analysis did not account for clinicians' time spent on device setup or delivering the intervention. A more comprehensive cost-benefit analysis would provide greater insights into the feasibility and sustainability of such interventions.

Finally, the study used a single-group pre-post design, which limits the ability to draw definitive conclusions about the causal effects of the intervention and understand the effects of its various components. A future comparative effectiveness study could incorporate a control group receiving either minimal support or specific subsets of the intervention components. This approach would enable researchers to evaluate the impact of individual elements within the intervention and identify which ones are most critical to achieving successful outcomes while still ensuring all participants derive some benefit. In addition, the treating OTs collected intervention outcomes, such as AFPI and self-perceived performance or satisfaction, which could bias responses due to social desirability or reluctance to give negative feedback. Future studies should use independent evaluators and observation-based tools to ensure objectivity and reduce bias.

Conclusions

This study demonstrated the immediate benefits of the ASSIST intervention in promoting functional independence and improving satisfaction with MSHT among individuals with complex physical disabilities. The findings showed MSHT's potential to address diverse daily living needs at a lower cost than traditional AT. However, challenges such as digital literacy and accessibility gaps, device setup barriers, and limited caregiver involvement present significant obstacles to broader implementation. Future work should prioritize overcoming these barriers by developing scalable models that incorporate funding solutions, caregiver engagement, and enhanced training programs. This study laid a strong foundation for advancing MSHT integration into the lives of individuals with disabilities and emphasized the need for a comprehensive, tailored approach to maximize its benefits and address implementation challenges.

Abstract

Background: Tetraplegia imposes significant challenges on affected individuals, caregivers, and health care systems. Assistive technologies (ATs) such as assistive robotic arms have been shown to improve the quality of life of persons with tetraplegia, fostering independence in daily activities and reducing caregiver burden. Despite potential benefits, the integration of AT innovations into daily life remains difficult. Implementation science offers a systematic approach to bridge this know-do gap.

Objective: This study aimed to (1) identify and involve relevant stakeholders; (2) identify relevant contextual factors (barriers and facilitators); and (3) suggest a general outlook for the implementation of AT, specifically an assistive robotic arm, into the everyday private lives of individuals with tetraplegia in Switzerland.

Methods: A qualitative design was used, involving 3 semistructured online focus group interviews with 8 stakeholder groups, including persons with tetraplegia as well as those who could provide perspectives on engineering or technology, legal matters, nursing or care, therapy, social counseling, social insurance, and political considerations. The interviews were analyzed using the Focus Group Illustration Mapping tool, and the data were aligned with the domains of the Consolidated Framework for Implementation Research.

Results: 3 focus group interviews comprising 22 participants were conducted, and data were mapped onto 21 constructs across the Consolidated Framework for Implementation Research domains. Identified barriers were customization to users' needs, safety concerns, and financing issues for the high AT costs. The collaboration with different stakeholders, including those who provided perspectives on political engagement, proved crucial. Identified facilitators included the enhancement of autonomy for persons with tetraplegia, improvement of quality of life, reduction of caregiver dependency, and addressing health care labor shortages. The implementation outlook involved the formation of an experienced team and the development of an implementation plan using hybrid type 1 and type 2 designs that incorporate both qualitative and quantitative implementation and innovation outcomes.

Conclusions: Robotic arms offer promising benefits in terms of improved participation for users, while high costs and regulatory complexities as to who will assume these costs limit their implementation. These findings highlight the complexities involved in implementing AT innovations and the importance of addressing contextual factors. A specific framework for the implementation of AT is needed to ensure the successful integration in Switzerland and other countries with comparable social and health insurance systems.

Introduction

Background

Recent technological advancements have led to the proliferation of assistive technologies (ATs), including assistive robotic arms, improving the quality of life for individuals with spinal cord injury (SCI) [1]. SCI is a profound, life-altering condition that affects approximately 15.4 million people worldwide [2], with significant impacts on individuals, caregivers, and health care systems [3-6]. Tetraplegia, the partial or complete loss of motor and sensory function in all 4 extremities and the trunk, is a common manifestation of cervical SCI [7]. Upper extremity function ranks highest in importance among individuals with tetraplegia, often prioritized over functions such as bowel, bladder, sexual, or walking abilities [7]. Disabled upper extremities not only diminish independence and social participation but hinder employment prospects, leading to increased care costs [8,9]. Comparatively, individuals with SCI often experience lower quality of life levels than their able-bodied peers [10,11], and regardless of the specific nature of their impairments, they frequently depend on caregivers to meet their daily needs [12,13]. Paid caregiving services can impose a significant financial burden on either the individual or the funding agency [14], whereas unpaid caregiving, provided mainly by family members, results in significant psychological implications [11,15,16].

Persons with impaired upper extremities, whether due to tetraplegia or other causes, such as multiple sclerosis or cerebral palsy [17], heavily depend on ATs to enhance independence and participation in activities of daily living (ADLs) [18,19]. ATs augment individuals' capabilities and broaden the range of activities they can engage in. Commonly used adaptations include cutlery, environmental control systems, writing orthoses [20], wheelchairs, prosthetics, and orthotics [21]. The application of AT not only aids the user but also indirectly benefits caregivers, notably family caregivers. Atoyebi et al [22] emphasize the potential of AT in reducing caregiver burden and alleviating stress. Specifically assistive robots, as defined by Kyrarini et al [17], serve as compensatory ATs and offer external assistance controlled by the user through an interface [23,24]. They facilitate a wide range of activities for persons with upper extremity disabilities, enhance care and promote independence across different areas [25,26]. One example is the Functional Robot with Dexterous Arm and User Friendly Interface for Disabled People (FRIEND) system, a wheelchair-mounted robotic manipulator designed to assist users with tetraplegia in tasks such as drinking and eating. The FRIEND IV, the latest iteration, integrates a 7-degree of freedom robotic arm and a 2-finger gripper and has been tested in a use-scenario, achieving a 95% success rate for cataloging books (of a performed 100 runs) with the end user's intervention [27]. The Jaco 2 robotic arm (Kinova Inc), a widely used commercially available system, offers 6- or 7-degree of freedom configurations and can be equipped with 2- or 3-finger grippers. It has been applied in various contexts, such as adaptive feeding systems that integrate force sensors and cameras to detect and manipulate food for users. In an efficacy study with 31 participants, the Jaco robotic arm has demonstrated the potential to reduce caregiving time by approximately 41% [28]. Beyond feeding and drinking tasks, assistive robotic systems have also been implemented in other ADLs. The Baxter humanoid robot, for example, has been used to provide personalized dressing assistance, using force-minimizing methods to help users with upper-body impairments wear sleeveless jackets [29]. Other experimental systems have explored applications such as beard shaving, hair brushing, and bathing, although these tasks remain in early stages of development and require further research to ensure safety and usability [17]. However, most robotic systems are still in the research phase and require significant customization and personalization to effectively assist persons with impaired upper extremity in their daily life.

There have been efforts to promote high-performance AT as prototypes, such as international contests like the CYBATHLON hosted by the Swiss Federal Institute of Technology Zurich in Switzerland [30,31]. Nonetheless, the need [32,33], the transfer, and the adaptation of AT in everyday life remain a transnational challenge [1,34,35], and many robotic innovations fail to reach the market [36]. This discrepancy can be attributed to various factors, including a focus on technical feasibility over user needs, complexity, cost, and the need for technical assistance for use [36,37]. For effective market integration, factors such as reliability, cost-effectiveness, esthetics, functionality, and usability must be carefully considered, with user-centered design principles playing a relevant role [23,38,39].

Objectives

The need of structured knowledge transfer, reimbursement strategies, and the assessment of the readiness of the AT market to successfully transition a prototype into a market-ready product [30] can be met with implementation sciences, offering valuable methods for the systematic uptake of evidence-based practices [40]. The implementation sciences acknowledge the relevant influence of economic, political, professional, and sociohistorical context factors on the adoption of evidence in practice [40]. The aim of this study is to investigate and reduce the research translation gap of implementing ATs into social and health insurance systems, with a specific focus on integrating a user-centered designed assistive robotic arm into the everyday private lives of individuals with tetraplegia in Switzerland [41]. The study's objectives are (1) identifying and involving relevant stakeholders, (2) assessing contextual factors (barriers and facilitators), and (3) proposing an implementation strategy for the robotic arm.

Methods

Qualitative Design

A qualitative design was applied, conducting 3 online focus group interviews with representatives from 8 stakeholder groups relevant to the robotic arm's implementation, aiming to identify barriers and facilitators. This study was performed from a constructivist or interpretivist point of view using a general deductive approach. This research was reported in accordance with the Standards for Reporting Qualitative Research by O'Brien et al [42].

Conceptual Framework

The Consolidated Framework for Implementation Research (CFIR) serves as a widely used guide in implementation research, comprising 39 constructs synthesizing existing theories applicable across all implementation phases, allowing researchers to select the most relevant constructs for their specific study setting [43-45]. It aims to identify and explain factors influencing implementation outcomes, consisting of 5 major domains: innovation, outer setting, inner setting, individuals involved, and implementation process [45]. The innovation is related to the characteristics of the innovation being implemented into a particular setting. Outer and inner settings represent a dynamic interface, where the outer setting generally includes the political, social, and economic context, such as community and state factors, while the inner setting comprises the structural and cultural context. Individuals involved represents the individuals involved with the innovation and the implementation process. In this domain, cultural, organizational, and professional aspects as well as individual mindsets and norms are considered. The implementation process includes the development needed during implementation. According to Damschroder et al [46], researchers should choose the most relevant constructs from the 39 offered in the CFIR to suit their specific study context. These constructs can guide diagnostic evaluations of the implementation environment, monitor implementation progress, and interpret findings in the research studies or qualitative improvement initiatives.

Context

The robotic arm at the center of the focus groups was a prototype developed by the Bern University of Applied Sciences in Switzerland. It competed in the Assistance Robot Race at the CYBATHLON 2024, mastering 10 different tasks of daily life, such as removing a parcel from the mailbox or navigating a touch screen. However, it has not yet been subjected to trials beyond this competition [47]. The robotic arm system consists of a Kinova Gen3 robotic arm with 7 joints, which can be mounted on an electric wheelchair. A 3D camera positioned near the gripper provides visual input for the current task. The vision system uses machine learning algorithms to identify objects, enabling the robot to approach and grasp them in a semiautomated manner, thereby saving time in completing the task. A graphical user interface displayed on a tablet near the user presents live and processed images from the camera. Users with some arm mobility can interact with the system by using the tablet's touch screen to issue commands, while those without sufficient mobility rely on speech recognition powered by Whisper (OpenAI) [48]. The robotic arm system is designed to ensure simple operation and intelligent robotic behavior. The architecture of the system itself is independent of the robotic arm, allowing for flexibility in implementation. For instance, while the current configuration uses the Kinova Gen3 robotic arm, it could be replaced with an alternative model, such as the BATEO (ACCREA Engineering) arm, without compromising the system's functionality. In addition to the existing literature on different robotic arm systems, a cross-sectional study focusing on the identification of needs for ATs for upper limbs in persons with tetraplegia was considered for the design of the robotic arm (N Hutmacher, unpublished data, March 2025). An overview of the robotic arm system can be found in Multimedia Appendix 1.

Representatives from 8 stakeholder groups (affected persons, as well as those who could provide perspectives on engineering or technology, legal matters, nursing or care, therapy, social counseling, social insurance, and political considerations) participated in the focus group interviews. The nursing or care stakeholder group included professional caregivers and family members who provided caregiving, the therapy group comprised occupational and physical therapists, and the social insurance group included representatives from various Swiss social insurance organizations (Swiss social insurers according to Federal Accident Insurance [UVG], Federal Military Insurance [MVG], and Federal Law on Invalidity Insurance [IVG]). Inclusion criteria required stakeholders to have specific professional roles or specialized knowledge, be aged >18 years, and have a good understanding of German.

Sampling Strategy

Stakeholders were organized into focus groups, each consisting of 6 to 9 participants, with a minimum of 4 stakeholder groups represented in each focus group. This approach aimed to facilitate discussions and ensure diverse perspectives were represented among stakeholders in a heterogenous group composition [46,47].

Purposive sampling aimed to achieve maximum variation in specialty by using a snowball approach to contact official representatives from insurance institutions, government offices, medical clinics specializing in SCI, assistive product retailers, and personal contacts. Recruiting involved contact via email or phone by the main researcher [42].

The researchers found consistent discussion of similar barriers and facilitators after 3 focus group interviews, confirming data saturation.

Data Collection Methods

To avoid increased time expenditure with long journeys, the 120-minute focus group interviews were conducted online via Microsoft Teams during January 2024 to February 2024.

Data collected for the general implementation outlook were informed by extensive literature research.

Data Collection Instruments and Technologies

Data collection followed a semistructured interview guide (Multimedia Appendix 2) developed by the research team based on literature review. The interview guide was refined in 3 one-on-one online interviews with participants (including a representative of engineering or technology, legal perspective, and social insurers) who did not participate in the focus groups. The guide was supplemented by the discussion and answers from the participants in the one-on-one meetings. The final guide contained the areas first impressions, opportunities, barriers, dealbreakers, and outlook or solutions.

Ground rules, a schedule, and a photograph of the robotic arm as stimulus material (Multimedia Appendix 3) were introduced at the start of each focus group interview. Participants identified themselves by role and name, with sessions being video and

XSL•FO
RenderX

audio recorded using the Microsoft Teams application. Moderation was handled by the main researcher, and note-taking was handled by a note-taker.

Units of Study

A total of 3 focus group interviews were conducted with 6 to 9 representatives of the different stakeholder groups shown in Table 1 (focus group 1: 9/22, 41%; focus group 2: 6/22, 27%; and focus group 3: 7/22, 32%). A total of 7 stakeholder groups were represented in at least 1 focus group; no participant engaged in more than 1 group. Family caregivers from the nursing or care and political perspective groups did not participate in the study. Most study participants (13/22, 59%) were female. Participants appeared to be highly experienced in their professional roles; they had worked on average 15 (SD 9.23) years in the current professional function.

Table 1. Units of study in total and stratified per focus group (N=22).

	Participants, n (%)	Experience in years, mean (SD; minimum/maximum)	Participants in focus group 1, n (%)	Participants in focus group 2, n (%)	Participants in focus group 3, n (%)
Affected persons[a]	4 (18)	—[b]	2 (22)	1 (17)	1 (14)
Engineering or technology	5 (23)	14 (6.34; 6/20)	0 (0)	3 (50)	2 (29)
Legal matters	1 (4)	5 (—; 5/5)	1 (11)	0 (0)	0 (0)
Nursing or care	2 (9)	18 (19.80; 4/32)	1 (11)	1 (17)	0 (0)
Therapy[c]	5 (23)	14 (9.98; 5/25)	3 (33)	0 (0)	2 (29)
Social counseling	2 (9)	17 (4.24; 14/20)	2 (22)	0 (0)	0 (0)
Social insurance[d]	3 (14)	20 (11.72; 11/33)	0 (0)	1 (17)	2 (29)
Total	22 (100)	15 (9.23; 4/33)	9 (100)	6 (100)	7 (100)

[a]Disability years for the affected persons: mean=27; minimum/maximum: 5/46.

[b]Not applicable.

[c]Therapy included physiotherapists and occupational therapists.

[d]Swiss social insurers according to Federal Accident Insurance, Federal Military Insurance, and Federal Law on Invalidity Insurance.

Data Processing

The Focus Group Illustration Mapping tool, as outlined by Pelz et al [49], facilitated a comprehensive summary of focus group interview content by combining survey methods with content evaluation. It used the semistructured interview guide as its framework, with key aspects first impressions, opportunities, barriers, dealbreakers, and outlook or solutions serving as central nodes. Relationships between concepts were represented using connecting arrows, with color codes distinguishing stakeholder groups. Visualizations were created using the web-based tool Miro [50], and PDF versions were sent to participants for consensual validation (Multimedia Appendices 4-6). The illustration maps were translated from German to English (Multimedia Appendices 7-9).

Data Analysis

The CFIR constructs were selected after intensive examination of all 39 constructs according to the time of the study. A deductive approach was used to code data from the illustration maps, which were aligned with domains 1 to 4 of the CFIR framework.

For the implementation outlook, a similar deductive approach was used to code data extracted from literature research, focusing exclusively on the implementation process domain.

Techniques to Enhance Trustworthiness

To ensure credibility of the findings, participant validation was used. A link to a Microsoft Forms survey allowed the validation of the illustration map by each participant anonymously, where either the option "I agree with the visual summary" or the option "I do not agree with the visual summary," followed by an open text field for feedback, could be chosen (Multimedia Appendices 10 and 11). The response rate for the validation was 77%, with 17 participants completing the survey. The illustration maps were translated from German to English using 3 translation programs: DeepL (DeepL SE), LEO (LEO GmbH), and Dict.cc (dict.cc GmbH). Data triangulation was achieved through semistructured interviews and document analysis of online research, converging multiple data sources to validate identified themes and patterns [42].

Ethical Considerations

Written informed consent was obtained from all participants outlining the investigation's purpose, the use of data, and their publication (Multimedia Appendix 12). Given the design of the study and the nature of the data collected, formal ethics approval was not required. According to Risk Category A as defined in Article 7 of the Swiss Human Research Ordinance (HRO), studies involving noninvasive procedures and fully anonymized qualitative data, such as focus group interviews, are exempt from requiring ethics approval [51]. The research was conducted in accordance with ethical principles respecting the dignity, privacy, and autonomy of the participants.

Results

The selected constructs of the 39 CFIR constructs for all 5 domains are displayed in Figure 1.

XSL•FO
RenderX

Figure 1. Overview of the selected Consolidated Framework for Implementation Research constructs.

Barriers and Facilitators to Implementation

Overview

Multimedia Appendix 13 summarizes the barriers and facilitators across 21 constructs within the CFIR domains innovation, outer setting, inner setting, and individuals domain. In the following, quotation marks are used to mark direct phrasing from the illustration maps.

Domain I: Innovation

Innovation Evidence Base

Facilitators that were mapped on the innovation evidence base could be supported with published literature. Overall, participants noted the robotic arm to enhance "self-care" and the facilitating aspect of increased quality of life through more autonomy [28,52]. In addition, it was reported that the robotic arm "saves on skilled labor" in the health care system, supporting its effectiveness [52]. Moreover, the robotic arm represented an "opportunity in the second labor market" [52].

Innovation Relative Advantage

According to participants, the robotic arm allowed an advantage over caregiver dependency, where simultaneously "autonomy is enabled." Regarding this, one participant mentioned a potential negative aspect, namely, "there may be fewer human interactions." The robotic arm's inability to support critical activities such as transfers was noted, rendering users dependent on caregiver support. Participants mentioned reduced dependence on social insurance benefits, potentially enabling "work ability and integration."

Innovation Adaptability

Identified barriers included the robotic arm's inability to fit both electric and active wheelchairs and the challenge of customizing it to each user's environment. Recognized opportunities to overcome these barriers were customization through the interface and the integration of a "combination with existing wearables," noted as a facilitator by a technical stakeholder.

Innovation Trialability

Testing the robotic arm in everyday life and then having the opportunity to decide in favor of it was seen as necessary by the participants.

Innovation Complexity

The complex requirement for the robotic arm to replace the human arm function was seen as a challenge, where "technical limitations," such as "recognizing material" and adjusting gripping force, were noted. However, one affected person emphasized functionality over speed of execution. Although the decision-making would always remain with the user when using the robotic arm, cognitive limitations were seen as a factor, highlighting the importance of the arm's intuitiveness and ease of operation. The introduction of differing user profiles and operating modes, as well as the automatization of the robotic arm, were seen as facilitators for innovation complexity. This

XSL•FO
RenderX

would allow for shared use of the robotic arm, for example, in "residential homes." The interaction of the robotic arm with a dynamic human instead of a static object presented another barrier, with safety concerns, particularly regarding "spasticity" adding complexity to the innovation.

Innovation Design

he size and the one-sided weight of the robotic arm were perceived to affect the maneuverability of the electric wheelchair, potentially obstructing proximity to objects and hindering activities such as approaching a table. Concerns about the robotic arm's "robustness" and "sensitivity" were raised due to potential damage from impacts or road conditions. The life expectancy of the robotic arm was considered a possible barrier, and features such as "material resistance to temperature, dust, and moisture" were mentioned as decisive. Environmental settings such as "car or taxi transport" or interactions with "young children" were also seen as potential hindrances to the innovation design. One participant noted that a "noisy environment" could affect the voice control of the robotic arm. The power regulation and dependency of the robotic arm were additional barriers identified. Some stakeholders found the robotic arm to be conspicuous, particularly when added to the already large wheelchair. However, affected persons prioritized practicality over aesthetics.

Innovation Cost

High costs of the robotic arm emerged as a significant barrier across all focus group interviews. The current estimated cost of the robotic arm system is around 50,000 Swiss francs (US $55,000), with additional expenses for customization, maintenance, repair, and indemnity insurance. "Savings on structural measures or technical aids" and the saving of resources as well as increasing work ability were noted as facilitators, potentially offsetting costs in the long term. Participants suggested expanding the target group to "other disorders with impaired upper extremity" or healthy individuals simplifying market entry and potentially lowering prices. However, this change in scope could affect assumptions about cost bearers.

Domain II: Outer Setting

Critical Incidents

Participants identified user involvement in both the development and financing processes, as well as public acceptance, as key factors that facilitate successful implementation. However, general dependency on technology and user helplessness in emergencies were seen as barriers, emphasizing the need for robust safety protocols and self-help capabilities. "WWarranty and availability of materials and spare parts" were critical barriers, and one stakeholder noted that "success depends on retention services, service intervals, duration of use, and guarantee pages." "High costs" emerged as a significant barrier across all focus group interviews, emphasizing economic considerations and financial implications.

Local Attitudes

While some participants viewed technology, including robotics, as the future, concerns were raised about potential stigmatization. Furthermore, the need of political engagement to enhance social inclusion was stated by the participants, and it appeared relevant to manage expectations and clarify the robotic arm's role as an assistive product.

Local Conditions

One facilitating factor noted was the possibility of using the robotic arm on public transportation in Switzerland, similar to how an electric wheelchair is used. Concerns were raised about potential damage to the robotic arm or injury to others during its use. In addition, it was mentioned that international travel with the robotic arm could be limited.

Partnerships and Connections

Collaborative opportunities, including partnerships with universities and "media partners," and the involvement of therapists were seen as facilitating for the robotic arm's implementation. One stakeholder representing the engineering or technical perspective emphasized the importance of involving specialist retailers and technology partners. Furthermore, the political involvement and collaborations with specialized foundations, such as "Swiss Paraplegic Foundation," were seen as a facilitating aspect to the robotic arm's implementation. The collaboration with already existing applications was seen as enhancing; however, reliance on third-party providers for services such as "servers and applications" was also identified as a barrier.

Policies and Laws

Participants identified various legal barriers to the implementation of the robotic arm, including authorization processes and compliance with European regulations. Stakeholders emphasized the need for compliance with Swiss laws, particularly regarding data protection and the use of integrated cameras in public spaces. Additional concerns arising with the assumption of costs by the Swiss Invalidity Insurance (IV) were noted as barriers to the robotic arm's implementation.

Financing

During the focus group interviews, potential funding sources discussed included the IV, the Swiss National Accident Insurance Fund (SUVA), indemnity insurance, and foundations. Concerns were raised that the robotic arm might cover activities already provided with other ATs, reducing its relevance and likelihood of financing. The reallocation of resources from other services, if IV covered costs for items such as "door openers," was seen as another barrier, as it could potentially limit the autonomy of the affected persons. The absence of a specific category for robotics in IV regulations posed a barrier to financing, despite "federal court judgments" indicating otherwise. Conflicting motives between cost bearers and developers were further identified as a barrier to financing efforts. Establishing a clear application area for the robotic arm was deemed necessary but challenging, although a "step-by-step approach" was identified as a facilitating factor.

External Pressure

Participants noted the duplicating and commercializing of prototypes as barriers. The existing competition from robots, such as "comparable robot arm Lio" in the Swiss market, was

XSL•FO
RenderX

cited as a barrier, while Switzerland's small market size posed challenges in effectively meeting demand.

Domain III: Inner Setting

Structural Characteristics

The range of the field of application of the robotic arm from personal household of the user to public space was seen as a facilitator by the participants. However, the individuality of the user and the environmental settings also represented a barrier, where, for example, the variety of door handles could be limiting. Furthermore, the discrepancy between indoor and outdoor settings was perceived as a barrier.

Relational Connections

The enhancement of autonomy by the robotic arm was perceived to have a positive influence on the users' state of mind, reducing tension in the immediate vicinity and improving relationship quality.

Tension for Change

The "reduction of shortage of skilled labor" within the Swiss care setting was perceived as a facilitator to the implementation of the robotic arm.

Domain IV: Individual Domain

Opinion Leaders

The current "wheelchair-bound Swiss National Councilor" was mentioned as a facilitator by an engineering stakeholder.

Innovation Deliverers

Physical and occupational therapists, as well as specialist retailer and distribution centers, were identified by the participants as innovation deliverers. Here, "Swiss Med Tech, Ortho Reha Suisse, Otto Bock, and the United States Military" were mentioned to enrich the project with expertise and possible resources.

Innovation Recipients

Persons with tetraplegia were identified as innovation recipients, where living independently was seen as a facilitator, while for users requiring 24-hour care, such as those dependent on a tracheostomy, the robotic arm was considered unsuitable.

Characteristics Subdomain: Need

The "desire for independence" was seen as the main need for the innovation across all focus group interviews. The fact that the robotic arm enabled additional autonomous activities was seen as a facilitator by the participants. Activities such as applying makeup, "eating meals while still warm," "scratching the face," and "blowing the nose" were mentioned. In addition, dressing, shopping, and pursuing hobbies such as "art" and "playing games" were cited. However, with additional functions, safety concerns were emphasized. Furthermore, it was seen as a barrier that other supplementary services would still be required and should not be excluded for the user when using the robotic arm.

Implementation Outlook

The implementation outlook was structured on the fifth domain of the CFIR (implementation process) displayed in Table 2; the included data came from literature research. The formation of an experienced implementation team is proposed to lead the implementation [40], while the needs for ATs for individuals with tetraplegia have been identified in a cross-sectional study (N Hutmacher, unpublished data, March 2025). As the project progresses, insights will be mapped to CFIR constructs, and an implementation plan will be developed, including pilot testing. The use of hybrid type 1 and type 2 designs will allow to assess both effectiveness and implementation within real-world contexts [53].

XSL•FO
RenderX

Table 2. Implementation outlook mapped on the fifth Consolidated Framework for Implementation Research (CFIR) domain (constructs with no barriers or facilitators were omitted).

Constructs	Propositions
Domain V: Implementation process	
Teaming	• An implementation team with experienced representatives from Switzerland [37]
Assessing needs	• A cross-sectional study assessing the needs for assistive technologies for individuals with tetraplegia (N Hutmacher, unpublished data, March 2025) • Stakeholder representatives from the focus groups for ongoing dialogue and refinement of understanding the needs of both innovation deliverers and recipients • Stakeholder groups identified in the focus group interviews to ensure comprehensive understanding of needs
Planning	• With project advances, mapping of further insights on context with identified and omitted CFIR constructs • The rating of identified constructs within the CFIR reflects both their valence and magnitude [54] • An implementation plan developed by the implementation team, including specific steps such as pilot testing and measures • Use of hybrid type 1 design (effectiveness within real-world contexts), preceded by a hybrid type 2 design [53]
Engaging	• Possible key players for engagement: the SCI[a] community in Switzerland and the Swiss Paraplegic Centre and its foundation (national and international scope) [49,55]
Reflecting and evaluating: implementation outcomes	• Combination of qualitative and quantitative measurements • Fidelity: fidelity of implementation assessment and stages of implementation completion [53], including self-reporting • Feasibility: surveys • Acceptability: surveys and interviews • Appropriateness: surveys and focus groups • Sustainability: sustainment measurement system and RE-AIM[b] framework [52,53] • Readiness for innovation and implementation: stages of implementation completion tool (postimplementation sustainment outcomes [53]
Reflecting and evaluating: innovation outcomes	• Combination of qualitative and quantitative measurements • Innovation effectiveness: used cases and controlled trial design • Functional independence for ADLs[c]: Functional Independence Measure • Quality of life: Short Form 36 Health Survey not only for users but also caregivers and ISCoS[d] quality of life questionnaire [54] • User satisfaction: Quebec User Evaluation of Satisfaction with Assistive Technology [56] • Specific function outcomes: mobility and communication subscores of Spinal Independence Measure [57]

[a]SCI: spinal cord injury.

[b]RE-AIM: Reach, Efficacy, Adoption, Implementation, and Maintenance.

[c]ADLs: activities of daily living.

[d]ISCoS: International Spinal Cord Society.

Discussion

This study aimed to explore the research translation gap in integrating ATs into social and health insurance systems. It specifically focused on identifying stakeholders, assessing contextual factors, and proposing an implementation outlook for introducing an assistive robotic arm into the everyday private lives of individuals with tetraplegia in Switzerland.

Stakeholders

Throughout all focus group interviews, there was agreement that the present stakeholder groups were relevant to the implementation of the robotic arm. A stakeholder group that was frequently discussed among the interviews was individuals providing a political perspective, which is also emphasized by Wolfenden et al [54]. According to a recent study by MacLachlan et al [56], AT policy should be grounded in evidence, but its foundational framework must go beyond rigid scientific criteria and be more inclusive. This is an important consideration for governments because the capacity to implement can be hindered by the volume of concurrent initiatives, potentially leading to low prioritization of the implementation, which could cause the implementation to fail [57]. In this context, stakeholder perspectives, contextual factors, cultural nuances, available resources, and systemic viewpoints should be systematically evaluated and synthesized in a transparent manner to enhance their credibility and inform policy decisions. MacLachlan et al [56] even propose the role of policy entrepreneurs, translating technical content into compelling information to engage politicians, to network and interact with the key stakeholders. Involving the current wheelchair-bound Swiss national councilor, as discussed in the focus group interviews, could facilitate cross-sector collaboration and have positive effects on the implementation of the robotic arm [58].

XSL•FO
RenderX

Barriers and Facilitators

All stakeholder groups agreed that the innovation addresses the needs of the recipients, specifically the desire for greater autonomy among individuals with tetraplegia. The robotic arm would allow for improvement in daily life participation, and although some activities may still be challenging or time consuming [59], addressing the impairment of the upper extremities and the autonomy provided was valued by the users [7]. Because the robotic arm may not allow complete independence for affected persons, partial or continuous assistance from a caregiver might still be needed, which was perceived as negative in the focus group interviews. Similar results were found by Gelderblom et al [24] assessing the MANUS robotic arm, where the continued dependence on caregivers was perceived as stressful to the user. Nevertheless, according to the focus group interviews, users' quality of life was expected to improve with the use of the robotic arm. This is reflected in the observations of Maheu et al [28], where the empowerment of the user enables an improvement in the quality of life, not only of the user but also of the caregiver. This facilitator must be emphasized as an important contribution of the robotic arm [60]. Specific assessment of how ATs, more precisely robotic arms, influences the quality of life of affected persons and of caregiver needs to be addressed in future research.

The complexity of the requirements of the innovation and the need for individuality with each user were perceived as barriers to the implementation of the robotic arm. The involvement of users in the development and implementation process was emphasized across the focus group interviews. This not only provides valuable insights that can enhance the effectiveness of the innovation [61,62] but also leads to higher user satisfaction. According to Martin et al [63], users that possess a greater understanding of ATs and feel more informed tend to exhibit higher satisfaction with the devices. Likewise, when their requirements are unmet, the users tend to express less satisfaction levels with the technology. It is anticipated that if usability limitations, such as use efficiency and overall satisfaction, remain unaddressed, users are prone to abandon their AT shortly after acquiring it [30,64]. This is an important factor to consider when assessing the readiness of the AT market and the implementation of the robotic arm moving forward. Furthermore, piloting, as mentioned in the focus group interviews, would allow users to gain experience and further adapt the innovation based on their feedback [65].

According to Nicolet et al [66], it is crucial to involve not only users but also other diverse stakeholders in the early stages. This facilitates the dissemination and transfer of findings, while also enhancing credibility and acceptance within the population. This is relevant as the implementation of the robotic arm could be further facilitated by support from the population. The general positive attitude among the focus groups toward technology as the future presents an optimal prerequisite for this aspect. The favorable view of robots was also shown among the older adult population in Switzerland, although concerns about personal connection and data privacy were raised, supporting similar statements from the focus groups [67]. Understanding patient needs and resources and effectively prioritizing them in combination with the involvement of the public, strongly correlate with successful implementation and are seen as a way to secure the acceptance and implementation of policies [57,68]. These are relevant aspects to consider as we move forward with the implementation of AT, specifically the robotic arm.

A relevant barrier discussed across all the focus group interviews was the financing of the robotic arm. Its current costs as a prototype exceed individual financial resources of affected persons, making it unaffordable. In Switzerland, the governmental social or health insurance system is expected to reimburse costs for ATs. The primary focus of social insurers lies in the cost-effectiveness of the assistance they are considering reimbursing, which according to Romer et al [69] specifically refers to the extent of cost savings achievable through the acquisition of the AT in relation to the overall cost of care for the user (cost of labor of the caregiver and cost of technical aids), which the robotic arm could replace. Additional indirect economic advances of the robotic arm encompass various benefits, such as reductions in unemployment compensation expenses, as users regain employment opportunities or increased workload can be allowed or area of application of work be expanded [69]. According to Bensi et al [56], cost savings of €290 (US $319) per individual over a span of 5 years resulted from enhanced autonomy through ATs and decreased reliance on personal assistants. The delicate balance between affordable supply of needed assistive products and high quality to foster social benefits alongside financial profitability remains a challenge. However, evidence on the effectiveness and cost-effectiveness of assistive robotic arms is limited [70], necessitating further research contributing to the implementation process [71].

In addition, determining the cost bearer within Switzerland's social insurance system is crucial for the implementation of ATs and was mentioned as a barrier across the focus group interviews. Laws in Switzerland require the IV to provide rehabilitation services, while the SUVA covers the economic consequences of accidents or occupational diseases [72,73]. The complexity and fragmentation of the Swiss social insurance system [74] could hinder the implementation process. This is supported by Schusselé Filliettaz et al [75], who found in a survey on integrated care initiatives in Switzerland between 2015 and 2016 that chronic care integration presents a notable challenge due to issues with the allocation of responsibilities, payment structures for health care professionals and institutions, and financing mechanisms. This is further complicated by the different conditions that apply to the assumption of costs by the various cost bearers within the social insurance system. The assumption of costs by the IV, which was emphasized in the interviews, requires the robotic arm to fulfill the criteria effectiveness, appropriateness, and economic efficiency [76]. In addition, the List of Remedies and Equipment (MiGeL) outlines the device categories eligible for coverage and specifies the maximum reimbursement amounts, including approximately 20 groups of approved devices [77]. Currently, no category that includes robotics as an AT is listed in the MiGeL. Without a designated category, similar ATs listed on the MiGeL may receive compensation, potentially leading to higher costs or inadequate support compared to the robotic arm. According to

XSL•FO
RenderX

MacLachlan et al [78], the absence of a clear framework for ATs such as robotics hinders implementation efforts, further compounded by a lack of familiarity and knowledge regarding disability and impairment. The clarification of competence and the assumption of costs among the various cost bearers need to be addressed for AT and the robotic arm in the Swiss context.

Moving forward with the implementation of the robotic arm, a focused approach targeting the identified barriers is necessary. The key recommendations from the authors for addressing the most relevant barriers currently identified are listed below:

- Conduct a detailed cost-effectiveness study to demonstrate the robotic arm's long-term financial savings (e.g., reduction of reliance on personal assistance, improvement of workability, and saving unemployment benefits).
- Perform pilot studies, where individuals with tetraplegia can trial the robotic arm in real-world settings. Continuous feedback should be collected to identify potential issues with usability, fit, and comfort. Furthermore, caregivers should be involved in the trial process of the robotic arm. This will help to construct the robotic arm to meet the user's needs and make it more effective.
- Clarify cost assumptions with insurers and enter into dialogue with the IV, SUVA, and other relevant insurance bodies to establish clear guidelines for the reimbursement of the robotic arm and comparable ATs. Here, the demonstration of the robotic arm's cost-effectiveness will help justify reimbursement.

Implementation Outlook

Moving forward, an implementation team overseeing and facilitating key activities in the selection and implementation is needed [79]. Representatives of implementation teams should encompass various viewpoints, including those of practitioners, supervisors, administrative leaders, and policy makers. The relevance of implementation teams was also acknowledged by Metz and Bartley [79], stating that in a survey of implementation frameworks, 17 (68%) of 25 frameworks emphasized the formation and use of implementation teams as essential elements of the implementation framework to ensure high-quality implementation. Furthermore, a stakeholder analysis by Reed et al [80] would allow a thorough investigation of relevant stakeholders for overall stakeholder engagement and their change over time [40,81-83] for the implementation of ATs.

In addition to the implementation context, successful evaluation of innovation and implementation is needed. In this research, the combination of innovation and implementation outcomes was given as an implementation outlook, as suggested by Hung et al [84]. According to Albers et al [40], clinical outcomes may be inaccurate or poorly understood if implementation outcomes are not measured, making it crucial to combine both types of assessments. Previous research emphasizes the construct relative advantage of the CFIR as a decisive factor for successful adoption and implementation of the innovation [85]. This suggests that successful implementation is more likely when users recognize a clear advantage in the innovation's effectiveness. Stakeholders must clearly observe the benefits of the innovation, emphasizing the importance of efforts to demonstrate these benefits [57]. Therefore, giving early attention to the relative advantages in implementation planning could be a strategic approach and should be considered as we move forward with the robotic arm and its implementation.

The use of a hybrid design, combining elements of clinical effectiveness and implementation research to explore not only what works but also how, where, and why, was further proposed in the implementation outlook. This would allow to incorporate complexity to establish external validity and gain insights on scaling up and disseminating [86]. The use of mixed methods designs would enable exploratory and confirmatory research, according to Palinkas et al [87], incorporating the perspectives of potential consumers, practitioners, and clients. To assess innovation effectiveness, standardized ADLs were suggested in this research. Integrating outcomes with the International Classification of Functioning, Disability, and Health could further refine functional evaluation tasks, ensuring a comprehensive assessment that goes beyond basic activities and allows for better comparison across research groups [88]. These considerations for methodology, including design and data collection techniques, need to be incorporated in the future research on the robotic arm's effectiveness and implementation and comparable ATs.

Strength and Limitations

Some limitations should be considered together with the results of this research. First, although efforts were made to include a broad coverage of stakeholder groups, the distribution of representatives varied, potentially introducing bias with certain perspectives dominating the discussion [42]. To decrease this group dynamic bias, sampling procedures were used to group similar perspectives together in focus groups. However, the absence of a family caregiver representative within the nursing or care stakeholder group and representatives from the political perspective group was acknowledged as a limitation, as this may have led to missed important insights. Second, the study focused on implementation within the Swiss social insurance system, limiting its generalizability in terms of governmental financing of the robotic arm and similar ATs. Furthermore, the direct end users of the robotic arm considered in this study are persons with impaired upper extremity due to tetraplegia. However, the target population could be broadened to include individuals with upper extremity impairments caused by congenital conditions, such as cerebral palsy, as well as other medical conditions. Expanding the target group will require further research to address the specific needs and challenges associated with these conditions.

The analysis of the contextual factors was conducted early in the development of the robotic arm. This is a strength, as it provides valuable insights and identified barriers and facilitators that should be considered moving forward. However, further exploration and development may highlight additional aspects influencing context, and identified contextual factors need to be reassessed with the process. Another strength of this research is its potential applicability to future AT implementation processes in Switzerland and countries with comparable social and health insurance systems. The use of the CFIR framework allows for building on these results and integrating findings from other studies, contributing to knowledge about the

XSL•FO
RenderX

interaction between innovations and context. Another strength of this study is the contribution of valuable insights to the implementation of ATs, specifically assistive robots.

Conclusions

This research explored the current contextual factors influencing the implementation of an assistive robotic arm in the everyday lives of individuals with tetraplegia in Switzerland. As an example of AT, the robotic arm offers promising benefits in terms of autonomy and improved participation for users, positively influencing their quality of life. Challenges such as high costs and regulatory complexities regarding cost coverage in its implementation need to be addressed, highlighting the need for a framework for implementing ATs. The need for political lobbying, stakeholder engagement, and user involvement throughout the implementation process were identified to facilitate the widespread adoption of ATs in Switzerland and other countries with comparable social and health insurance systems.

Acknowledgments

The authors extend their gratitude to all focus group participants for sharing their expertise and dedicating time and effort to this research. The authors also acknowledge the project team at the University of Applied Sciences for their contributions. This research received no financial support from public, commercial, or nonprofit funding agencies. Open access funding is provided by the School of Health Professions at Bern Universities of Applied Sciences.

Data Availability

The datasets generated or analyzed during this study are available from the corresponding author on reasonable request.

Authors' Contributions

Participant recruitment and data collection were conducted by VF; all authors (VF, MR, and AMR) analyzed and interpreted the data and contributed to writing the manuscript, with VF playing the lead role overall. Each author read and approved the final manuscript to be submitted to *JMIR Rehabilitation and Assistive Technologies* and agreed both to be personally accountable for the author's own contribution and to ensure adequate investigation and resolution of questions related to the accuracy or integrity of any part of the work.

Conflicts of Interest

None declared.

Multimedia Appendix 1
Overview of the robotic arm system.
[DOCX File , 226 KB - rehab_v12i1e65759_app1.docx]

Multimedia Appendix 2
Semistructured interview guide for focus groups (German).
[DOCX File , 19 KB - rehab_v12i1e65759_app2.docx]

Multimedia Appendix 3
Stimulus material for robotic arm system.
[DOCX File , 1363 KB - rehab_v12i1e65759_app3.docx]

Multimedia Appendix 4
Illustration map for focus group 1 (German).
[DOCX File , 474 KB - rehab_v12i1e65759_app4.docx]

Multimedia Appendix 5
Illustration map for focus group 2 (German).
[DOCX File , 540 KB - rehab_v12i1e65759_app5.docx]

Multimedia Appendix 6
Illustration map for focus group 3 (German).
[DOCX File , 477 KB - rehab_v12i1e65759_app6.docx]

XSL•FO
RenderX

Multimedia Appendix 7
Illustration map for focus group 1 (English).
[DOCX File , 470 KB - rehab_v12i1e65759_app7.docx]

Multimedia Appendix 8
Illustration map for focus group 2 (English).
[DOCX File , 202 KB - rehab_v12i1e65759_app8.docx]

Multimedia Appendix 9
Illustration map for focus group 3 (English).
[DOCX File , 467 KB - rehab_v12i1e65759_app9.docx]

Multimedia Appendix 10
Example of participant validation of the illustration map in Microsoft Forms (German).
[DOCX File , 337 KB - rehab_v12i1e65759_app10.docx]

Multimedia Appendix 11
Example of participant validation of the illustration map in Microsoft Forms (English).
[DOCX File , 124 KB - rehab_v12i1e65759_app11.docx]

Multimedia Appendix 12
Patient information and informed consent form.
[DOCX File , 2932 KB - rehab_v12i1e65759_app12.docx]

Multimedia Appendix 13
Barriers and facilitators identified (constructs with no barriers or facilitators were omitted).
[DOCX File , 22 KB - rehab_v12i1e65759_app13.docx]

Abstract

Background: COVID-19 has given impetus to an already growing trend around the use of ambient assisted living (AAL) technologies to support frail older adults who live alone. However, the challenge is that systematic research on the long-term use of AAL technologies remains in its nascent stages, leaving gaps in the understanding of the predictors that contribute to the routine embedding of AAL technologies in older adults' care.

Objective: This paper aims to share key lessons from a longitudinal study on the routine embedding of AAL technologies in older adults' care within a hitherto under-studied Southeast Asian context. Our objective was to design and deploy an AAL system termed Ubiquitous Service Management and Reasoning Architecture (Ubismart), evaluate its impact on older adults' quality of life (QOL), and distill lessons to inform the sustainable and culturally sensitive adoption of AAL technologies in similar settings.

Methods: We conducted an in-depth case study using a mixed methods design. First, we designed and deployed Ubismart to unobtrusively monitor and visualize older adults' activities of daily living. To assess changes in QOL, we administered a simplified, gamified version of the validated Older People's Quality of Life Questionnaire. Finally, we conducted semistructured interviews with older adults and their caregivers to triangulate the quantitative findings and explore evolving perceptions of the technology and its integration into daily routines.

Results: Quantitative analysis revealed significant improvements in (1) psychological and emotional well-being (P=.01) and (2) leisure and social activities (P=.03) following the AAL intervention. Other QOL dimensions showed no statistically significant change. Qualitative findings reinforced the improvement in psychological and emotional well-being, with many participants describing a heightened sense of safety and peace of mind, often likening the technology to "insurance" or a silent companion. However, the impact on social relationships was paradoxical; some older adults felt more cared for, while others perceived a decline in in-person visits. This paradox highlighted the complexities of technology's role in caregiving, as it might simultaneously enhance feelings of safety while unintentionally diminishing social connection for some older adults.

Conclusions: AAL technologies such as Ubismart enhance older adults' psychological and emotional well-being and sense of safety but may inadvertently reduce social interaction. Sustainable integration requires balancing these benefits with efforts to maintain meaningful caregiver connections, supporting both safety and social engagement for older adults.

ambient assisted living; Internet of Things; IoT; normalization process theory; older adults; quality of life

Introduction

Background

"I am afraid of dying alone at home" [1]; this fear, expressed by an older woman in Singapore, underscores a growing global phenomenon. As health care advances have prolonged life expectancy [2], demographic projections suggest that by 2030, 1 in 6 people worldwide will be aged ≥60 years, thus entering older adulthood. Unfortunately, many factors, including declining birth rates, changing norms, urbanization, and migration, have led to the evolution of family structures, causing a considerable proportion of these older people to live alone. In the United States, about 28% of the people aged ≥65 years live by themselves, including slightly <6 million men and slightly >10 million women [3]. Similar trends are seen across the globe, such as in Canada [4], Singapore [5], and France [6]. While living alone as an older adult is not inherently problematic and can be an indicator of robust health [7], it remains challenging for some individuals, particularly impoverished older adults who rely on government or not-for-profit organizations' support.

In response, developments in the Internet of Things (IoT) technologies and computational data science have introduced novel digital health interventions, such as ambient assisted living (AAL) technologies. AAL technologies are a type of smart home technology that enables individuals to remain socially connected while living independently [8]. Smart homes denote residences equipped with a high-technology network, linking sensors and other IoT-based domestic devices, appliances, and features that can be remotely monitored, accessed, or controlled and provide services that respond to the needs of the inhabitants [9]. The use of AAL technologies among older adults started to gain increasing research attention around the early 2000s [10,11]. These technologies hold an innovative promise in providing support for older adults, offering tools that enhance safety, independence, and overall quality of life (QOL) for those facing challenges associated with living alone [12,13].

However, end-user adoption and continued use of AAL technologies are still very low [8]. We believe that a significant obstacle to the sustainable use of AAL technologies lies in the absence of a robust, theory-driven approach to understanding how AAL technologies become routinely integrated and normalized in their social contexts. Intervention development and evaluation require a strong theoretical foundation [14]. Because social distancing protocols implemented during the COVID-19 pandemic have given impetus to an already growing trend in the adoption of AAL technologies [15,16], we believe that work theorizing the processes by which AAL technologies become routinely embedded in the care of older adults is both timely and relevant. Thus far, 3 distinct bodies of literature on AAL technologies have emerged: technical, human, and integrative perspectives [17]. The technical perspective primarily addresses design challenges and the implementation of AAL technologies. In contrast, the human perspective concerns the sociopsychological factors influencing adoption and shaping the use of AAL technologies.

While a great deal of good work has been done, recent research still highlights a lack of richer contextual and long-term approaches to understanding technology use among older adults requiring assisted living [18]. Indeed, most theoretical tools researchers use in the humanistic perspective of AAL technologies imply a psychological approach focusing on older adults as a unit of analysis. This is exemplified by the use of rational choice theories and theories of individual motivation, such as the theory of planned behavior, the technology acceptance model, and self-determination theory [19-21]. Such psychologizing of AAL technologies' use greatly curtails an understanding of how sociopsychological factors shape the routinization of these technologies in the care of older adults. It neglects that technology acceptance in this context is culturally dependent and will vary from one society to another [18,22]. Indeed, older adults cannot be studied in isolation, especially those requiring assisted living, because they live in interdependence with one another, their caregivers, and technological interventions [17,18].

Aims

Against this background, the aim of this paper is to promote the sustainable use of AAL technologies in the care of older adults by sharing a qualitative narrative and lessons learned from a longitudinal mixed methods study involving 19 older adults in Southeast Asia, a hitherto under-studied context. In doing so, we contribute to an emerging agenda of a rich sociological understanding of how older adults adopt and continue using AAL technologies by investigating an assemblage of sociotechnical linkages between different actors, including older adults, their caregivers, and the AAL technologies [18,23]. Such a focus is vital because AAL technologies can significantly impact the QOL for both older adults and caregivers if and only if they can be effectively integrated into routine practice [14].

To this end, we draw on 2 longitudinal AAL technology deployment studies to address the following research questions:

- How can AAL technologies be integrated and embedded into the care of older adults in context-dependent ways?
- What factors facilitate or impede the routine embedding of AAL technologies in the care of older adults?

In this paper, we first review related literature and introduce the theoretical framework guiding our narrative and proposed recommendations. Next, we detail the study's context and the specific AAL technology implemented. Finally, we share key lessons from the technology deployment process.

Prior Work

As mentioned earlier, a lot of great work has been done, and some researchers have also shared personal narratives and lessons learned. While these lessons learned by other researchers provide valuable insights, they lag in 3 important ways that motivate our work.

First, a few of these studies have used quantitative methods and found that several barriers, including usability concerns, a lack of perceived usefulness, and low technological efficacy, impede the routine integration of AAL technologies in older adults' care [24-26], and indeed, these are helpful. However, richer contextual insights are difficult to capture through quantitative data [27]. Beyond their contributions to specific areas of empirical research, qualitative narratives can also serve to reorient theories. They may influence theories not only relating to individual AAL technology users but also regarding the society within which the use occurs. This is done by bringing attention to the social and cultural dynamics through which the routinization of these technologies occurs [28]. There are surely exceptions. Drawing insights from an ethnographic case study, Doyle et al [29] presented recommendations on the 4 interrelated and dynamic life cycles of independent living technology development: ethnographic inquiry, design, deployment, and ongoing evaluation. However, this differs from our objective to investigate sociopsychological and cultural dynamics that facilitate or impede the integration of AAL technologies into older adults' care.

Second, some personal narratives lack an overarching theoretical framework to organize the key recommendations. For example, Consolvo et al [30] highlighted design insights supported by practical experiences, such as keeping the ambient sensors out of older adults' view and providing a "human touch." "Human touch" here refers to capturing qualitative details, such as the reasons behind specific actions or feelings, to create a more empathetic and personalized understanding of older adults' experiences instead of focusing solely on sensor data. However, there is a lack of an overarching theory to create a complete and meaningful picture by linking their work to existing theories and previous research [31], which is understandable, as their work is design oriented and not psychosocial in nature. Still, to build a cumulative body of knowledge, personal narrative studies should be theoretically driven [32], as this will provide valuable support to the identification of patterns, themes, and connections in the narratives.

Third, only a handful of these studies were conducted in Southeast Asia. Most of those conducted in Southeast Asia used rational choice theories and quantitative approaches [9,33,34]. As indicated earlier, we believe qualitative research is more suited to understanding how AAL use evolves over time and why it evolves this way. The use of rational choice theories, with older adults being the primary data source, assumes that the decision to adopt and use a technology lies with the individual older user. However, the reality is far different because AAL technologies are better understood as complex adaptive systems, which are systems composed of interacting agents described in terms of rules [35]. Agents include the IoT components, older adults, and caregivers [35]. Such a view of AAL technologies' use focuses attention on the fundamental mechanisms of emergence [36]; that is, the interactions between users and AAL technologies, along with their caregivers, are intricately linked and shape the overall context of AAL use [37]. Therefore, adoption, acceptance, and use are culture dependent and will vary from one society to another [18,22]. From such a perspective, the use of AAL technologies is viewed as (1) socially and culturally situated and (2) determined by the interactions of multiple actors, including older adults, their caregivers, and the AAL technologies themselves, who engage in nonlinear and, at times, chaotic ways [38].

Organizing Theoretical Framework

It is recommended that personal narratives be shared within the confines of extant theoretical frameworks to better organize the lessons presented [32,38]. Therefore, we anchor our narrative and present our lessons based on normalization process theory (NPT) [14,39] because a fundamental theoretical and empirical puzzle in the complex health care interventions literature relates to how the use of these technologies can transcend conscious behavior and become part of normal routine in care activities [14,36]. NPT is a sociological theory explaining key mechanisms that facilitate or impede the implementation, embedding, and integration of new health techniques, technologies, and other complex interventions [39]. It is based on the premise that health care interventions are complex social interventions that require multiple people to work together to achieve a desired outcome [14]. It identifies 4 key mechanisms of the normalization process.

First, "coherence" pertains to target users' sensemaking or understanding of the nature and purpose of the intervention. It is related to the notion of perceived usefulness in the information systems and human-computer interaction literature [40]. The intervention must make sense to the target users and be compatible with their values and expectations to be perceived as useful [41]. Second, "cognitive participation" means that the intervention must engage and include everyone at every health care system level, from patients and their families to health care professionals and administrators. Third, "collective action" means that the intervention needs to be integrated into routine practice and be supported by the necessary resources, infrastructure, and training. Finally, "reflexive monitoring" means that the intervention needs to be evaluated and monitored regularly to ensure that it remains effective and sustainable over time.

Methods

Ethical Considerations

This study received ethics approval from the institutional review board of the National University of Singapore (A-16-349; protocol title: "City for All Ages: Elderly friendly City Services for Active and Healthy Aging") and is registered with ClinicalTrials.gov (NCT06486935). All participants were referred to the study by their caregivers. No reimbursement was offered for participation. Informed consent was obtained from each participant prior to enrollment, including consent for the future use of their data in research. All data used for analysis were deidentified to preserve participant confidentiality.

XSL•FO
RenderX

Study Context

We situated our research within the context of older adults living alone in Singapore's subsidized public housing, relying on professional caregiving services provided by government-supported care centers, specifically senior activity centers (SACs). Currently, SACs are expanding their reach and services under the newly adopted designation of active aging centers. The SACs provide various services, including social activities, monitoring homebound older adults, befriending them, and responding to emergency alerts. As with any other care facility, a daunting challenge for SACs is a shortage of workforce. Therefore, AAL technologies were found to be an innovative promise to help older adults age in place, which can be defined as remaining in the community, with some level of independence, rather than in residential care [42].

Recruitment and Data Collection

Overview

Given the limited theoretical insights available, we adopted a mixed methods case study approach to explore the use of AAL technologies in this hitherto underexplored context. Our mixed methods approach consisted of semistructured interviews, a quantitative survey, and the AAL technology described in the subsequent sections.

We collected data at the individual level of analysis from 19 older adults and 2 caregivers. Drawing from our ethics review, the inclusion criteria for the older participants were (1) cognitively abled older adults living alone or with no more than 2 roommates; (2) English, Mandarin, or Cantonese speakers; and (3) members of the SAC. For ethical reasons, we excluded older adults with (1) severe disabilities, (2) reduced mobility (those who used a wheelchair), and (3) severe dementia. Older participants' demographics are presented in Table 1, with most (10/19, 53%) participants in their 70s. Participants primarily spoke Mandarin or a combination of Mandarin and English, with varied educational backgrounds ranging from no formal education to secondary schooling. Most (16/19, 84%) were widowed and lived alone, although a few (3/19, 16%) resided with 1 or 2 family members.

Table 1. Demographic characteristics of older adults in this study.

ID	Sex	Age (y)	Language	Education	Marital status	Living arrangements
ID1	Female	65	Mandarin	None	Widowed	Alone
ID2	Female	70	English	Primary	Widowed	Alone
ID3	Female	74	Cantonese and Mandarin	None	Separated	Alone
ID4	Male	79	English	Primary	Married	Family
ID5	Female	86	Mandarin	Secondary	Single	Alone
ID6	Female	67	Mandarin and English	Primary	Widowed	Family
ID7	Female	67	Mandarin	None	Widowed	Alone
ID8	Male	72	Mandarin	Secondary	Married	Alone
ID9	Male	69	Mandarin and English	Secondary	Divorced	Alone

ID11	Female	67	Mandarin and English	Secondary	Widowed	Alone
ID12	Female	71	Mandarin and English	Primary	Widowed	Alone
ID13	Female	70	Mandarin and English	Secondary	Widowed	Family
ID14	Female	90	Mandarin and English	None	Widowed	Alone
ID15	Female	70	Mandarin and English	None	Widowed	Alone
ID16	Male	83	Mandarin and English	Primary	Divorced	Alone
ID17	Male	77	Mandarin and English	None	Single	Alone
ID18	Female	73	Mandarin and English	Secondary	Widowed	Family
ID19	Female	82	Mandarin and English	None	Widowed	Alone

Quantitative Survey

Our primary dependent variable was older adults' QOL. To assess this, we adopted the Older People's Quality of Life Questionnaire (OPQOL) [43], which captures key dimensions of QOL relevant to older adult populations. Specifically, we focused on six core domains: (1) health, (2) independence and freedom, (3) psychological and emotional well-being, (4) social relationships, (5) home and neighborhood safety, and (6) leisure and social activities.

Semistructured Interviews

To complement and build on the quantitative findings, we conducted semistructured interviews with older adults. These interviews explored 3 key areas: Older adults' perceived QOL, expectations of the AAL technology, and overall satisfaction with the AAL system following installation. First, perceived

XSL•FO
RenderX

QOL was captured at baseline and throughout the study (Table 2). Perceived QOL included questions as follows: (1) How would you describe your QOL as a whole? (2) To what extent do you feel safe, given that you live alone? and (3) How is your relationship with the SAC caregivers? Questions related to expectations of the technology were as follows: (1) What are your expectations of this technology? (2) What do you think this technology can do for you? and (3) What would you like this technology to do for you? Questions related to satisfaction with the AAL technologies were as follows: (1) Overall, how satisfied are you with the sensor technology? (2) Would you recommend this technology to a friend or a relative? (3) What else would you like the technology to do for you? and (4) How has your relationship with the SAC caregivers changed since the technology implementation?

Table 2. Ubiquitous Service Management and Reasoning Architecture deployment details.

Region	Duration (mo)	Starting date	Homes, n	Sensors
Geylang Bahru, Singapore	1	August 2016	3	×10[a]
Geylang Bahru, Singapore	>6	March 2017	5	×10
Geylang Bahru, Singapore	>6	March 2017	5	Z-Wave
Ang Mo Kio, Singapore	>9	May 2018	6	Z-Wave

[a]10 sensors deployed throughout the 2 homes.

We included caregivers who were full-time staff members at the SAC and fluent in English, Mandarin, or Cantonese. Both caregivers were male, held the position of senior executive at the SAC, and were actively involved in caregiving responsibilities across 2 centers.

Our questions for the caregivers covered aspects of their job and how AAL technologies could help (ie, gauging expectations at baseline) and have helped (ie, gauging experiences following deployment and the older adults' perceptions of the technology). Examples of questions are as follows: (1) What aspects of your job do you like, and what aspects of your job do you find fulfilling? (2) What prospective improvements do you wish to see in your work? (3) What technologies are currently available to you in your daily work? (5) How do you think sensor-based technology can facilitate your work? (6) How do you think sensor-based technology can hinder your work? (7) To your understanding, what are some of the older adults' concerns pertaining to technology? and (8) What were some of the reasons for some individuals not providing consent to participate? All interviews were recorded and transcribed.

The AAL Technology Intervention

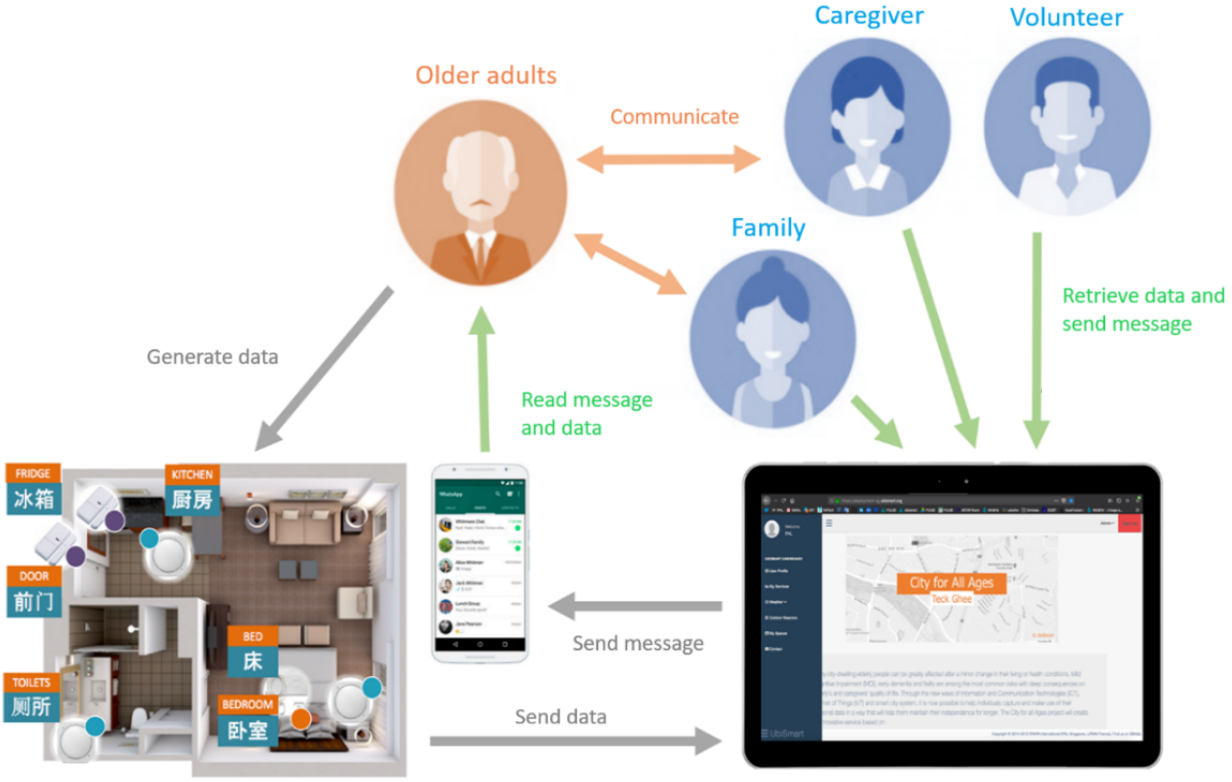
Overview

We developed an AAL technology platform termed Ubiquitous Service Management and Reasoning architecture (Ubismart), a live web-based platform with multiple interfaces and communication channels that are continuously expanded [44,45]. The platform has been deployed in real homes in France and Singapore. In this paper, we focused on Singapore deployments, which occurred in 3 waves with incremental features in 2016, 2017, and 2018 (Table 2).

The entire process that was organized using the NPT spanned, on average, 14 months, from ethics approvals and development to reflexive monitoring (Table 3).

Table 3. Global timeline from user needs to deployments.

Months	Activities	
	NPT[a] phase	Descriptions
1-5	Development and approvals	• Observations, discussions, and prototyping • Validation and demo • Applications for ethics approval • Initial trial and field test
5	Coherence	• Briefing sessions
6	Cognitive participation	• Recruitment sessions and baseline interviews
7	Collective action	• AAL[b] intervention deployment
8-12	Reflexive monitoring	• Feature updates and maintenance • Follow-up interviews • Data analysis and feedback
13-14	Feedback on AAL normalization	• Interviews and impact on validation



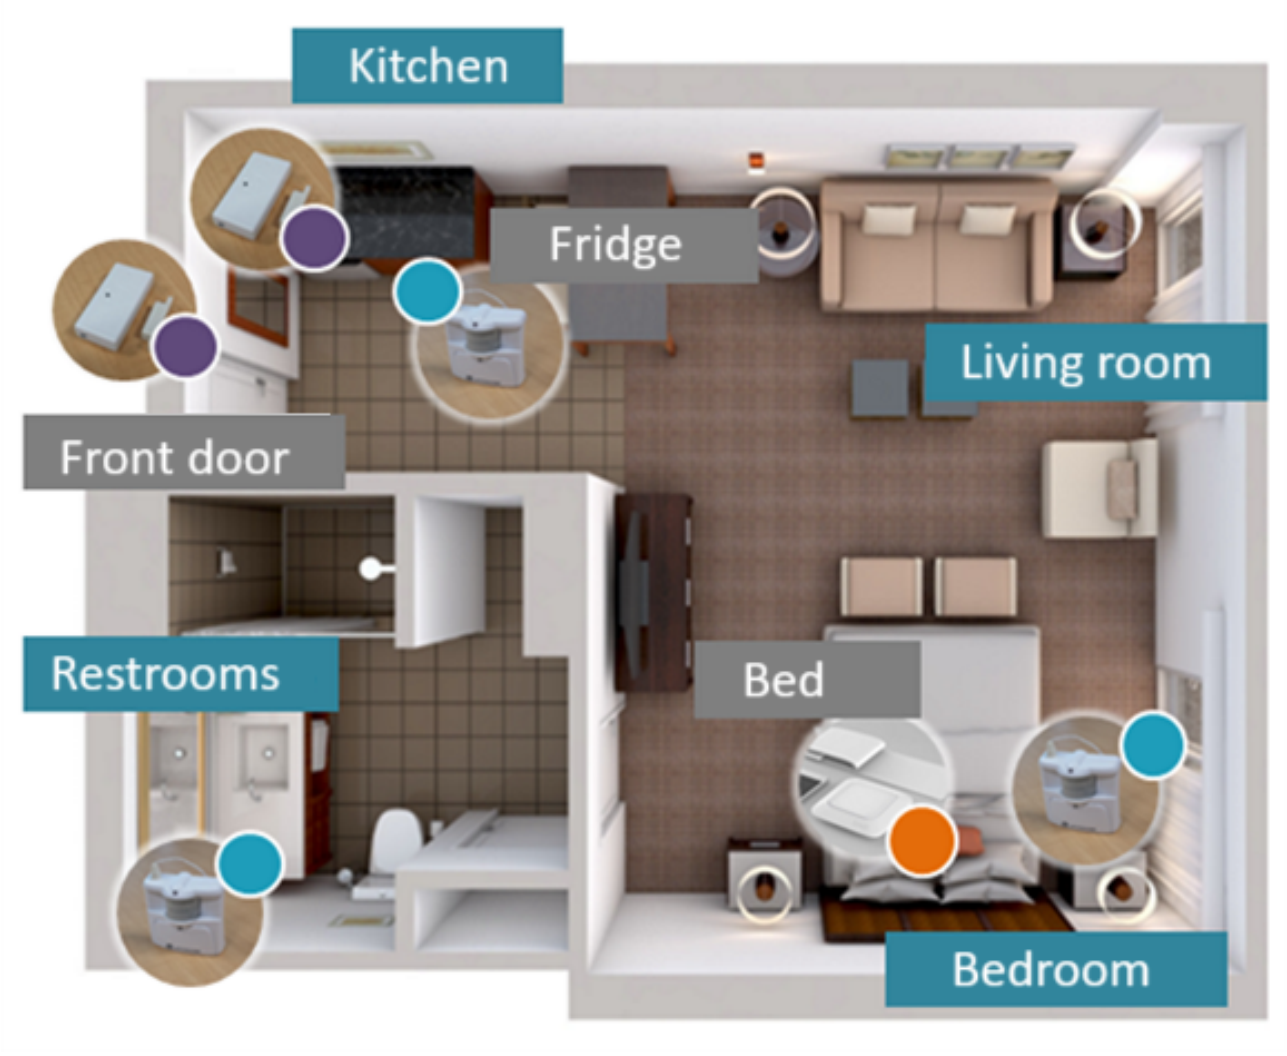
[a]NPT: normalization process theory.

[b]AAL: ambient assisted living.

XSL•FO
RenderX

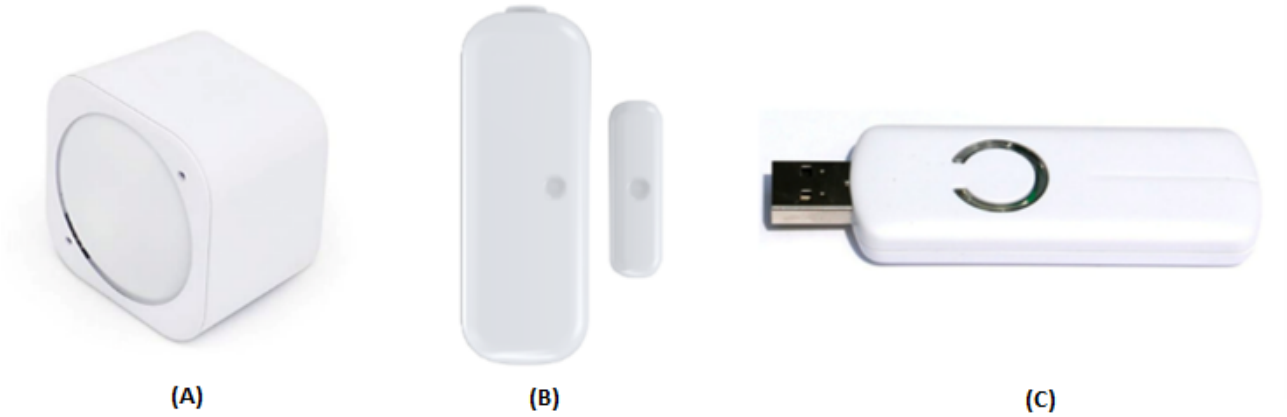
We subsequently present the components of the Ubismart system depicted in Figure 1. The system unobtrusively monitored older adults' activities of daily living (ADLs) and generated data through sensors placed in key areas of their homes. These data were then accessible to caregivers through a connected platform, allowing for remote communication, data retrieval, and message exchange to support the older adults' well-being. Ubismart consisted of 3 key modules, discussed in the subsequent sections.

Figure 1. Overview of the Ubiquitous Service Management and Reasoning Architecture setup and stakeholder interactions.



Module 1: Multimodal Sensors

Multimodal sensors with wireless data transmission capability were installed at different locations (eg, bedroom, kitchen, toilet, bathroom, and living room) to monitor and detect the activities performed by individual older adults, such as cooking, sleeping, going to the bathroom, going out of the apartment, etc. As illustrated in Figure 2, we installed (1) contact sensors on the fridge and house doors; (2) motion sensors in the kitchen, bedroom, and toilet; and (3) bed sensors under the mattress.



XSL•FO
RenderX

Figure 2. Deployment layout in older adults' apartments.

Contact sensors capture when doors are opened and closed [46]. Motion sensors emit a signal when there is a significant change in the infrared spectrum; therefore, they are used to detect movement (Figure 3). The technical specifications of the sensors are discussed elsewhere [47].

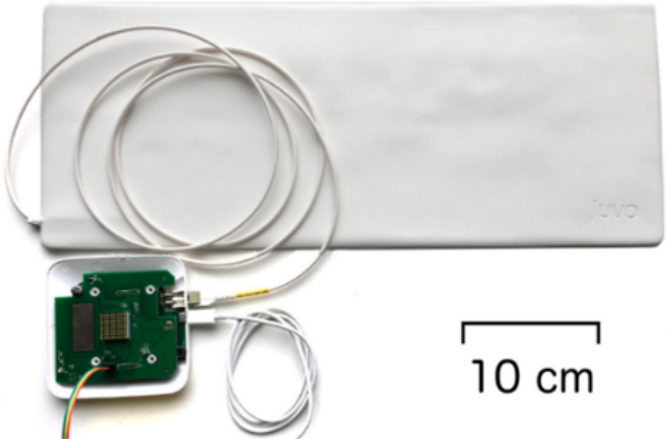


Figure 3. Z-Wave equipment—multisensor (eg, motion and humidity temperature), contact sensor, and Z-Wave receiver (from left to right).

The microbend fiberoptic pressure sensor mat, developed by Juvo Labs Pte Ltd (Figure 4), was placed unobtrusively below the bed mattress or sheet to measure heart rate and respiratory rate during sleep. This mat provides information on sleep parameters, such as sleep-wake rhythms, and can be used to detect sleep disorders. Technical specifications of this mat and related algorithm development are published elsewhere [47-50].

XSL•FO
RenderX

Figure 4. Sleep mat from JUVO.

The collected data were transferred through a secure gateway with a Raspberry Pi (Raspberry Pi Foundation) to a dedicated server for data processing and analysis. A Raspberry Pi is a pocket-sized computer commonly used in IoT applications because of its small size and ability to run Unix-like systems that ease the portability of algorithms (Figure 5). Our installation was strictly devoid of any video and audio processing or recording to respect the privacy of our participants.

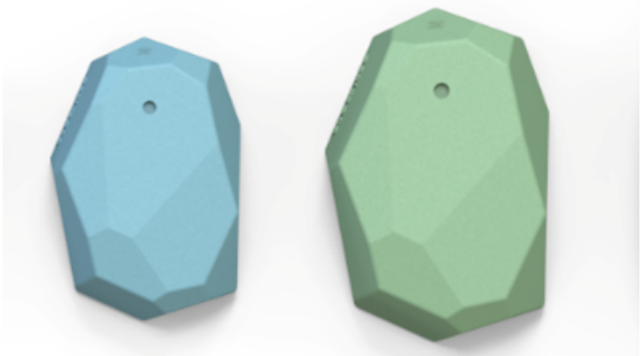

Figure 5. Raspberry Pi 3 Model B.

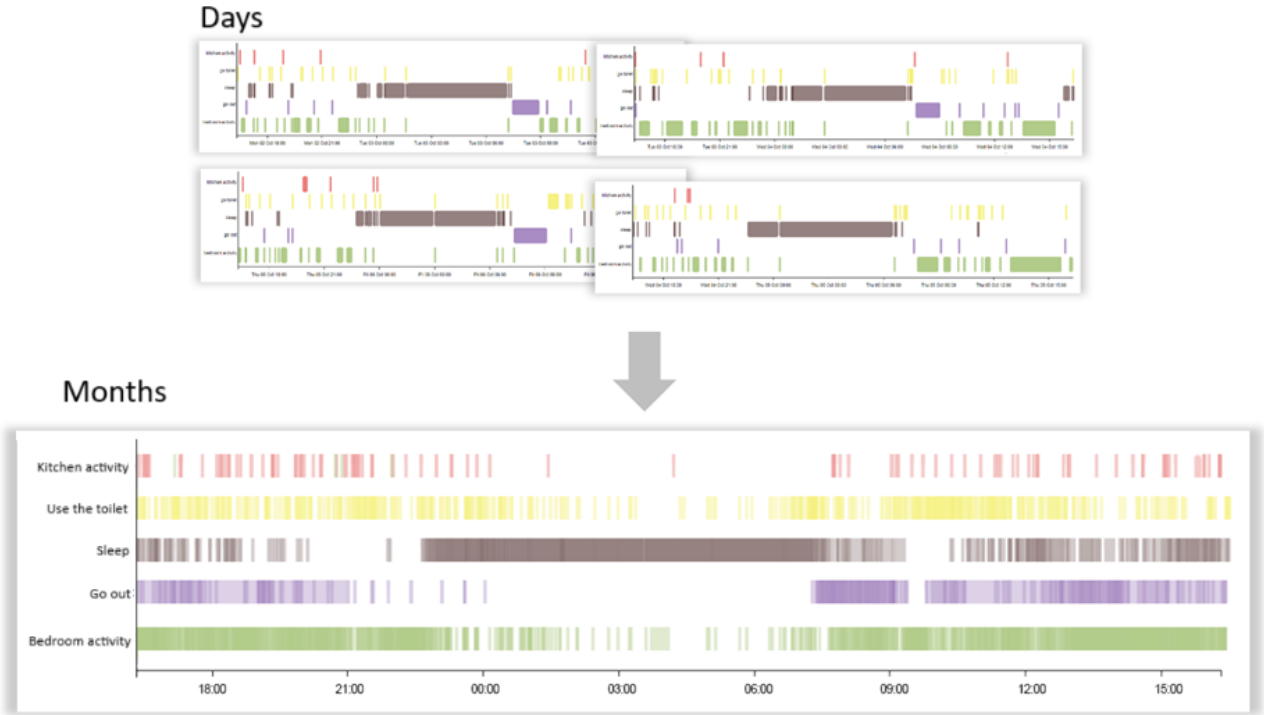
Module 2: Bluetooth Beacons

We strategically placed Bluetooth beacons from Estimote (Figure 6) in public areas to track the engagement of older adults in outdoor events organized by the SAC. These activities included gardening sessions, bingo games, and various social gatherings. It is important to note that the beacons do not receive or process any data, and they are not aware of any detections. They are placed at specific locations, and at regular intervals, they emit their own identifiers. The tracking is performed using a custom-made smartphone app that detects these signals and sends data to our servers.

Figure 6. Bluetooth beacons.

XSL•FO
RenderX



Module 3: Mobile App

The data from the sensors were processed in real time to provide a visualization of older adults' activities on a mobile app, as schematized in Figures 7 and 8. This app was accessible to the local staff at the SAC and the adults' relatives (if applicable). The goal of the app was to provide information on older adults' QOL in a cognitively efficient manner. As shown in Figures 7 and 8, visualized data included sleep duration, relative duration spent indoors and outdoors, and washroom and kitchen activities [51,52]. Caregivers received notifications of any irregularities (ie, deviations from the established baseline) through the mobile app. The baseline ADLs for the older adults were established through comprehensive semistructured interviews before deployment (Table 3). Risk alerts were activated when there were indications of significant and concerning behavioral changes. These could be detected through various parameters, including reduced participation in social events (as recorded by SAC data); noticeable deterioration in performing basic ADLs, including mobility or challenges in preparing meals during regular hours; and a decrease in sleep quality or sleep-related concerns.

Figure 7. Screenshot of an older adult's activities of daily living in Ubiquitous Service Management and Reasoning Architecture.

Figure 8. Personalized processing to detect deviations from older adults' baseline data.

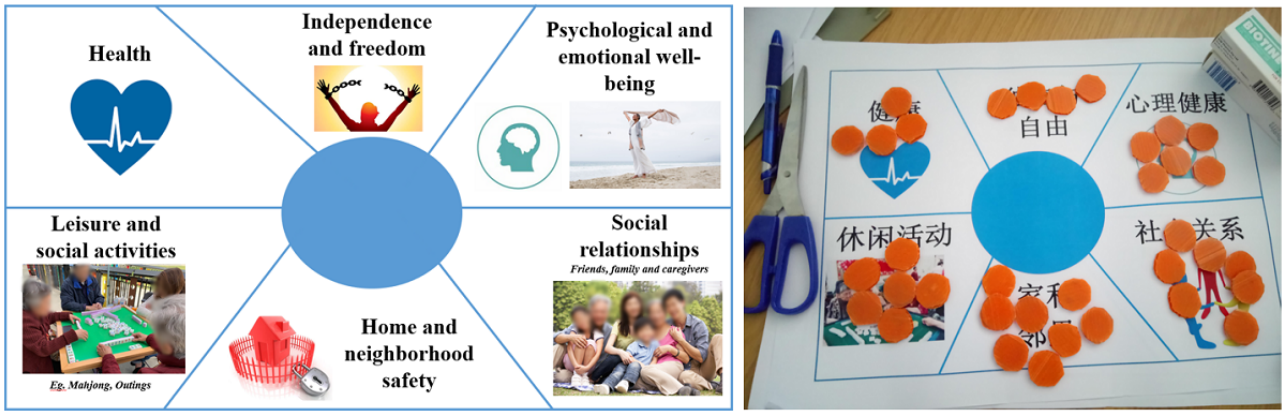
RenderX

Shortcomings of Previous AAL Technologies Versus This Study's Approach

Having described the Ubismart system, we turn to how it deviates from systems in previous literature. As mentioned, the number of studies on AAL technologies started to soar around 2015 [53], meaning that our deployment was one of the first studies to use AAL technologies in the care of older adults, with our first deployment in August 2016 (Table 2). Previous and current AAL technology deployments made use of audio or visual input. This is an increasingly pressing issue that our deployments avoided by excluding these sources of information. Privacy and fear of recordings are important aspects during deployments. From a technical perspective, we realized the concept of a "smart home in a box" by developing a system that can be deployed in any environment within 30 minutes. This was achieved through efforts to streamline sensor registration and create an easily extensible system built on semantic web principles [54,55]. In addition, our proprietary algorithms enabled noninvasive sleep tracking and could detect potential respiratory issues [56].



Results

Quantitative Survey: the Impact of Ubismart on QOL

As outlined earlier, we had initially planned to assess QOL using the validated OPQOL instrument. However, pilot testing revealed significant difficulties. Many participants, especially those with no formal education (7/19, 37%) or only primary schooling (6/19, 32%), struggled to meaningfully differentiate between points on the Likert scale, even when the survey was translated into local dialects. These challenges posed a risk of introducing measurement error and participant disengagement.

To ensure comprehension and more meaningful self-expression, we developed a gamified version of the QOL assessment (Figure 9). Participants were given 35 coins and asked to allocate those across 6 core QOL dimensions. The root question was simplified to "How do you feel you are doing in each of these areas?" The number of coins assigned to each domain served as an intuitive proxy for participants' self-assessed well-being in that area.

Figure 9. The gamified quality of life measurement tool.

We selected 35 coins to strike a balance between simplicity and sensitivity. The number was large enough to allow participants to express meaningful variation across the 6 domains while still being cognitively manageable for older adults with limited numeracy.

Using data collected through the gamified QOL assessment tool, we conducted a paired sample, 2-tailed *t* tests to examine whether the installation of AAL technology led to significant changes in the distribution of perceived well-being across QOL domains. Because the total number of coins (n=35) was fixed at all time points, our focus was not on changes in overall QOL scores but rather on how participants reallocated their perceived well-being across individual dimensions. Because the assessment was simplified to the domain level, we interpreted any meaningful shifts in specific domains as indicative of potential changes in participants' overall QOL.

When we analyzed QOL across its individual dimensions, 2 areas showed statistically significant gains. For leisure and social activities, participants reported a significant increase in scores following the intervention (before: mean 2.67, SD 2.29; after: mean 4.67, SD 1.22; *P*=.03), indicating enhanced social engagement and participation. Similarly, psychological and emotional well-being improved significantly (before: mean 5.44, SD 1.51; after: mean 6.78, SD 1.48; *P*=.01), suggesting a positive impact on emotional stability and mental wellness.

No statistically significant changes were observed in the dimensions of health, independence and freedom, social relationships, or home and neighborhood safety (all *P*>.05). The absence of change in "independence and freedom" was expected, given that the system was designed to be unobtrusive and did not alter participants' physical mobility or routines. Similarly, "health" was largely outside the scope of the AAL system, which did not provide direct medical interventions. However, the lack of significant changes in "social relationships" and "home and neighborhood safety" was unexpected. These findings are further explored in the A Qualitative Narrative of the Impact of Ubismart on Older Adults' QOL section, which offers deeper insight into how participants perceived and experienced these domains beyond what was captured through quantitative measures.

A Qualitative Narrative of the Impact of Ubismart on Older Adults' QOL

Overview

Triangulating findings from the quantitative analysis, our semistructured interviews likewise did not reveal any perceived impact on health and independence and freedom. As mentioned earlier, this was not unexpected. First, participants might have attributed their health status primarily to age-related conditions, and the system itself did not offer medical functions or interventions. In addition, no major health events occurred during the 14-month study period that would have activated the system's monitoring features. Second, participants continued to age in place, and the unobtrusive nature of the intervention meant their autonomy and routines remained unchanged, factors that likely contributed to a stable sense of independence and freedom.

In the subsequent sections, we have presented qualitative findings for the remaining 4 QOL dimensions: emotional well-being, safety, leisure and social activities, and social relationships. We highlighted how participants described the intervention's perceived impact in each area.

Home and Neighborhood Safety

Safety emerged as one of the most frequently discussed and emotionally resonant themes in the qualitative narratives, even though it did not register as statistically significant in the quantitative analysis. Participants consistently described a heightened sense of home-based safety, citing reassurance during emergencies, confidence in being monitored, and peace of mind while sleeping alone.

While the quantitative instrument combined home and neighborhood safety into a single construct, participants' narratives overwhelmingly emphasized in-home safety, suggesting that this specificity may have been masked in the statistical findings. These qualitative accounts highlighted that, even without measurable shifts in coin allocations, participants experienced the intervention as increasing their sense of security within their living spaces. The following quotes illustrate these perceptions:

> *I feel safer...* [Participant 2]

> *I feel that it [Ubismart] is very good for its sense of safety. If anything happens to me, [the caregivers] would know...If nothing is happening for the time being, then all is good...While we sleep at night, we feel safer.* [Participant 10]

Psychological and Emotional Well-Being

The deep-seated fear of dying or struggling alone, reflected in the Introduction section [1] and echoed by many older adults in our study, was a central theme in participants' narratives about psychological and emotional well-being. While the AAL system was not designed to provide emotional care, its unobtrusive presence appeared to ease anxieties and offer a sense of psychological reassurance. Indeed, both quantitative and qualitative data pointed to improvements in psychological and emotional well-being, making this one of the strongest areas of alignment across methods. Participants frequently described feeling calmer, more secure, and less fearful since the installation of Ubismart. The system was perceived not just as a technological safeguard but as a "silent companion" that offered comfort in the absence of continuous human presence. The following excerpts illustrate this enhanced psychological and emotional state:

> *Without your [the team's] help, my troubles will still persist. As [a senior], I have so much to be fearful of. But with these sensors, I feel so much at ease. I need not fear anything. It's better than not having the sensors...It's like having someone by my side...Without the sensors, there's nothing else I have; who else other than God can I ask?* [Participant 5]

> *It's psychology. You feel more confident, you feel more secure. It's the psychology.* [Participant 6]

> *It is like having insurance for us. If anything happens to us, the [caregivers] will know, for example, if we have a fall. So, the sense of safety is very good...It is like my personal insurance, which is very good for me.* [Participant 7]

These individual accounts were echoed by caregivers, who also observed shifts in the participants' sense of security:

> *They feel that there is a heightened sense of security, meaning that even when they are at home, they have a better peace of mind with this technology.* [Caregiver 1]

Leisure and Social Activities

Quantitative analysis showed a statistically significant improvement in leisure and social activities, suggesting increased participation or engagement following the intervention. However, this domain was not particularly salient in older adults' qualitative narratives. When probed, most participants did not mention any changes in their social routines or activity levels that they attributed to Ubismart. To better understand this discrepancy, we consulted the caregivers, who offered a potential explanation:

> *...the whole deployment doesn't really affect their sense of independence and [SAC activities]. Those who before this research project are regular participants continue to be regular participants for the SAC's activities or community events. Those who are mostly home-bound continue to stay home-bound.* [Caregiver 2]

Social Relationships

Surprisingly, our findings revealed a mixed impact on the domain of social relationships. While some participants described strengthened bonds with caregivers following the deployment of Ubismart, others expressed feelings of being overlooked or less visible. One older adult noted that caregivers had become more attentive:

> *They have become more caring, clearer, and more understanding.* [Participant 10]

In contrast, another participant conveyed a sense of isolation:

XSL•FO
RenderX

> *I just hope that those downstairs [the caregivers] will look up to the old people more often. I am lonely in this flat and should have someone come up to visit me, right...Here is [senior] who cannot conveniently move her hands and legs, and yet there is no one to visit.* [Participant 5]

These divergent perspectives reflected the nuanced reality of digitally supported care in a low-income, high-need setting. In this study, most (16/19, 84%) older adults lived alone in subsidized rental housing and had limited or no regular contact with close family. For many, SAC caregivers represented their most consistent and trusted source of support not only for physical well-being but also for emotional connection and social presence. In such a context, even subtle shifts in caregiver engagement were felt acutely.

It is important to note the clear differences among these older adults. Participant 10 was relatively frail, while participant 5 was healthier and more independent. According to the caregiver, standard protocol required visiting older adults who needed more support 3 times a week, while healthier older adults received 2 visits per month. The caregiver further explained that if the Ubismart app showed no anomalies and the older adults remained active at the SAC, they sometimes forwent additional visits due to limited resources:

> *So, [participant 5] is not exactly frail and vulnerable, so it is a subjective comment, but I should say that sometimes this thing about home visits is because [participant 5] and [participant 10] are the more regular participants in the center. They come to the center on a weekly basis, at least three or four times. So, as long as the center gets to see them, interact with them, and understand whether they are okay or good for that day or that week. That is also a form of outreach.*

While some older adults interpreted Ubismart as a sign of care, others perceived it as a potential substitute for relational presence, a perception that risks reinforcing feelings of abandonment if not accompanied by continued in-person interaction. However, caregivers also highlighted that Ubismart facilitated deeper relational exchanges. The mobile app served not only as a monitoring tool but also as a conversational catalyst:

> *We have a more in-depth understanding of the [older person's] daily condition. We will use [the app] as a conversational starter so that we will get into a more in-depth interaction with them and be more able to care for particular characteristics.*

In fact, the technology was especially welcomed in light of staffing limitations. One caregiver explained the following:

> *So currently, we have five [full-time caregivers] as per headcount, so it's [divided with the other] SAC...so it's just two staff per center. Our latest estimate is slightly more than 800 [older people]; about 400 belong to the rental units, and the rest are all from the nearby blocks.* [Caregiver 1]

Against this backdrop, caregivers appreciated Ubismart's ability to extend their reach while maintaining dignity and privacy for older adults:

> *We are very supportive of this because we feel this approach is nonintrusive. It respects the seniors' privacy...and we are able to ensure that they are okay at home.* [Caregiver 2]

These reflections reinforced the view that AAL technologies, when thoughtfully implemented, could serve as a bridge rather than a barrier to meaningful human connection, especially in contexts where caregiving capacity is stretched thin.

Concerns of the AAL Technologies

Although our primary focus was on QOL, we also explored participants' broader experiences with the Ubismart system, including any concerns that arose during its use. As with many technological interventions, older adults expressed several reservations. Through open coding of the interview data, we identified 5 key concerns. The first related to electricity consumption, which was raised both during interviews with the research team and in conversations with SAC caregivers:

> *I asked them, "Why [is] my electric bill very high?" [The caregiver said] "No, you got a sensor, but this one is like a battery."* [Participant 2]
>
> *I think one of the most common [questions] is whether it consumes a lot of electricity. But right now, based on the 19 participants, they are aware that these things don't take much electricity.* [Caregiver 2]

Second, privacy violation was a major concern in the beginning. The older adults suspected that the sensors might have video recording capabilities. Some took afternoon naps on their chairs instead of the bed out of fear that the bed sensor would capture it, and they might be judged for unproductivity. However, we explained to the older adults that the goal is to keep them safe and not judge their sleep patterns. In addition, privacy concerns waned over time as the older adults understood that the sensors did not have video recording capabilities. This is reflected in the following quote:

> *I was initially concerned about the sensors taking videos in the toilet. But later I got used to it.* [Participant 6]

Third, physical harm was a major concern for one of the frail participants. She suspected that the sensors were the cause of her body pain:

> *I'm scared [that] maybe the [sensors] are affecting my whole legs...now my legs cannot go up, [it's] very painful* [Participant 2]

As a result, she wanted to uninstall the sensors. After reassurance from her nurse that the pain was not attributable to the sensors and that the sensors would be beneficial in case of an emergency, the participant chose to continue using the technology:

> *I asked if it's better for them [the team] to take out [the sensors], but the nurses said, "No, no need, no need because it is better for you." They're scared [if*

XSL•FO
RenderX

> *anything happens] when I go to the toilet and fall down or sleep and cannot wake.*

Fourth, two participants had concerns about the inconveniences caused by technology in some ADLs, such as cleaning:

> *I personally don't like the sensors under the bed. Every time I clean under the bed, it drops, and I do not know how to put it back. If I lay it on the floor, it looks untidy as well.* [Participant 3]

> *[It is already difficult] to clean the floor. Last time, I could clean. But with the sensors, I cannot [clean].* [Participant 2]

After a closer look at the sensors, we found that the bed sensor required an extension cable, which we informed the older adults could be elevated to not obstruct the cleaning. This resolved the issue. Once the aforementioned concerns were addressed, most of the participants were satisfied with the system. They seemed happy to have something new in their home. We believe that they felt special to have been chosen to participate in this study because the older adults consistently asked if the sensors could be left at their homes after the study had ended.

Fifth, fears about radiation exposure unexpectedly emerged as a key barrier to participation. Although we had addressed more common concerns, such as electricity consumption, privacy, and cleaning inconveniences, our initial planning did not anticipate that some participants might associate ambient sensors with radiation risk. During the initial briefing, one older adult who appeared to be an informal leader among peers voiced this concern and declined to proceed with installation. His decision significantly influenced others, some of whom had previously agreed to participate, leading to a noticeable drop in participation.

Lessons Learned and Recommendations

Overview

The subsequent sections present lessons learned at different phases of the AAL technologies' integration and normalization process. Before outlining specific insights, we reiterate the distinctiveness of the study context to make it salient for interpreting the recommendations mentioned subsequently. As previously described, our participants were older adults living in heavily subsidized rental housing in Singapore. Many (16/19, 84%) lived alone, had little or no regular contact with close family, and depended heavily on staff at the SACs as their primary source of emotional and social support. In this context, caregiving relationships were not merely transactional. They were deeply relational and, for many participants, irreplaceable. This high-need, low-resource environment shaped how the Ubismart intervention was introduced, understood, and integrated into daily life. The recommendations presented in this section are thus grounded in and should be interpreted through this unique caregiving and social ecosystem.

Coherence

Coherence refers to how individuals and collectives make sense of a new intervention, that is, what it is, why it matters, and how it fits into their lives [14,39]. In this study, fostering coherence required more than technical explanation; it demanded sensitivity to the lived realities of older adults who relied heavily on SAC caregivers for trust, translation, and emotional anchoring. Recognizing that caregivers played a pivotal role in participants' day-to-day lives, we engaged SAC staff members early and invited them to colead participant briefings. Their presence not only facilitated translation because many (16/19, 84%) older adults communicated in Hokkien, Mandarin, or Cantonese but also lent credibility to the project. Because SAC caregivers were often viewed as family-like figures, their involvement helped older adults feel reassured and respected during the introduction of Ubismart. On the basis of these insights, we present some recommendations.

The first recommendation is to engage trusted caregiving intermediaries early and include them in participant briefings, as their involvement plays a critical role in fostering coherence by translating, legitimizing, and contextualizing the intervention.

The second recommendation is to deliver briefings in linguistically and culturally appropriate formats, such as using translated materials, visual aids, and caregiver-facilitated discussions, to ensure understanding among older adults with diverse language abilities and educational backgrounds.

Cognitive Engagement

Cognitive engagement focuses on individuals' active participation in the intervention [14,39]. Routine integration of AAL technologies into older adults' care hinges on their willingness to actively engage in field deployment and commitment to maintaining the presence of ambient sensors within their homes. In our context, we initially assumed that older adults' trust in SAC caregivers, coupled with a clear understanding of the AAL system's benefits, would translate into widespread acceptance. However, our experience revealed that this assumption overlooked the layered dynamics of peer influence and perceived risk, which proved critical to engagement.

Despite initial enthusiasm, a subset of participants opted out of deployment due to fears surrounding radiation exposure, a concern introduced by one particularly influential older adult. This individual's withdrawal prompted others to follow suit. Notably, this occurred even after the system's safety and privacy features were explained. While the Ubismart system used only low-power, off-the-shelf electronics, technical reassurance alone was insufficient to counteract socially transmitted anxieties. This experience highlighted that engagement depended not only on formal information channels but also on informal social dynamics. Surfacing and addressing these perceived risks (however unfounded) required relational attentiveness and not just technical accuracy. Drawing from this, we make further recommendations.

The third recommendation is to identify and engage both formal (eg, SAC caregivers) and informal (eg, respected peers at the SAC) influencers early in the process. For older adults who spend much of their time in communal settings, peer relationships significantly shape perceptions and decisions. Addressing perceived risks requires not only technical transparency but also relational attentiveness and messaging that resonates with these trusted figures.

XSL•FO
RenderX

The fourth recommendation is to provide ample time for reflection on the proposed intervention. Although we asked the older adults about their concerns at the joint briefing, we may not have given them sufficient time to reflect. Therefore, it would be best to allow older adults sufficient time (eg, a few days) for reflection, encouraging them to document their apprehensions for a thorough concern mitigation process.

The fifth recommendation is to facilitate low-pressure, small-group discussions at SACs where participants can share thoughts with peers and caregivers. These informal settings encourage open dialogue and can serve as early warning systems for surfacing emerging concerns or misinformation. They also provide a trusted space for gently debunking myths, such as health risks from sensors, through respectful, peer-sensitive conversation.

Collective Action

Collective action addresses how stakeholders within an ecosystem work together to enact the new intervention [14,39]. In the context of this study, successful deployment of Ubismart required not only technical infrastructure but also thoughtful collaboration between older adults and SAC caregivers to ensure the system was meaningfully integrated into everyday life. While our team gleaned many general insights about sensor placement, connectivity, and troubleshooting (eg, SIM card recharging, battery drain, and optimal sensor placement), we focused on lessons uniquely shaped by our study context—a dense, low-income housing estate in Singapore where older adults often lived alone, had limited family interaction, and relied heavily on SAC caregivers for daily support.

A critical insight that emerged during early deployment was the influence of “saving face,” a deeply rooted cultural value in many Asian societies. Face is the social esteem accorded by others or the respectability or deference that a person can claim for themselves from others by the degree to which they are judged to have behaved appropriately [57]. To avoid losing face, one participant reported napping on a chair rather than on the bed so her rest would not be captured by the bed sensor. She feared that being seen as inactive during the day might reflect poorly on her. The technology itself did not drive this concern but a broader social anxiety around appearing unproductive or burdensome did.

This behavior underscored a central challenge in the era of big data, namely data accuracy. Sensor-based systems like Ubismart generate large volumes of behavioral data that, if interpreted without cultural context, can misrepresent reality. Inaccuracies, especially those stemming from altered behavior due to social pressure, pose a serious threat to the quality and utility of big data in AAL systems. Ensuring data integrity requires building environments where users feel safe to act naturally. To support this, clear and culturally sensitive messaging is essential. Repeatedly emphasizing that the system is not intended to evaluate or penalize routine behaviors but instead to detect deviations that may signal distress can prevent compensatory behaviors that compromise data fidelity. Therefore, we make some recommendations mentioned subsequently.

The sixth recommendation is to reinforce early and often that the goal of the AAL system is to detect anomalies and not to surveil or judge daily behavior. This framing supports cultural values like dignity and reduces compensatory behaviors that compromise data quality.

The seventh recommendation is to leverage peer-led and caregiver-facilitated discussions at SACs to build trust and clarify how sensor data are used. These relational channels help reduce fear, promote natural behavior, and improve data reliability in a context where both peer influence and caregiver relationships are central.

Along the same vein of data accuracy, one of the core challenges in big data systems like AAL is maintaining reliable sensor performance over time. In our context, many (16/19, 84%) older adults lived alone and lacked the technical know-how to detect or report sensor issues, while SAC caregivers were already operating at full capacity. This made routine manual checks unfeasible. However, regular interactions with peers and caregivers at the SACs present a culturally grounded opportunity. By integrating informal sensor checks into existing social routines, such as weekly visits or group activities, we can support data reliability without adding strain to caregiving staff. Therefore, we make the recommendation mentioned subsequently.

The eighth recommendation is to leverage trusted peer and caregiver networks to identify sensor issues. SAC caregivers and socially influential peers should be equipped with simple cues to detect malfunctions, and informal checks during regular interactions should be encouraged. These efforts should be paired with automated alerts for a hybrid approach to reliability.

Reflexive Monitoring

This phase of the NPT is concerned with how users will perceive the intervention once it has been in use for a while [14,39]. In our study, both older adults and SAC caregivers perceived Ubismart as a helpful, dignified addition to daily routines. Caregivers reported that the system facilitated more personalized and proactive care, while older adults described a growing sense of safety, particularly within the home environment. This perceived security appeared to catalyze subtle behavioral improvements, including increased confidence and reduced anxiety, aligning with the statistically significant gains observed in psychological and emotional well-being.

However, the same system also revealed unintended consequences. As the technology assumed a more active monitoring role, some participants perceived a decline in relational contact. While caregivers relied on Ubismart to allocate limited resources and prioritize high-need cases, this shift risked reinforcing feelings of neglect or abandonment among older adults who previously received more frequent visits. In the context of this study, where most (16/19, 84%) participants lived alone and SAC caregivers served as their main source of emotional support, the reduction in in-person interactions carried emotional weight.

These dynamics underscored a core tension in digitally supported care; while ambient technologies might improve efficiency and safety, they could inadvertently diminish the

XSL•FO
RenderX

very human connections older adults value most. Therefore, reflexive monitoring requires ongoing attentiveness not only to technical metrics but also to lived experiences and shifting care relationships. Drawing from the aforementioned lessons, we present two recommendations.

The ninth recommendation is to embed structured opportunities for older adults and caregivers to share how technology affects their care experiences and relationships. These feedback mechanisms not only surface unintended consequences (eg, reduced visit frequency) but also provide a relational check on system use, reinforcing dignity, trust, and care continuity.

The 10th recommendation is that in high-need, low-resource settings, where caregivers are the primary source of support, AAL technologies should augment relational care and not replace it. To address capacity gaps, caregivers should partner with community volunteers, students, or nonprofits to ensure older adults' emotional and social needs are met.

Discussion

Principal Findings

Motivated by the shortage of longitudinal studies on the integration of AAL technologies in older adults' care, especially in Southeast Asia, we used an in-depth case study to explore the deployment and impact of an AAL technology, which we termed Ubismart, on older adults' QOL. Our study revealed that AAL technologies positively impacted certain QOL dimensions for older adults, particularly enhancing psychological well-being and a sense of security. Many participants reported feeling safer with the technology, describing it as a reassuring presence in their homes. However, the impact on social relationships was mixed; while some older adults felt more cared for due to the technology, others experienced fewer in-person visits and a sense of isolation, as caregivers increasingly relied on AAL systems for monitoring.

Key lessons emerged regarding the integration and normalization of AAL technology. First, to establish coherence, it is essential to prioritize culturally grounded and relationally sensitive strategies that help older adults understand the purpose and relevance of AAL technology. Involving caregivers (ie, trusted figures in participants' lives) in joint briefings would be especially effective in building trust and reinforcing the system's value within existing care relationships. Second, to support cognitive engagement, it is crucial to recognize that adoption is shaped not only by formal caregivers but also by influential peer networks within the ecosystem. In our study, a single participant's concern about radiation led others to withdraw, demonstrating how quickly skepticism can spread in tightly connected communities. Third, collective action requires sensitivity to cultural norms such as saving face. Some participants altered their behavior, such as napping on a chair, to avoid perceived judgment. Reinforcing that the system monitors for anomalies, not habits, is key to preserving data accuracy. Finally, reflexive monitoring brought attention to an important unintended consequence; while the technology promoted safety, it also inadvertently reduced social interactions for some older adults, highlighting the need for vigilance in balancing AAL technology's benefits with ongoing human connection.

Comparison With Prior Work

As mentioned earlier, much good work has been done on the use of AAL in the care of older adults. Similar to other projects, including HomeAssist [58] and NESTORE [59], both conducted in the European Union, our intervention supported aging in place by offering unobtrusive monitoring. Overall, our findings align with previous AAL studies that reported improved QOL among older adults [60,61]. However, our work contributes novel insights into several key areas.

First, as Taramasco et al [60] mentioned, data pertaining to QOL are scarce. They highlighted the methodological challenge of having to adjust for baseline imbalances in QOL measures before detecting a significant effect, underscoring how sensitive and complex this construct can be to capture. Our study contributes to this conversation not only by examining QOL outcomes but also by reflecting critically on the measurement process itself. We document the challenges of using standard Likert-based tools with older adults who have limited formal education and propose a culturally adapted, gamified alternative that offers a more accessible way for participants to express their perceived well-being. This approach enables us to surface meaningful shifts in specific QOL domains while also contributing to a broader methodological discussion on how best to measure QOL in underserved populations.

Second, recent works have shown that about 5 countries (ie, the United States, the United Kingdom, France, Canada, and Japan) have been leading research in AAL technologies thus far, and of these 5, only Japan has a collectivistic culture [62]. Answering the call for more research from diverse cultures [62], our study offers rare empirical insights from a subpopulation within a collectivistic culture. Specifically, we focused on older adults in Singapore who, despite living in a society that values familial interdependence, often experience social isolation due to impoverishment, limited education, and estrangement from close family. These older adults reside in heavily subsidized housing and depend primarily on caregiving staff at community-based SACs for emotional and social support. Unlike the typical AAL studies conducted in individualistic, high-resource settings, our work surfaces how the adoption and routinization of AAL technologies are mediated by unique cultural and relational dynamics, including peer influence, saving face [57], and the central role of institutional caregivers. These findings highlight the importance of designing AAL systems not only for technical robustness but also for cultural fit and relational integration within the lived caregiving ecologies of susceptible older adults.

Third, the OPQOL is one of the most widely used and validated instruments for assessing QOL in older adult populations, offering a multidimensional perspective that includes domains such as health, independence, social relationships, emotional well-being, and home and neighborhood safety [43,63]. However, our findings suggest that this latter domain, particularly in both the full [43] and brief versions [63] of OPQOL, may mask intervention-specific effects when home and neighborhood safety are treated as a single construct.

XSL•FO
RenderX

Although our quantitative analysis using a gamified proxy of the OPQOL did not show a statistically significant change in the aggregated safety domain, qualitative narratives consistently revealed an increased sense of home-based safety. Participants described feeling reassured knowing help would be available during emergencies, especially at night or when living alone. In contrast, neighborhood safety was rarely mentioned and remained largely unaffected by the intervention. While the OPQOL-brief includes the item "I feel safe where I live," this phrasing still conflates 2 distinct contexts. On the basis of our findings, we suggest that future studies consider explicitly separating this domain into "I feel safe at home" and "I feel safe in my neighborhood" to more accurately detect the localized effects of AAL interventions and avoid measurement dilution.

Taken together, these contributions reinforce the need for culturally sensitive, relationally grounded, and methodologically flexible approaches to designing and evaluating AAL technologies, particularly in diverse, underrepresented populations.

Limitations

As with all research, this study is not without its limitations. We highlight 3 limitations that we believe are particularly important. First, a potential limitation of this study is that we focused on one context, Singapore. While the findings of our study may be generalizable to similar cultures (ie, collectivistic), some of our findings, especially pertaining to the relationship between older adults and caregivers, may not be applicable in individualistic cultures. However, our goal was to explore a context-specific understanding of the routinization of AAL technologies in this hitherto under-studied context. In doing so, we answer calls for research that redirects focus from general theories of technology use to context-specific theorizing [64]. Second, even though we explored our study context comprehensively, by having 19 older adults in this study, we are again unable to claim broad generalizability of the proposed recommendations. More research is needed before such claims can be made. However, we note that our sample size is comparable to similar studies with sample sizes ranging from 9 to 20 [24,29], owing to the cost of deployment. Third, we used a validated measure of QOL that is largely used in Western contexts [43]; therefore, our participants struggled to understand it, and we had to improvise and create the "gamified QOL measurement tool" as a conversation starter. Indeed, QOL may be experienced differently based on demographic differences [65].

Future Directions

Future research should address the aforementioned limitations to enhance the study's robustness and applicability. First, cross-cultural studies that examine AAL technology use in both collectivistic and individualistic contexts could provide insights into the role of cultural values in shaping older adults' and caregivers' dynamics. This would help determine the extent to which our findings apply beyond Singapore. Second, while our sample size aligns with similar studies, larger and more diverse samples would strengthen the generalizability of our recommendations. Future studies could partner with health care organizations to increase sample size and diversity. Finally, developing culturally responsive QOL measurement tools would mitigate the challenges we encountered with Western-centric QOL assessments, allowing a more accurate understanding of well-being across diverse populations.

Conclusions

In conclusion, this study highlights the promise of AAL technologies in addressing the challenges faced by older adults living independently; however, it underscores that no technology is a panacea. While AAL tools can enhance safety, social connection, and QOL, they cannot fully substitute for the support systems that older adults need. Future research should continue to explore these technologies' potential across different cultural contexts and emphasize the importance of complementary social and familial support in promoting older adults' well-being.

Acknowledgments

This work was supported by the European project City4Age, which received funding from the Horizon 2020 research and innovation program (grant 689731). The authors would like to thank all the participants who agreed to be part of this experiment and all the collaborating geriatricians and professional and informal caregivers.

Abstract

Background: Falls and fear of falling adversely affect the quality of life and independence of older adults. Although various robotic systems have been developed for fall prevention, their psychological effects, particularly on self-efficacy, remain underexplored. A ceiling-mounted fall impact mitigation robot offers continuous protection with almost no limitations on the range of movement; however, its impact on users' psychological state and functional performance is unclear.

Objective: This study aimed to evaluate the effect of a fall impact mitigation robot on psychological reassurance and task performance during dynamic balance tasks in healthy young adults, with a focus on self-efficacy and functional reach capacity.

Methods: Twenty-four healthy adults (age: mean 28.9, SD 7.9 years) were randomly assigned to experimental (n=12) or control (n=12) groups. All participants performed a baseline functional reach test, followed by a series of progressively challenging reach tasks (starting at 98% of maximum reach and increasing by 2% until failure). The experimental group performed tasks while wearing the fall impact mitigation robot; the control group performed without it. Self-efficacy ratings (–5 to +5 scale) were recorded before each trial. Center of pressure (COP) data were continuously collected. Statistical analyses included Mann-Whitney *U* tests for self-efficacy, Kaplan-Meier survival analysis for task performance, and *t* tests for functional reach test and COP changes.

Results: During reach trials ≥102% of baseline, the experimental group (median 1.0, IQR 0.0 to 3.0) reported significantly higher self-efficacy ratings than did the control group (median 0.0, IQR –1.0 to 2.0; U=1292.5; P=.047). However, no significant differences were observed in changes in functional reach capacity (experimental: mean 104.2%, SD 3.8%; control: mean 103.6%, SD 2.5%; P=.62) or COP displacement (experimental: mean 108.9%, SD 10.4%; control: mean 114.1%, SD 9.8%; P=.23). Survival analysis revealed a nonsignificant trend toward greater task persistence in the experimental group (χ^2_1=0.36, P=.55).

Conclusions: The fall impact mitigation robot significantly improved self-efficacy during challenging balance tasks, despite providing no active physical support. These findings underscore the role of psychological reassurance in modulating balance-related behavior and suggest that robotic safety systems may influence motor performance through psychological mechanisms. Integrating psychological support into robotic fall prevention strategies may enhance their effectiveness.

Introduction

The rapid aging of the global population presents major challenges to health care and social security systems. Among these, age-related declines in physical function, particularly mobility limitations, adversely affect the quality of life and independence of older adults [1]. To address these challenges, assistive robotic technologies are being developed for various domains, including mobility, transfer, bathing, and communication [2-6]. These systems are anticipated to play a key role in promoting healthy longevity by supporting physical, social, and psychological well-being [7,8].

Fall prevention is a central concern in the context of age-related functional decline, as falls compromise both safety and independence. Approximately one-third of older adults experience at least one fall annually [9,10], and the risk of fall-related injuries increases due to age-associated impairments in musculoskeletal, cardiovascular, visual, vestibular, and proprioceptive functions [11-15]. Beyond physical injury, the fear of falling contributes to a cycle of reduced mobility, decreased activity, and social withdrawal [16,17]. This fear can negatively influence balance control and movement behavior [18], particularly in older adults with physical disabilities, thereby limiting social participation and increasing the risk of future falls [19-21].

To mitigate these risks, various robotic solutions for fall prevention have been proposed. These include “smart robotic walkers” that anticipate movement patterns to provide proactive support [22] and “robotic canes” that adapt to users’ gait characteristics [23-25]. While promising, these systems are often optimized for clinical settings and may be impractical for home use due to space and mobility constraints [26]. Moreover, their potential psychological benefits remain poorly characterized, despite the crucial role of fall-related self-efficacy in fall prevention outcomes.

Recent studies have emphasized the importance of psychological factors in fall prevention. Self-efficacy, as defined by Bandura [27], refers to an individual’s belief in their ability to carry out actions necessary to achieve specific outcomes. Tinetti et al [28] introduced the concept of falls efficacy as a domain-specific form of self-efficacy, meaning the confidence to perform daily activities without falling. Building on this, Powell and Myers [29] developed the Activities-specific Balance Confidence Scale, which assesses confidence in maintaining balance during a range of activities. More recently, Soh et al [30-32] proposed a multidimensional framework for fall efficacy, encompassing 4 distinct domains across the fall continuum: balance confidence (pre-fall), balance recovery confidence (near-fall), safe-landing confidence (fall-landing), and post-fall recovery confidence (post-fall). This expanded model highlights the need for psychological resilience not only to prevent falls but also to manage their occurrence. Clinical findings suggest that such psychological constructs can directly modulate balance control mechanisms, potentially masking or compensating for physical impairments [18]. As such, effective fall prevention strategies should integrate both physical safeguards and psychological reinforcement.

Motor learning theory provides a framework for understanding how to effectively provide such psychological reinforcement. Self-efficacy influences task engagement, and learning is optimized when difficulty appropriately matches ability [27,33]. However, people naturally tend to be conservative, using only a portion of their available stability capacity due to inherent safety mechanisms [34]. This suggests that effective balance training must address both the physical and psychological barriers that limit engagement with appropriately challenging tasks.

The present study focuses on a ceiling-mounted fall impact mitigation robot designed to address both physical and psychological aspects of fall prevention. This suspended system provides continuous support during daily activities in home environments, with almost no limitations on the range of movement. While the system was primarily designed to reduce the physical risk of fall-related injuries, its impact on psychological factors, particularly fall-related self-efficacy, has not been fully elucidated. Specifically, it remains unclear whether the constant presence of such a safety system influences users’ psychological state, and if so, whether this influence translates into measurable changes in motor performance when facing such challenging tasks.

This study aims to examine the effect of the fall impact mitigation robot on psychological reassurance and task performance during dynamic balance challenges. Young healthy adults were selected as participants to establish a baseline understanding of these mechanisms, unconfounded by age-related impairments. We used the functional reach test (FRT), a validated tool for assessing dynamic balance and fall risk across age groups [35]. The FRT was particularly suited to this study, as it provides a quantitative measure of physical reaching ability and reflects the confidence required to perform challenging balance tasks [34]. Participants were asked to perform progressively demanding reaching tasks that exceeded their maximum capacity, either with or without robotic safety support depending on their group assignment. Prior to each attempt, participants were asked the self-efficacy ratings to quantify how perceived safety influences both confidence and motor performance. By investigating this relationship, we aim to elucidate how robotic safety systems modulate human movement behavior, thereby informing the development of comprehensive fall prevention strategies that promote safe, independent living among older adults.

Methods

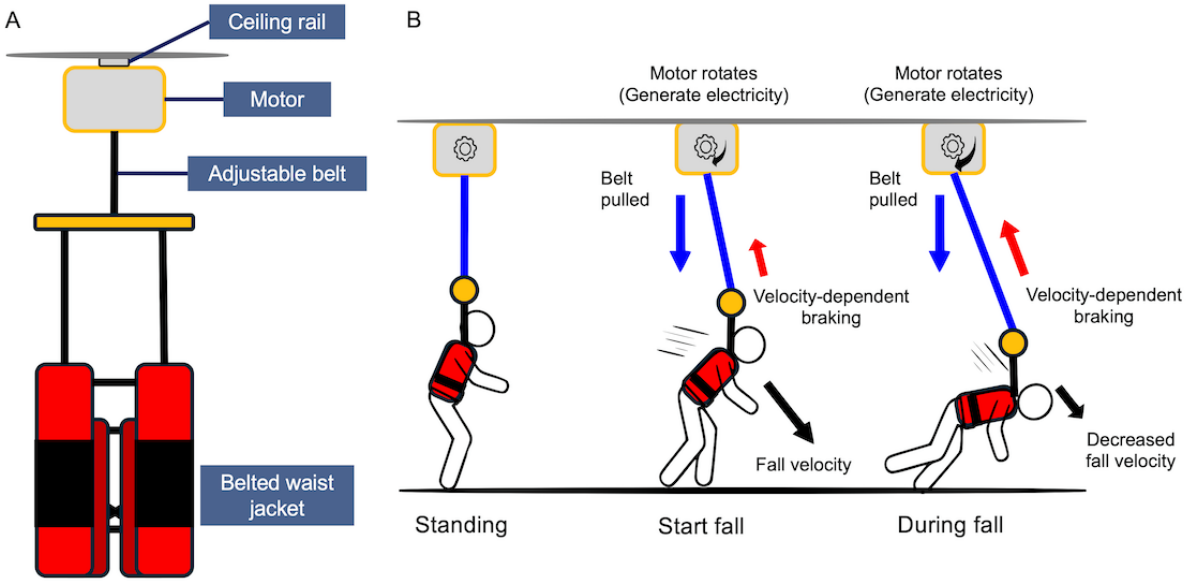
Participants

Twenty-four healthy adults (12 men and 12 women; age: mean 28.9, SD 7.9 years; height: mean 1.64, SD 0.09 m; weight: mean 59.1, SD 12.5 kg) participated in this study. Participants were randomly assigned to either the experimental group (n=12; 7 men, 5 women; age: mean 27.5, SD 7.9 years; height: mean 1.65, SD 0.08 m; weight: mean 59.9, SD 13.8 kg) or the control group (n=12; 5 men, 7 women; age: mean 30.3, SD 8.1 years; height: mean 1.62, SD 0.10 m; weight: mean 58.3, SD 11.6 kg). There was no significant association between grouping and gender distribution (χ^2_1=0.67; *P*=.41). Statistical analysis showed that the randomization achieved an adequate gender ratio, and this slight demographic variation does not represent a methodological flaw. All participants provided written informed consent prior to the study.

Ethical Considerations

The study protocol was approved by the Ethics and Conflict of Interest Committee of the National Center for Geriatrics and Gerontology (approval number 1636).

Apparatus and Protocol



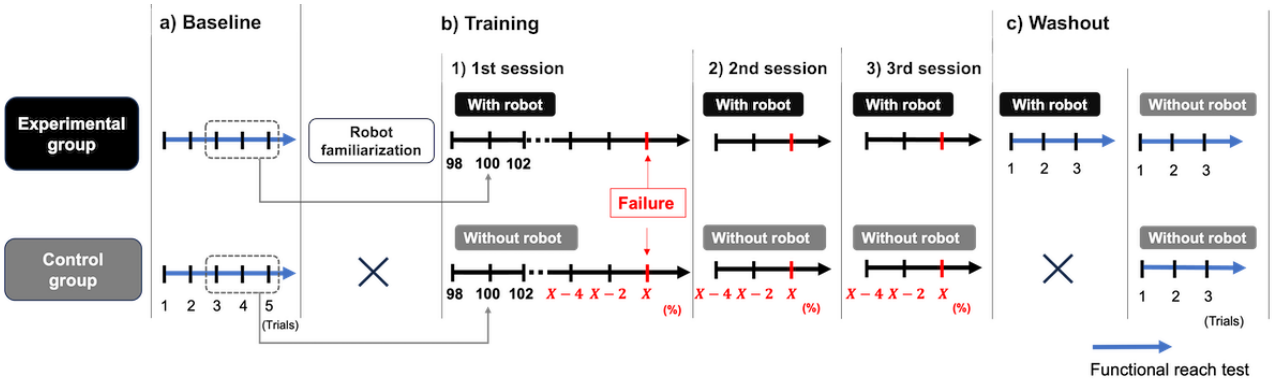
Measurement Equipment

FRT distance was measured using a dedicated device (T-2795, TOEI LIGHT Co., Ltd.). Center of pressure (COP) data were acquired using 2 force plates (BP400-600, Advanced Mechanical Technology, Inc.) operating at a sampling frequency of 1000 Hz. Data acquisition was managed via A-Cap, an AD conversion system and its accompanying software (version 1.26.1, 4Assist, Inc.).

Fall Impact Mitigation Robot

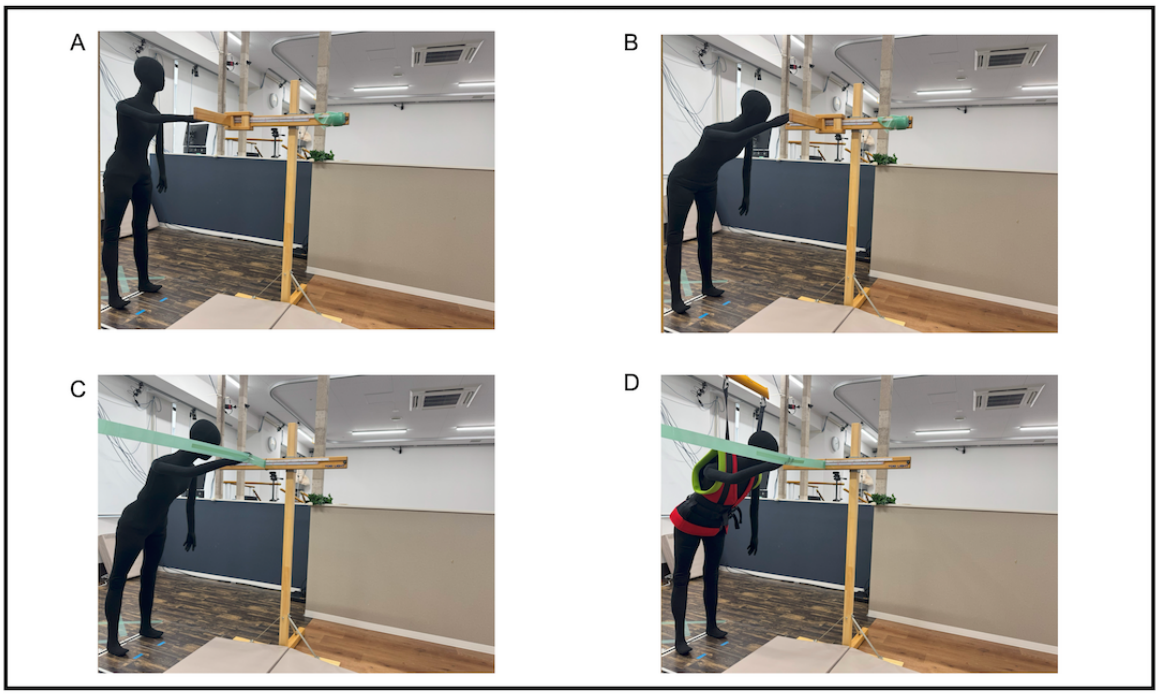
The experimental group used a ceiling-mounted fall impact mitigation robot (Yorisoi Robot, Sanyo Homes Co., Ltd.) equipped with a high-performance DC motor (model SS40E8; Figure 1). The system is permanently installed in the Living Lab, a real-world simulation environment designed for evaluating daily activities [36]. The robot remains inactive during normal movement and activates only upon detecting accelerations consistent with falling, engaging a braking mechanism to mitigate impact without interfering with normal movement.

Figure 1. Fall impact mitigation robot system. (A) System configuration showing ceiling rail, motor unit, adjustable belt, and belted waist jacket. (B) Fall response mechanism: when a fall occurs, the adjustable belt around the motor shaft is pulled, causing motor rotation that generates electricity for velocity-dependent control to reduce fall impact during the descent sequence.



Experimental Procedure

The intervention consisted of three sequential phases (Figure 2): (1) a baseline phase to determine individual maximum reach capacity, (2) a training phase for robot familiarization and dynamic reaching tasks, and (3) a washout phase to assess residual effects without robotic assistance. To ensure participant safety throughout the experiment, a research assistant was positioned in close proximity to provide manual support if necessary, and shock-absorbing mats were placed on the floor in the forward reaching direction as a further precaution.



XSL•FO
RenderX

Figure 2. Schematic overview of the experimental procedure comparing reaching tasks performed with and without the fall impact mitigation robot.

Baseline phase: All participants first completed a standard FRT to establish baseline performance (Figure 3A). Participants stood barefoot with feet shoulder-width apart on the force plates (right foot on right plate, left foot on left plate). The measuring device was adjusted to acromion height. From this standardized position, participants extended the right arm horizontally and pushed the measuring device forward using the extended fingers (Figure 3B). A trial was considered successful if the participant returned to the starting position without foot displacement; heel lift was permitted. After 5 trials, the average distance from the third through fifth attempts was recorded as the maximum reach distance (defined as 100%).

Figure 3. Experimental setup for the functional reach and challenging reaching tasks. (A) Initial posture for the functional reach test, with the participant standing on force plates and the measuring device aligned to acromion height. (B) Standard reach assessment, with the participant extending the right arm horizontally. (C) Challenging functional reach test, in which the participant attempts to reach beyond their baseline maximum distance. (D) Challenging reach task with the participant wearing the fall impact mitigation robot.

Training phase: The control group performed the training tasks without the robot (Figure 3C), while the experimental group performed with robotic support (Figure 3D). Participants in the experimental group were introduced to the robot's functionality, with emphasis on its passive operation during normal movement and its role in fall impact mitigation. A researcher conducted a forward fall demonstration while wearing the robot to illustrate activation of the braking mechanism. Participants then wore the device and performed 3 controlled forward falls with robot safety support to familiarize themselves with the system's protective function. The control group did not participate in this familiarization procedure.

Subsequently, all participants performed a series of challenging reach tasks designed to exceed the maximum reach capacity established during baseline. The same posture and setup were maintained. The task began at 98% of the individual's maximum reach distance, increasing by 2% with each successful attempt until failure. Task failure was defined as inability to reach the target distance, any foot movement, or loss of balance preventing return to the starting position. Targets were marked with tape and reached using the extended right arm.

Before each trial, participants rated their confidence in their ability to perform the forward reaching task to the specified target distance without losing balance or moving their feet,

XSL•FO
RenderX

using an 11-point scale from –5 (completely unconfident) to +5 (completely confident), with negative values indicating low confidence and positive values indicating high confidence. Upon failure, participants completed 2 additional sets of 3 trials at the failure distance and 2 easier levels (–2% and –4%). One-minute rest intervals were provided between sets to minimize fatigue.

Washout phase: After the challenging reach task, the experimental group completed 3 standard FRT trials (shown in Figures 3A and 3B) while still wearing the robot. Subsequently, both groups performed another 3 standard FRT trials without the robot to assess any residual effects (washout) of robotic support.

Data Analysis

Statistical Analysis

Outliers in the FRT and COP datasets were identified and excluded using the Smirnov-Grubbs test. Data distribution was assessed using the Kolmogorov-Smirnov test for normality, followed by the Bartlett test to evaluate the homogeneity of variance across groups. Based on these preliminary assessments, parametric tests (independent samples *t* tests) were applied to normally distributed data with equal variances. When these assumptions were not met, nonparametric alternatives were used as appropriate. Statistical analyses for FRT variables were conducted using EZR software (version 1.55; Saitama Medical Center, Jichi Medical University) [37]. COP data were preprocessed in MATLAB 2022b (MathWorks) prior to statistical analysis in EZR. Analyses of the challenging reach task and self-efficacy ratings were performed using Python 3.12. A significance level of $P<.05$ was adopted for all statistical comparisons.

Self-Efficacy Analysis

To evaluate psychological responses, self-efficacy ratings were analyzed for all trials conducted at or beyond 102% of each participant's baseline maximum reach. Given the ordinal nature of the self-efficacy scale (–5 to +5) as described above, between-group comparisons were performed using the Mann-Whitney *U* test.

Functional Reach Test Analysis

To assess the effects of the intervention on functional reach capacity, percent changes in reach distance from baseline to washout were calculated for each participant. Between-group differences in these percent changes were analyzed using independent samples *t* tests.

Challenging Reach Task Analysis

Performance during the challenging reach task was analyzed using Kaplan-Meier survival analysis. Reaching distances, expressed as percentages of baseline maximum, were treated as the time variable. Task failure, defined as an inability to reach the target distance, foot movement, or loss of balance, was designated as the event of interest. Survival curves for the experimental and control groups were compared using the log-rank test to determine differences in performance persistence.

COP Analysis

Composite COP coordinates were calculated from ground reaction force components recorded by 2 force plates. COP data were filtered using a fourth-order Butterworth low-pass filter with a 6.0 Hz cutoff frequency. The analysis window for each FRT attempt was defined by synchronizing COP trajectories with corresponding video recordings. Anteroposterior COP displacement was computed as the difference between minimum and maximum positions during baseline and washout measurements. Changes in COP displacement from baseline to washout were expressed as percentages of baseline values. Between-group comparisons of these percent changes were conducted using independent samples *t* tests.

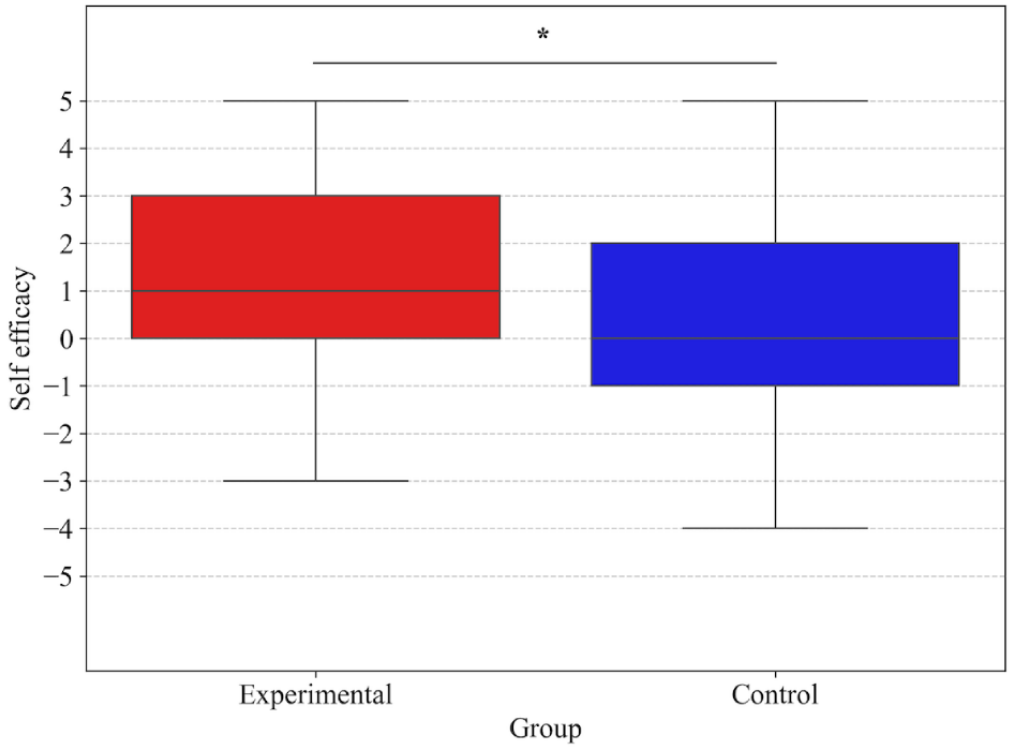
Results

Self-Efficacy Analysis

Self-efficacy ratings during challenging reach trials (≥102% of baseline maximum reach) were significantly higher in the experimental group (median 1.0, IQR 0.0 to 3.0, range: –3.0 to 5.0; trials: 62) than in the control group (median 0.0, IQR –1.0 to 2.0, range: –4.0 to 5.0; trials: 53) (Figure 4). This between-group difference in Figure 4 was statistically significant (Mann-Whitney *U* test: $U=1292.5$, $P=.047$). The mean self-efficacy ratings from all participants are shown in Figure 5. Self-efficacy was higher in the experimental group (ie, when using the robot), mainly in reaching trials of 110% or more.

XSL•FO
RenderX

Figure 4. Box-and-whisker plots of self-efficacy ratings during challenging reaching tasks (≥102% of baseline maximum reach) in the experimental (red) and control (blue) groups. The y-axis represents self-efficacy scores on an 11-point scale from –5 (completely unconfident) to +5 (completely confident).



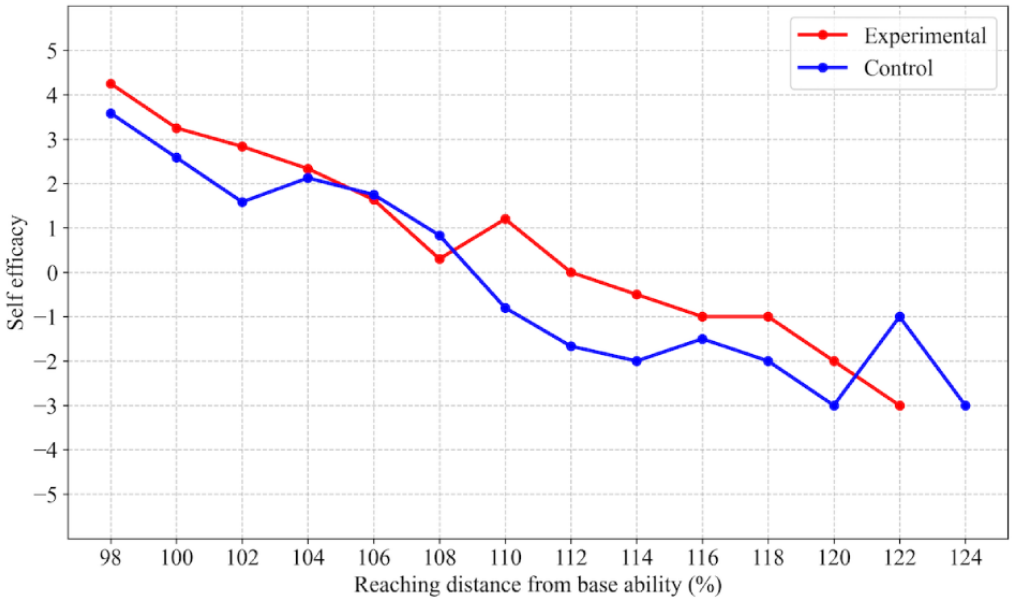


Figure 5. Self-efficacy ratings across different reaching distances during the challenging task for the experimental (red) and control (blue) groups. The x-axis shows reaching distance as a percentage of baseline maximum reach (100% = participant's baseline maximum). The y-axis displays mean self-efficacy scores on an 11-point scale from –5 to +5.

The standard FRT

There were no significant between-group differences in percent changes in functional reach capacity from baseline to washout (experimental: mean 104.2%, SD 3.8%; control: mean 103.6%, SD 2.5%; $t_{22} = 0.510$, P=.62; Table 1). Both groups exhibited modest improvements in maximum reach distance following the intervention protocol.

XSL•FO
RenderX

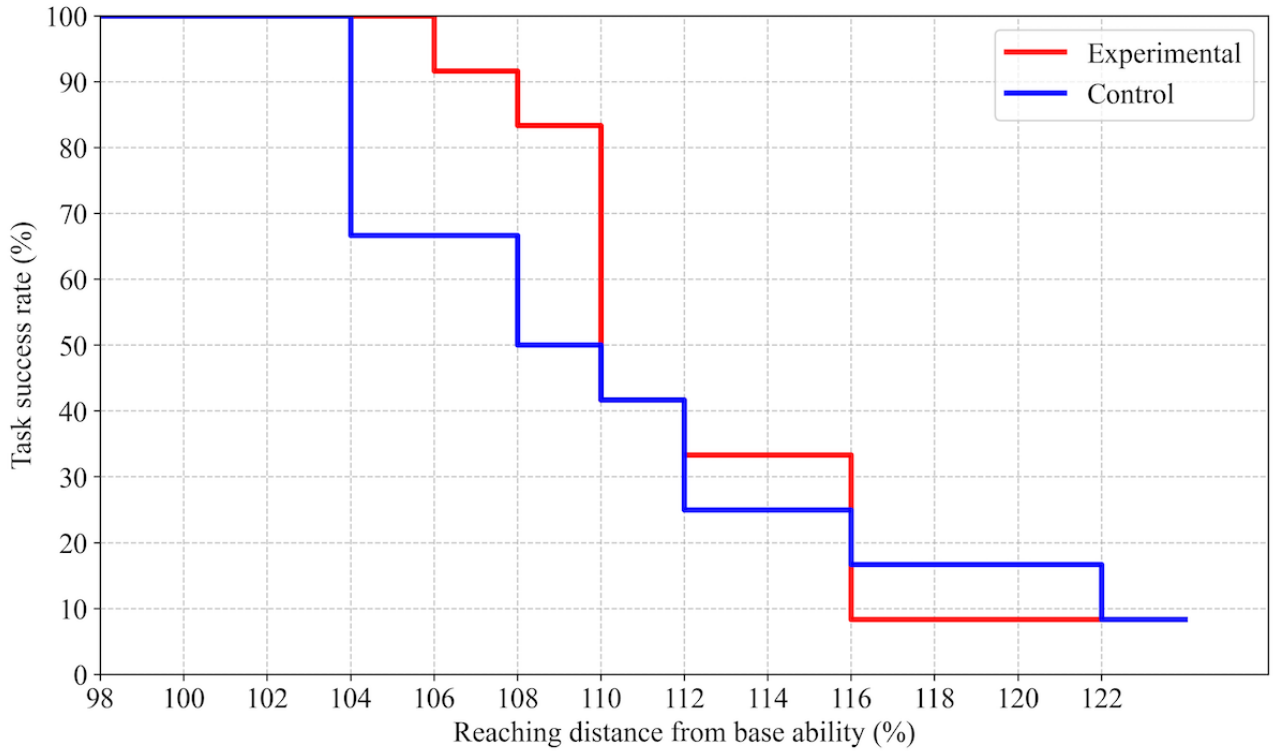

Table 1. Comparison of physical performance measures between experimental and control groups. Data are presented as mean ± standard deviation and reflect percentage changes from baseline to washout for the functional reach test (FRT) distance and center of pressure (COP) displacement.

Outcome Measure	Experimental (n=12), mean (SD)	Control (n=12), mean (SD)	*t* value	*P* value
FRT (%)	104.2 (3.8)	103.6 (2.5)	0.510	.62
COP (%)	108.9 (10.4)	114.1 (9.8)	1.244	.23

Challenging Reach Task

Kaplan-Meier survival analysis of maximum reaching distances revealed no significant difference between groups (log-rank test: χ^2_1=0.36, *P*=.55), although the survival curve suggested a trend toward greater task persistence in the experimental group (Figure 6).

Figure 6. Kaplan-Meier survival curves comparing maximum reaching distances achieved during the challenging task in the experimental (red line, with fall impact mitigation robot) and control (blue line) groups. The x-axis denotes reaching distance as a percentage of baseline maximum reach. The y-axis indicates the proportion of participants able to successfully complete each reach distance.

COP Analysis

No significant differences were observed between the groups in anteroposterior COP displacement from baseline to washout (experimental: mean 108.9%, SD 10.4%; control: mean 114.1%, SD 9.8%; t_{22}=1.244, *P*=.23; Table 1), indicating that COP dynamics during the functional reach task were not differentially influenced by the intervention.

Discussion

Principal Findings

This study investigated the psychological effects of a fall impact mitigation robot, focusing on its influence on self-efficacy and physical performance during balance-challenging tasks. Participants in the experimental group who wore the robot exhibited significantly higher self-efficacy ratings, particularly prior to reaching tasks that exceeded their individualized maximum reach thresholds (Figures 4 and 5). Although survival analysis suggested a trend toward greater task persistence in the experimental group (Figure 6), no statistically significant differences were observed in physical performance metrics, such as FRT scores or COP displacement (Table 1). These findings indicate that the fall impact mitigation robot provided psychological reassurance and enhanced self-efficacy, even in the absence of active robotic assistance.

Implications for Fall Prevention

The observed enhancement in self-efficacy has direct implications for fall prevention strategies. Fear of falling contributes to activity restriction and social withdrawal, which in turn negatively impact balance control and motor behavior [18]. Among older adults, fear of falling is associated with reduced social participation and elevated risk of subsequent falls [19]. Robotic interventions that bolster self-efficacy may help interrupt this deleterious cycle. Existing evidence links higher self-efficacy with increased motivation for activities of daily living and outdoor mobility [16], suggesting that such

XSL•FO
RenderX

interventions could support long-term improvements in physical activity and social engagement. However, further longitudinal research is needed to substantiate these potential benefits.

Integration With the Falls Self-Efficacy Framework

To contextualize our findings within current theoretical models, we refer to the framework proposed by Soh et al [32], which delineates falls self-efficacy into 4 domains: balance confidence (pre-fall), balance recovery confidence (near-fall), safe-landing confidence (fall-landing), and post-fall recovery confidence (post-fall). While the fall impact mitigation robot was designed to enhance safe-landing confidence, the observed increase in self-efficacy suggests a broader psychological effect, potentially extending toward balance confidence. This cross-domain influence implies that perceived protection during potential falls may generalize to increased confidence during pre-fall activities, offering a novel direction for fall prevention strategies.

Dissociation Between Psychological and Physical Outcomes

A key observation in this study was the dissociation between psychological and physical outcomes, namely, significant improvements in self-efficacy without parallel changes in FRT or COP displacement. As suggested by Bandura [27], enhancements in self-efficacy typically precede measurable behavioral changes, which may emerge over longer timeframes. The use of healthy young adults likely introduced ceiling effects, limiting the detection of performance-related differences. Moreover, the single-session intervention design may have been insufficient to elicit observable physical adaptations. Longitudinal studies incorporating diverse populations are needed to clarify the temporal relationship between self-efficacy and physical performance.

Insights Into Motor Learning and Human-Robot Interaction

Our findings provide a new perspective on the application of the challenge point framework [33] to balance training. The framework posits that learning is most effective at the edge of a person's ability. Modulating the level of physical assistance is a common approach to guide learners to this optimal state. Our results, however, demonstrate that psychological safety is a powerful, alternative modulator. The increase in self-efficacy without a change in physical performance indicates that the robot enabled participants to perform closer to their true physical limits, not by making the task easier, but by removing the fear of falling. This suggests a potential model for effective training, where psychological barriers are addressed first to allow a learner to safely engage with their optimal challenge point.

Furthermore, the enhancement of self-efficacy in the mere presence of the robot contributes to the growing body of literature on human-robot interaction. Broadbent et al [7] found that robots can fulfill both physical and psychological roles. Our results support this dual-function hypothesis, demonstrating that robotic presence alone can provide psychological reassurance and influence behavior.

Limitations and Future Directions

Several limitations of this study warrant consideration. First, the small sample size limited statistical power and generalizability. Second, the focus on healthy young adults constrains the applicability of findings to clinical or older populations. Third, only short-term effects were assessed, leaving the long-term psychological and behavioral impacts unexamined. Fourth, the interaction between fear of falling and physical function may differ across age groups, underscoring the need for population-specific studies. Future work should incorporate validated scales aligned with the multifactorial model of falls self-efficacy proposed by Soh et al [32]. Finally, our analysis of motor behavior was restricted to coarse indicators such as COP displacement. Future investigations may benefit from high-resolution, markerless motion capture technologies, already implemented in our Living Lab environment [38], to enable fine-grained analysis of postural and movement strategies associated with robotic safety systems.

Conclusions

These findings demonstrate that a fall impact mitigation robot can enhance self-efficacy via psychological reassurance, even in the absence of active physical assistance. This indicates that psychological support enhances self-efficacy, but that physical assistance is also necessary, highlighting the need for fall prevention strategies that integrate both. The observed enhancement in self-efficacy may promote greater engagement in physical activity and, in turn, contribute to improved functional capacity, a hypothesis that warrants validation through longitudinal investigation.

Acknowledgments

We gratefully acknowledge all participants for their time and willingness to contribute to this study. We also extend our sincere appreciation to Hiroko Nakamura, Azusa Asai, and Junko Inagaki for their invaluable assistance with data collection and their continued support throughout the research process.

Abstract

Background: Freezing of gait (FOG) is a common and debilitating symptom of parkinsonism. Although visual cues have proven efficacy in alleviating FOG, most current visual cues are fixed in place, restricting their use to controlled environments such as clinics or homes. Mobile open-loop cueing devices have been developed to address this limitation; however, they typically require manual activation to deliver the visual cues, which can be particularly challenging for patients with attention or cognitive impairments, leading to equivocal results in improving gait performance.

Objective: The aim of the study is to assess the efficacy of an ankle bracelet laser, a new mobile visual cue designed for practical use, in improving gait performance in patients with parkinsonism and FOG.

Methods: A randomized controlled 2-period crossover trial was conducted from June 15, 2020, to October 1, 2020, at Ramathibodi Hospital. In total, 10 patients with parkinsonism and FOG were enrolled in 2 conditions: walking with laser-off first and walking with laser-on first. Gait speed, the timed up and go test, stride length, and the locomotor rehabilitation index were assessed twice in each trial with a 10-minute washout period.

Results: The results showed favorable improvement in all parameters. Gait speed and stride length improved by 0.07 m/s (95% CI 0.04-0.09 m/s; *P*<.001) and 0.17 m (95% CI 0.11-0.23 m; *P*<.001), respectively, with laser-on. The timed up and go test duration was reduced by 7.69 seconds (95% CI 2.82-12.55 seconds; *P*=.002). The locomotor rehabilitation index improved by 4.46% (95% CI 2.56%-6.36%; *P*<.001). When using the device, there were no adverse effects, such as dizziness or blurred vision.

Conclusions: The ankle bracelet laser cue produced immediate improvements in gait speed, stride length, and balance in patients with parkinsonism and FOG, suggesting that the device can acutely enhance gait performance. Further research is needed to determine whether these benefits are sustained and applicable to daily life activities.

parkinsonism; gait disorders; cues; self-help devices; lasers

Introduction

Background

Individuals with parkinsonism walk with a slower gait speed, shorter stride length, and higher cadence, resulting in an asymmetrical gait and increased energy expenditure compared to healthy people [1,2]. Freezing of gait (FOG) is one of the most common debilitating symptoms of parkinsonism and leads to multiple falls, related injuries, mobility limitations, functional dependence, restrictions in social activities, as well as psychological effects such as anxiety and depression.

XSL•FO
RenderX

Pharmacological and surgical interventions do not always provide satisfying outcomes [3-5]. External cueing has been used as a nonpharmacological intervention to alleviate FOG and improve gait parameters [6-8]. Visual cues may have more advantages in improving spatial parameters than auditory cues [9]. Fixed visual cues, such as taping a line on the floor to step over, have shown good immediate outcomes. However, this method is limited because it can only be used in environments where a fixed visual cueing line has been placed.

Currently, mobile visual cues mostly take the form of open-loop cueing (constant stimulus) [10] systems, such as laser light incorporated with a gait aid such as a walker or cane. Several studies have reported favorable outcomes regarding the immediate effect of reducing FOG and improving gait parameters; however, some results were equivocal [11], and some studies did not demonstrate improved outcomes [12]. In addition, gait speed as a predictor of ambulation ability [13] did not always improve with this method [14] and even slowed with the use of the device [15]. This may be because the open-loop system uses manual control to project the laser light and requires attention to project the cues at a constant distance in front of the foot. This dual-task process may be difficult for some patients to perform, especially for patients with some attention or cognitive impairment. Because cognitive impairment is commonly related to FOG in parkinsonism, this could be one of the factors leading to negative outcomes [16,17]. In addition, patients with parkinsonism and FOG showed greater sequence learning deficits than nonfreezers [18], and these deficits worsened further under dual-task conditions.

The long-term effect of visual cueing devices remains unclear. Some studies showed that these devices could not provide carry-on or retention effects [15], resulting in cue dependency for patients with FOG. This may be because of cognitive overload when using the device, which could distract attention away from walking [8,16], reducing the neural reserve for the motor relearning process [17].

Physical exercise could improve the motor function in parkinsonism. Nordic walking (NW) [2] is one of the exercise techniques using a specialized pole, working with arm swing to coordinate the rhythmic movement of the lower extremities and enhance the body's ability to move forward with an increased range of motion in the upper and lower extremities. NW training could improve gait performance and reduce energy expenditures in patients with Parkinson disease (PD). However, studies of the efficacy of NW were limited to patients with mild to moderate PD, Hoehn and Yahr (H&Y) stage 1-1.5 [2], or H&Y stages 1-3 [19], and only 1 person experienced FOG. Another trial [20] also showed improvement of gait speed, timed up and go (TUG), and the locomotor rehabilitation index (LRI) in patients with PD with an average of H&Y stage 1.5, but only 3 of 16 participants had FOG. Additional research has shown mixed results. One study reported that following an individualized and progressive NW training intervention, significant improvements were observed in walking function, daily activity level, and motor function, with participants sustaining independent NW exercise over 3 months and showing increased serum brain-derived neurotrophic factor levels after 5 months [21] Conversely, a systematic review and meta-analysis [22] found that NW did not lead to clinically significant changes in global motor impairment, functional mobility, balance, or physical fitness in patients with PD. However, it suggested that NW may improve walking ability and quality of life, though further research is needed to confirm these outcomes.

Recently, we developed ankle bracelet lasers as a new visual cueing device [23] aimed for ease and practical use to reduce cognitive overload. The ankle bracelet laser was designed as a closed-loop (intermittent stimulus) cueing system that provides a laser cue automatically following individual walking steps, so each patient can walk naturally. However, the device cost is too expensive for most people in our country due to the motion sensor and the software program that detects the gait motion to command the laser cue.

Therefore, we created another new version using ultrasonic sensors to detect the motion during the stance and swing phases. The command is simpler and fits with the low-income insurance cost. This device is currently a prototype. Electrical safety testing has been conducted by our engineering team to ensure safe operation; however, the device has not yet received formal medical device certification. The current version is planned to be sold at approximately US $185, reduced from US $490 in our earlier design.

The ankle bracelet laser operates intermittently, activating during the stance phase when the foot touches the floor, as detected by the integrated sensor. Once the foot contacts the floor, the laser line automatically projects in front of the patient's contralateral foot, providing a target to step to or over. This cycle of laser line projections repeats alternately and continuously throughout the walking period without the need for manual control or additional commands. The use of a mobile, laser-guided system might also promote neuroplasticity and motor relearning. This is achieved through a sensory-motor cycle in which an individual's own movement triggers intermittent sensory cues. This repeated feedback loop reinforces ongoing motor performance and may lead to long-term training effects [10,11]. The Velcro strap at the ankle position is easy to wear for a patient with a stiff back or tremors, which are commonly found in parkinsonism, because they do not need good hand function or to bend their back to put on the device. In addition, this device can be used with bare feet, which is suitable for Asian cultures, or with any kind of shoes.

Objective

The aim of the study is to study the efficacy of the ankle bracelet laser in improving walking performance in parkinsonism.

Methods

Study Design

We conducted a randomized crossover design study to lessen the between-patient variation. The study was conducted between June 15, 2020, and October 1, 2020. Patients with parkinsonism and FOG were enrolled in 2 conditions: walking with laser-off first and walking with laser-on first. The washout period was set at 10 minutes between the 2 conditions to avoid carryover effects.

XSL•FO
RenderX

Participants

Patients with parkinsonism were recruited from the Physical Medicine and Rehabilitation Outpatient Clinic of Ramathibodi Hospital. The inclusion criteria were as follows: (1) patients with parkinsonism diagnosed by a neurologist, (2) aged 18-90 years, (3) ability to walk at least 16 m with or without a gait aid, (4) no medication adjustment within the previous 3 months, and (5) H&Y stages 1-4. The exclusion criteria were as follows: (1) unable to see the laser line projection on the floor, (2) other neurological disorders, (3) unable to communicate well, (4) unable to use the device, and (5) denied or rejected from the study.

Ethical Considerations

This study was conducted in accordance with the principles of the Declaration of Helsinki. The protocol was reviewed and approved by the Human Research Ethics Committee, Faculty of Medicine, Ramathibodi Hospital, Mahidol University (approval COA. MURA2020/702). Written informed consent was obtained from all participants prior to enrollment, including consent for data collection and publication of deidentified results. To ensure confidentiality, all data were anonymized before analysis, and no personal identifiers were collected or stored in the dataset. Participants received compensation for their time as well as reimbursement for transportation costs related to study visits. This study was retrospectively registered with the Thai Clinical Trials Registry (TCTR20210511001) [24].

Intervention

The ankle bracelet laser was designed as a closed-loop cueing system that provides a laser cue automatically following an individual's walking steps. The ankle bracelet lasers were attached to both tibial areas. The device size was 4×5×2 cm, weighed 200 g, and is shown in Figure 1. The device uses an ultrasonic sensor to detect foot position from the ground and is integrated with a microcontroller to control the laser line projection correlated with an individual's walking steps. Once a patient performed a heel or foot strike, the laser line was projected in front of the contralateral foot to step on or over when entering the swing phase. The laser line disappeared once the foot was lifted off the ground. These cycles repeat alternately and automatically, following each individual's walking step.

Figure 1. Ankle bracelet laser attached to both tibias.

Experimental Design

The participants were informed of the objective and procedure of the study and provided signed informed consent before starting the trials. Each participant was randomized using a sealed envelope into 1 of 2 conditions: walking with the laser-off first or walking with the laser-on first. There was a 10-minute washout period between each condition.

Each participant walked a 10-m path twice at a comfortable speed, taking a break for a few minutes or until they felt ready to perform the TUG test twice. Gait speed and related spatiotemporal parameters were analyzed using a 6-m segment located in the middle of the total 10-m walking distance, excluding the initial and final 2 m. The start and end points of the 6-m segment were marked with striped floor lines to clearly identify the first and last strides.

A digital single-lens reflex camera, the Canon EOS 500D equipped with a Canon EF-S 18-55mm f/3.5-5.6 IS II kit lens, was used to record videos at 60 frames per second. The camera was positioned 4 m laterally from the walkway in a sagittal (lateral) view and was aligned to capture the entire 6-m measurement segment. This setup, which follows standard observational gait analysis techniques [25], enabled accurate visual identification of foot contact at both the start and end of

XSL•FO
RenderX

the measurement zone. The camera angle, zoom, and position, as well as the floor markers, were kept fixed and consistent across all participants to ensure uniformity and reduce variability in gait analysis, including for calculations of the LRI and optimum walking speed (OWS).

Gait Analysis and Parameter Calculation

To ensure objectivity and reliability, all video recordings were independently analyzed by 2 experienced physiatrists who were blinded to the study conditions and not involved in the recording process. Initial foot contact was defined as the moment the heel of the leading foot touched the ground on or beyond the starting line of the 6-m segment. The first completed step was then counted, followed by subsequent steps until the final foot contact on or beyond the end line of the segment. All identifications of foot contacts and steps were based on visual inspection of individual video frames, using heel strike as the reference point, in accordance with standard gait analysis protocols [25].

Gait parameters were calculated as follows: average gait speed (m/s) was calculated by dividing the 6-m distance by the time difference between the first foot contact and the last completed footstep, average cadence (steps per minute) was calculated as the number of completed steps divided by the total walking time (from the first foot contact to the last completed step), and average stride length (m) was calculated as average gait speed (m/s)×2×60/cadence (steps per minute) [25].

To ensure proper use of the device, all participants were given a standardized 5-minute familiarization period. During this time, they adjusted the distance of the laser line projection in front of their foot according to their personal preference, such as stride length or visual comfort. Participants were considered ready to begin the intervention once they reported feeling comfortable with the laser projection and could consistently step to the indicated distance. The same 5-minute period and readiness criteria were applied to all participants to ensure consistency across the intervention. Then, each patient would sit still for 10 minutes before starting the experiments to wash out the movement effect. Before beginning each trial, each participant took 10 alternating steps with both feet to warm up. One of the examiners followed the participants to prevent falls during all the tests.

Outcome Measures

Efficacy was primarily measured by the improvement in gait speed between the laser-off and laser-on conditions. Secondary measures included changes in stride length, TUG test results, and the LRI. The LRI is a method to determine the relationship between self-selected gait speed and the OWS, which is the speed that uses the lowest metabolic energy expenditure [26]. The OWS (m/s) was calculated from $\sqrt{(0.25\times9.81\times0.54}$ of height). The LRI (in percentages) was equal to 100× walking speed/OWS. We chose gait speed as the primary outcome because it is a reliable and sensitive tool to represent individual mobility and functional status and is easy to follow up clinically [13].

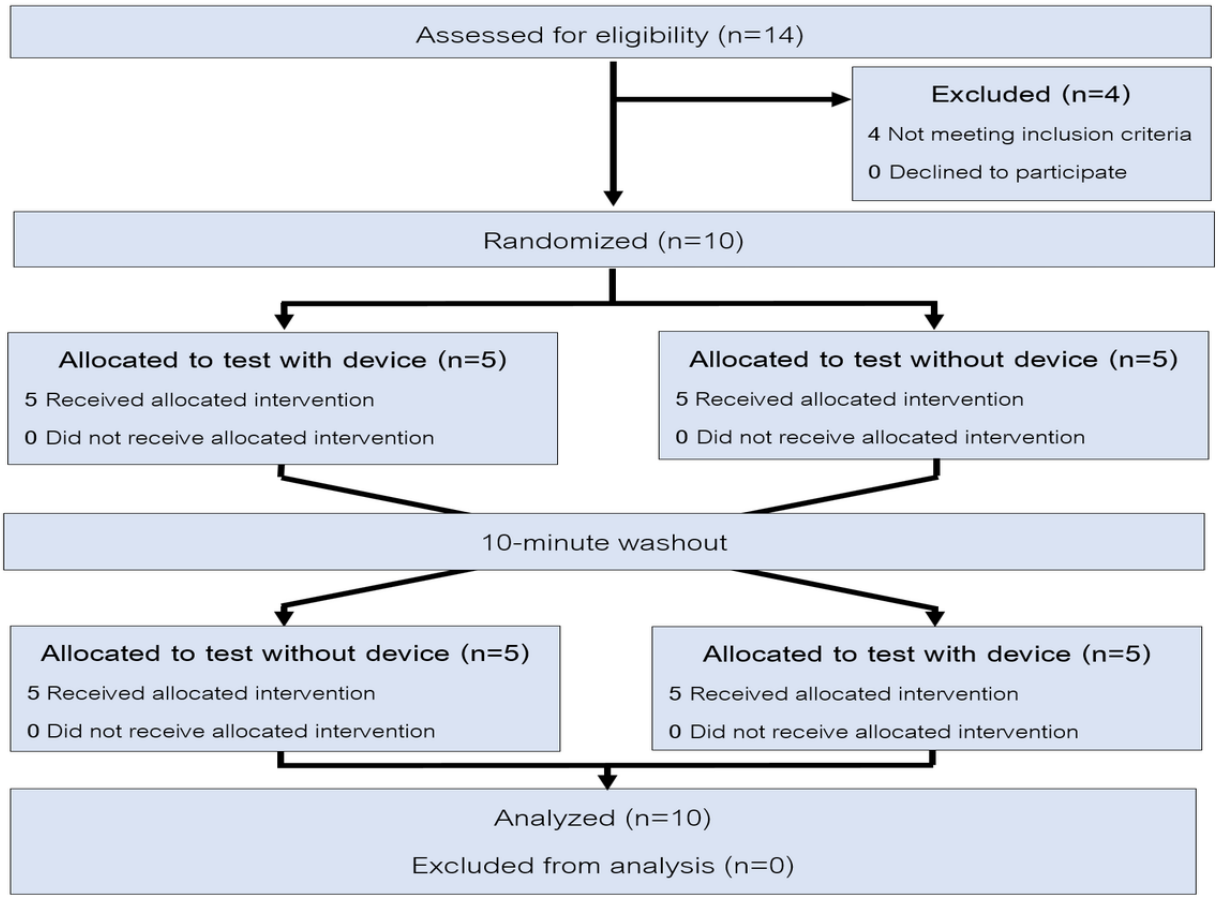
Statistical Analysis

Statistical analysis was performed using STATA (version 17; StataCorp LLC). A mixed linear regression model with adjusting the sequence effect was used to analyze the differences in gait speed, stride length, the TUG test, and the LRI between 2 conditions: walking with laser-off and walking with laser-on. Statistical significance was set at $P<.05$. Effect sizes were calculated using Hedges *g* to correct for small sample size bias, with values of 0.20, 0.50, 0.80, and 1.20 indicating small, moderate, large, and very large effects, respectively.

Sample Size and Analysis

The sample size was calculated based on the improvement of gait speed from comparable studies [27], with $\alpha=.05$ and $\beta=0.8$, equal to 10 patients. Therefore, we recruited and randomized 10 participants to see the feasibility and efficacy of this device.

This trial was conducted and reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) 2010 guidelines (Multimedia Appendix 1).



Results

Participant Flow

The flow diagram of this trial is shown in Figure 2.

XSL•FO
RenderX

Figure 2. Flow diagram for crossover trials.

Participant Characteristics

In total, 10 of the 14 screened patients with parkinsonism who met the inclusion criteria were included in the study. Among these participants, 6 (60%) were diagnosed with PD, while the remaining 4 (40%) had nonprimary parkinsonism—specifically, 2 (20%) with secondary parkinsonism and 2 (20%) with atypical parkinsonism.

In total, 6 (60%) participants were able to walk without the use of a gait aid. A total of 9 of the 10 participants had not previously used any cueing devices. In total, 1 (10%) participant with vascular parkinsonism had created her own visual cue by attaching a piece of wood to her cane; however, she was unable to concentrate and use the device effectively. The participants' clinical characteristics are summarized in Table 1.

[a]MSA-C: multiple system atrophy cerebellar type.

Gait Measures

Before comparing the results, the mixed linear regression model was used to test for a sequence effect—AB (laser-on followed by laser-off) versus BA (laser-off followed by laser-on)—for each parameter. Across all outcomes (gait speed, stride length, TUG, and LRI), no significant sequence effects were observed in patients with parkinsonism or within the PD and atypical parkinsonism subgroups, indicating that the order of laser-on and laser-off interventions had no impact on the results (Table S1 in Multimedia Appendix 2).

The results with the ankle bracelet laser showed statistically significant improvements in all parameters, with clinically meaningful differences in gait speed, stride length, and TUG test results. With the laser-on, gait speed and stride length improved by a mean of 0.07 m/s (95% CI 0.04-0.09 m/s; P<.001) and 0.17 m (95% CI 0.11-0.23 m; P<.001), respectively. The TUG test time decreased by a mean of 7.69 seconds (95% CI 2.82-12.55 seconds; P=.002). The LRI improved by a mean of 4.46% (95% CI 2.56%-6.36%; P<.001). The mean cadence with the laser-off was 98.55 (95% CI 81.32-115.78) steps per minute, whereas with the laser-on, it was 88.80 (95% CI 74.13-103.47) steps per minute. The overall results of the study are presented in Table 2.

XSL•FO

[b]LRI: locomotor rehabilitation index.

Subgroup and Effect Size Analysis

After separating the participants into Parkinson and atypical Parkinson groups, improvements in all parameters were also observed, as detailed in Tables 3 and 4. Furthermore, Table 5, which shows the coefficient and effect size (Hedges *g*) for all parameters, indicates a large effect size for stride length (Hedges *g*=0.81). The other parameters showed small to medium effects.

Table 3. The outcomes comparison between laser-off and laser-on in 6 patients with typical Parkinson disease.

Outcomes	Laser-off, mean (95% CI)	Laser-on, mean (95% CI)	Mean difference (95% CI)	*P* value
Gait speed (m/s)	0.62 (0.43-0.82)	0.68 (0.49-0.88)	0.06 (0.01-0.10)	.01

[a]TUG: timed up and go.

[b]LRI: locomotor rehabilitation index.

Subjective Aspects

There were no adverse effects while using the device, such as dizziness while looking at the laser line or blurred vision.

Discussion

Principal Findings

We developed the ankle bracelet laser as a new closed-loop visual cueing device to improve gait performance in patients with parkinsonism and FOG. Our study revealed the improvement of gait speed and stride length and a decrease in

XSL•FO
RenderX

TUG time in the laser-on condition compared to the laser-off condition. No participants experienced walking difficulties or adverse effects while using the device.

Efficacy and Clinical Significance

The improvement of gait speed by an average of 0.07 (95% CI 0.04-0.09) m/s reached the minimal clinically important difference for minimal change (0.06 m/s) in persons with PD [28]. Furthermore, in patients with H&Y stage 3, gait speed was improved by an average of 0.1 m/s, reaching this same minimal clinically important difference with a large effect size (Hedges g=0.75; Table S2 in Multimedia Appendix 2).

Gait speed is a key indicator for independent living and life in the community and is related to objective measures of balance such as the Berg balance, TUG, and severity in H&Y [29]. Slow gait speed and short stride length are related to falling and fragility in people with PD [1]. Therefore, increasing gait speed is related to greater mobility, increased independence, and improved balance for patients with parkinsonism. Stride length with laser-on showed a clinically significant average improvement of 0.17 m [1]. Increasing the stride length [1,30] also improves walking performance and reduces shuffling gait in FOG, which might help reduce the risk of falls. This study also showed the improvement in gait speed and stride length but decreased cadence after laser-on. These results are related to the walking characteristics of people with PD, in which gait speed is more related to stride length than cadence [1].

Our study found a clear change in these spatiotemporal parameters. In contrast, previous studies produced controversial or negative results [12,14,15,31]. Most previous mobile cueing devices need manual control and require attention and cognitive function to use the devices effectively. These may be impractical to some patients, especially those with cognitive impairments, which are commonly found in parkinsonism. Our ankle bracelet laser could project cues that automatically follow each walking step. Therefore, the demands on executive function and attention are lower [10,11] and may be the reason for the results in our study. In addition, the movable laser line following tibial movement might increase sensory input and improve motor performance, especially by increasing stride length [32]. This device also acts as a proof of concept for ease of use by leading to an immediate improvement in inexperienced participants; a total of 9 of 10 had no experience with visual cues, and only 1 person had a history of unsuccessful use of a self-made cue attached to a walking stick.

In the TUG test, the mean difference of 8.55 seconds reached the minimal detectable change in PD (3.5 seconds) [33,34]. The TUG test is one of the tools used to evaluate the risk of falls with good reliability and validity [35]; however, there was less evidence regarding visual cues and the TUG test [36]. Some studies have focused on sit-to-stand ability [37,38] and did not represent the dynamic balance in turning, which is usually impaired in patients with parkinsonism and FOG.

Our results suggest that the reduction in TUG time reflects improved balance and overall function by addressing the crucial phases—sit-to-stand, walking, turning, and stand-to-sit. Because FOG often occurs during initiation, turning, or directional changes, a shorter TUG time, particularly in the turning component, may have a direct and clinically meaningful impact on FOG reduction, since turning impairments are a frequent trigger for FOG and a common cause of falls [10,39]. These findings are consistent with improvements seen in previous studies using NW training [20] and align with recent research identifying TUG time and turning velocity as early indicators of gait abnormalities in parkinsonism [40]. Together, our results support the use of TUG time, alongside gait speed, as a primary outcome in future FOG intervention studies and highlight the potential for smartwatch-based monitoring to capture real-world events outside the clinic [41].

The higher LRI represents the improvement of the metabolic economy [26]. The LRI in our study was also improved, similar to the NW training, and reflected that walking speed in laser-on is closer to OWS and has a lower metabolic cost. However, the degree of improvement in our study was less than the 6-week NW training. In our study, 80% of the participants were in H&Y stages 3-4 with FOG episodes. On the other hand, the people in NW training were in an average H&Y stage of 1.5, with only a few individuals (3/16) experiencing FOG. Therefore, disease stage may influence the degree of improvement observed. The ankle laser may be more appropriate for individuals with advanced parkinsonism, whereas NW training appears most beneficial for improving walking economy in those with mild PD [2].

Due to the small sample size in each stage, further study should be done with a larger sample size in different H&Y staging to prove this hypothesis. Further study should also include coordinating the exercise training with the device, adjusting to each stage to see the different effects.

This study found significant improvements in patients with H&Y stages 2-4, with patients with H&Y stage 3 showing marked improvement in gait speed, TUG test, and the LRI with a large effect size, shown in Table S2 in Multimedia Appendix 2.

Our sample size of 10 was determined a priori based on power calculations from a previous study (α=.05 and β=0.8), which was sufficient to detect statistically significant improvements in all primary and secondary outcomes of this study. While we acknowledge that larger trials are ultimately necessary to achieve greater statistical power, this study was designed as an exploratory trial to evaluate the efficacy and feasibility of a novel device. Because of the small number of patients with each H&Y stage, future studies should examine these groups separately to identify any different outcomes, including long-term effects, between each stage. Based on sample size calculations from this study, a total of 39 participants would be required for a future crossover trial comparing the effects of this device in moderate to severe parkinsonism (H&Y stages 3-4).

Our device led to improvement in all 4 patients with atypical and secondary parkinsonism, which is very interesting because these patients have smaller responses to anti-parkinsonism drugs than patients with primary parkinsonism [42,43], and there is less evidence on the use of cueing devices in these groups. We

XSL•FO
RenderX

should conduct further studies with a larger sample size of patients with different types of parkinsonism.

Pathophysiology and Cognitive Considerations

Currently, the pathogenesis of FOG is still unclear. The basal ganglia are a group of nuclei that controlled the movement, such as walking from initiation to walk and maintain the walking process, by providing the internal cue via the connection pathway with the supplementary motor area [9]. It has been proposed that FOG is caused by frontal lobe dysfunction or a lack of connectivity between frontal lobe and the basal ganglia [27].

Visual cues could activate the dorsolateral premotor control system by bypassing the brain network via the cerebello-parieto-premotor loops instead of the usual route via the hypoactive basal ganglia-supplementary motor area. The single-photon emission computed tomography study [44] also showed more enhancement of cerebral blood flow in the right lateral premotor cortex, which is mainly influenced by cerebellar input [44], and middle frontal gyrus, as well as reduced left dorsolateral prefrontal cortex activity in patients with PD and FOG while walking on treadmills with visual cues compared to control.

The frontostriatal pathways [45] that connect the shifting between cognitive and motor control are less efficient in freezers than in nonfreezers [11]; thus, individuals with parkinsonism who experience FOG often have reduced cognitive reserve [16] and deficits in sequence learning [18]. These underlying cognitive issues lead to difficulties with dual-tasking and limit their ability for motor relearning.

Our ankle bracelet laser focuses on ease of use and natural walking to minimize cognitive overload, allowing patients to focus on gait training. This study did not compare the device directly with other visual cueing systems. Future trials should evaluate its efficacy relative to other systems to identify potential differences or add on data values.

The Closed-Loop Ankle Bracelet Laser System

Similar to the systems described in Ginis et al [11] and Muthukrishnan et al [46], our device is a closed-loop cueing system that uses wearable sensors to detect leg motion and automatically activates a laser cue via a microcontroller. Through this process, the external (visual) cue was projected based on real-time movement, which was considered the motor feedback. The combination of the feedback from the user's movement and the feedforward of the sensory stimuli may enhance the neuroplasticity and motor relearning. Therefore, incorporating the ankle bracelet laser into gait training or exercise programs should be investigated to determine its potential role in sensory feedback and motor relearning.

Study Limitations and Future Directions

This study found an immediate and significant improvement with less than 5 minutes of trials, which suggests the ease and practical use of the ankle bracelet laser system. However, we still lack a study of using the device in a home setting, which should be further done to prove this concept in daily living. Cognitive impairment is an important factor related not only to the efficacy of visual cues but also to the degree of FOG. Future studies should also investigate different degrees of cognitive impairment and evaluate correlations between gait improvement, the benefits of visual cues, and cognitive function.

The other limitation of using a visual cue is the need to look down at the laser line while walking, which the ankle bracelet laser projects continuously. This device could be programmed to project the laser cue on demand, providing feedback to the user only when FOG occurs. However, there is still controversy when comparing the efficacy of continuous cueing with on-demand cueing. Although previous studies have reported better results with continuous cueing, the patients also reported greater fatigue while using continuous cues than when using on-demand cues [38]. Because the long-term effects of the 2 methods remain unknown, future studies should compare results using the ankle bracelet laser with on-demand cues, such as determining the optimal time to project the laser line and comparing the results with continuous laser projection [47].

Conclusions

The ankle bracelet laser cue produced immediate improvements in gait speed, stride length, and balance in patients with parkinsonism and FOG, suggesting that the device can acutely enhance gait performance. Further research is needed to determine whether these benefits are sustained and applicable to daily life activities.

Acknowledgments

The authors would like to thank Dr Chareon Tangtrongbenchas for designing and building the first prototypes of the ankle bracelet laser.

Abstract

Background: People with moderate to severe intellectual disability can have difficulties accessing leisure stimuli and engaging in basic cognitive and physical activity independently. These difficulties may be even more marked in individuals with a combination of intellectual disability and sensory or sensory-motor impairments.

Objective: This study assessed a new program relying on touch screen technology, which was set up to support access to leisure stimuli and the performance of a simple form of cognitive activity and basic physical exercise for adults with intellectual or intellectual and hearing disabilities, lack of functional speech, and poor motor dexterity.

Methods: The program alternated access to preferred stimuli (ie, songs, comic sketches, or cartoons) with cognitive activity (ie, matching-to-sample tasks) and physical exercise (ie, body movements). The touch screen technology was modified to ensure that people with poor motor dexterity would be effective in their responding regardless of the accuracy of their responses. The program was implemented with 7 participants. Its impact was assessed through the use of single-case research methodology.

Results: During the baseline (when standard technology was used), the mean percentage of songs, comic sketches, or cartoons accessed; match-to-sample responses provided; and body movements performed correctly and independent of research assistants' help was 0% for all participants with a single exception. During the intervention (when the new program with modified touch screen technology was used), the participants' mean percentage of songs, comic sketches, or cartoons accessed correctly and independent of research assistants' help per session was virtually 100%. Their mean percentage for correct match-to-sample responses provided and correct body movements performed independent of research assistants' help was within the 90% to 100% range.

Conclusions: The findings suggest that the program may constitute a useful tool for helping people with intellectual and multiple disabilities access leisure stimuli and engage in cognitive and physical activity.

Introduction

Background

People with moderate to severe intellectual disability can have difficulties accessing leisure stimuli and engaging in basic cognitive and physical activity independently [1-7]. For example, their reduced manual dexterity and unfamiliarity with technological gadgets may limit their opportunities to operate standard devices available to select and activate preferred leisure stimuli, such as songs, comic sketches, and cartoons [8-12]. Their tendency to remain fairly isolated and their low motivation and self-determination may interfere with their possibility to (1) engage in cognitive activities such as listening to and answering questions related to their interest areas or performing stimulus discrimination and stimulus matching tasks [11-16] and (2) perform simple, beneficial body movements involving the arms, legs, or head and neck [17-20]. These difficulties may be even more marked in individuals with a combination of intellectual disability and sensory or sensory-motor impairments (eg, hearing loss and reduced ambulatory skills) [11,21-25].

The use of staff supervision to help people with intellectual and multiple disabilities access leisure options and practice cognitive activities and physical exercise may present 2 drawbacks. First, such supervision would be rather costly in terms of staff time and not always feasible in contexts in which staff availability is limited [3,7]. Second, the use of staff supervision would be unlikely to promote participants' independence [3,7,10,11]. A possible alternative to staff supervision may be the use of technology-aided programs [26-30]. A variety of technology-aided programs have been developed over the years to enable people to independently perform multistep tasks [3,6,7,31-33], engage in physical exercise [34-38], and produce verbal (easy-to-understand) requests for preferred events [39-45].

Programs have also been developed that have the objective of helping people engage in combinations of activities. The activities combined could include leisure and communication via telephone calls or messages [46]; leisure, communication, and occupational (functional) tasks [47]; or leisure, communication, and cognitive exercises via stories and related questions or series of questions [11,48]. In the last one of those studies [48], a program was assessed with 6 adults who were diagnosed with moderate intellectual disability, motor impairments, and lack of (functional) speech. The program relied on a tablet fitted with internet connection, a SIM card, WhatsApp Messenger, and the MacroDroid app and interfaced with pairs of response sensors. Every session started with the tablet presenting music and a telephone image and asking the participants whether they wanted to listen to music or call somebody. If the participants activated the sensor in front of the music image, the tablet presented the photos of 2 singers. Activating the sensor in front of one of the singers led the tablet to play a song by that singer for 1.5 minutes. The end of the song led the process to be repeated once or twice more. If the participants chose the telephone image, the tablet presented the photos of 2 preferred persons. Choosing one of them led to the start of a video call with that person.

Following the choice period, the tablet presented a series of 5 questions suitable to the participants' skills. For example, the tablet could present the image of a girl and the image of another person and ask, "Which one is a girl?" If the participants answered correctly by activating the sensor in front of the right image, the tablet provided verbal approval followed by the next question. If participants were incorrect, the tablet remained idle. Once all the questions had been answered, a new choice period started. A session included 4 choice periods and 3 series of questions. The results showed that, during the baseline, the participants were unable to use a standard tablet. During the intervention, they were successful in accessing songs, making video calls, and answering questions.

In light of (1) the encouraging results obtained with the program described previously and other programs targeting combinations of activities and (2) the positive implications of those results for participants and rehabilitation contexts, new research efforts in this area would appear quite relevant. Those efforts should be aimed at designing and evaluating new technology-aided programs for enabling people with intellectual and multiple disabilities to engage in different forms of activities (ie, activities promoting their enjoyment and vitalizing their intellectual and physical functions) independent of staff supervision.

Objectives

This study assessed a new program relying on touch screen technology that was designed to support access to leisure stimuli and the performance of a simple form of cognitive activity and basic physical exercise for adults with intellectual or intellectual and hearing disabilities, lack of functional speech, and poor motor dexterity. The program alternated access to preferred stimuli (ie, songs, comic sketches, or cartoons) with cognitive activity (ie, matching-to-sample tasks) and physical exercise (ie, series of body movements). The alternation was intended to motivate the participants to successfully manage the latter (presumably less preferred) forms of engagement [49,50]. The touch screen technology was modified to ensure that people with poor motor dexterity would be successful in their responding regardless of the accuracy of their responses. The program was implemented with 7 participants. Its impact was assessed through the use of single-case research methodology.

Methods

Participants

Table 1 lists the 7 participants involved in the study using pseudonyms and reports their chronological ages and their Vineland age equivalents obtained using the second edition of the Vineland Adaptive Behavior Scales [51,52]. The participants had a diagnosis of congenital or perinatal encephalopathy with intellectual disability. Three of them (Adriel, Lilah, and Wyatt) also presented with hearing loss, and one of these 3 (Wyatt) was nonambulatory. All participants had functional vision with or without glasses correction but lacked functional speech (ie, could only emit a few sounds or words) and had poor motor dexterity. Their chronological ages ranged from 24 to 64 years. Their Vineland age equivalents varied between 2 years and 3 months and 5 years and 9 months for daily living skills (the *personal* subdomain) and between 3 years and 1 month and 4

XSL•FO
RenderX

years and 8 months for receptive communication. No IQ scores were available for them. Psychological records of the rehabilitation and care centers that they attended reported their level of intellectual disability to be in the moderate or moderate to severe range.

The participants were recruited through direct contact with the centers that they attended. Their selection was based on a number of conditions, which were verified through preliminary observations or staff interviews. First, they did not access preferred stimuli and did not engage in forms of cognitive activity and physical exercise without staff supervision. Second, they were considered unfit to use standard technology because they had difficulties following the multiple operational steps required for that and because they also had difficulties in activating a touch screen monitor given their poor motor dexterity and erratic response patterns (eg, heavy pointing, tapping, and touching with the fingernails). Third, they seemed to enjoy music, comic sketches, or cartoons and, thus, were thought to be strongly motivated to access these stimuli. Fourth, they could engage in basic forms of cognitive activity, such as carrying out simple match-to-sample tasks with various types of stimuli, when staff arranged those tasks for them. Fifth, they were able to imitate body movements considered to be suitable forms of physical exercise (eg, raising their arms and bringing them down to their knees) both when shown by a person in front of them and when presented on a computer screen. Sixth, staff considered the program and the technology used for it (shown to them in advance) functional for the participants and supported the study.

Table 1. Participants' chronological ages and Vineland age equivalents for daily living skills (personal subdomain; DLSP) and receptive communication (RC).

Participant pseudonym	Chronological age (y)	Vineland age equivalent[a]	
		DLSP	RC
Paisley	61	2 years 3 months	4 years 3 months
Adriel	51	4 years 7 months	3 years 1 month
Lilah	63	4 years 11 months	3 years 8 months
Jade	64	5 years 9 months	4 years 3 months
Lainey	48	4 years 4 months	4 years 3 months
Jayden	24	4 years 2 months	3 years 4 months
Wyatt	49	2 years 3 months	4 years 8 months

[a]Age equivalents are based on the Italian standardization of the Vineland Adaptive Behavior Scales [51].

Ethical Considerations

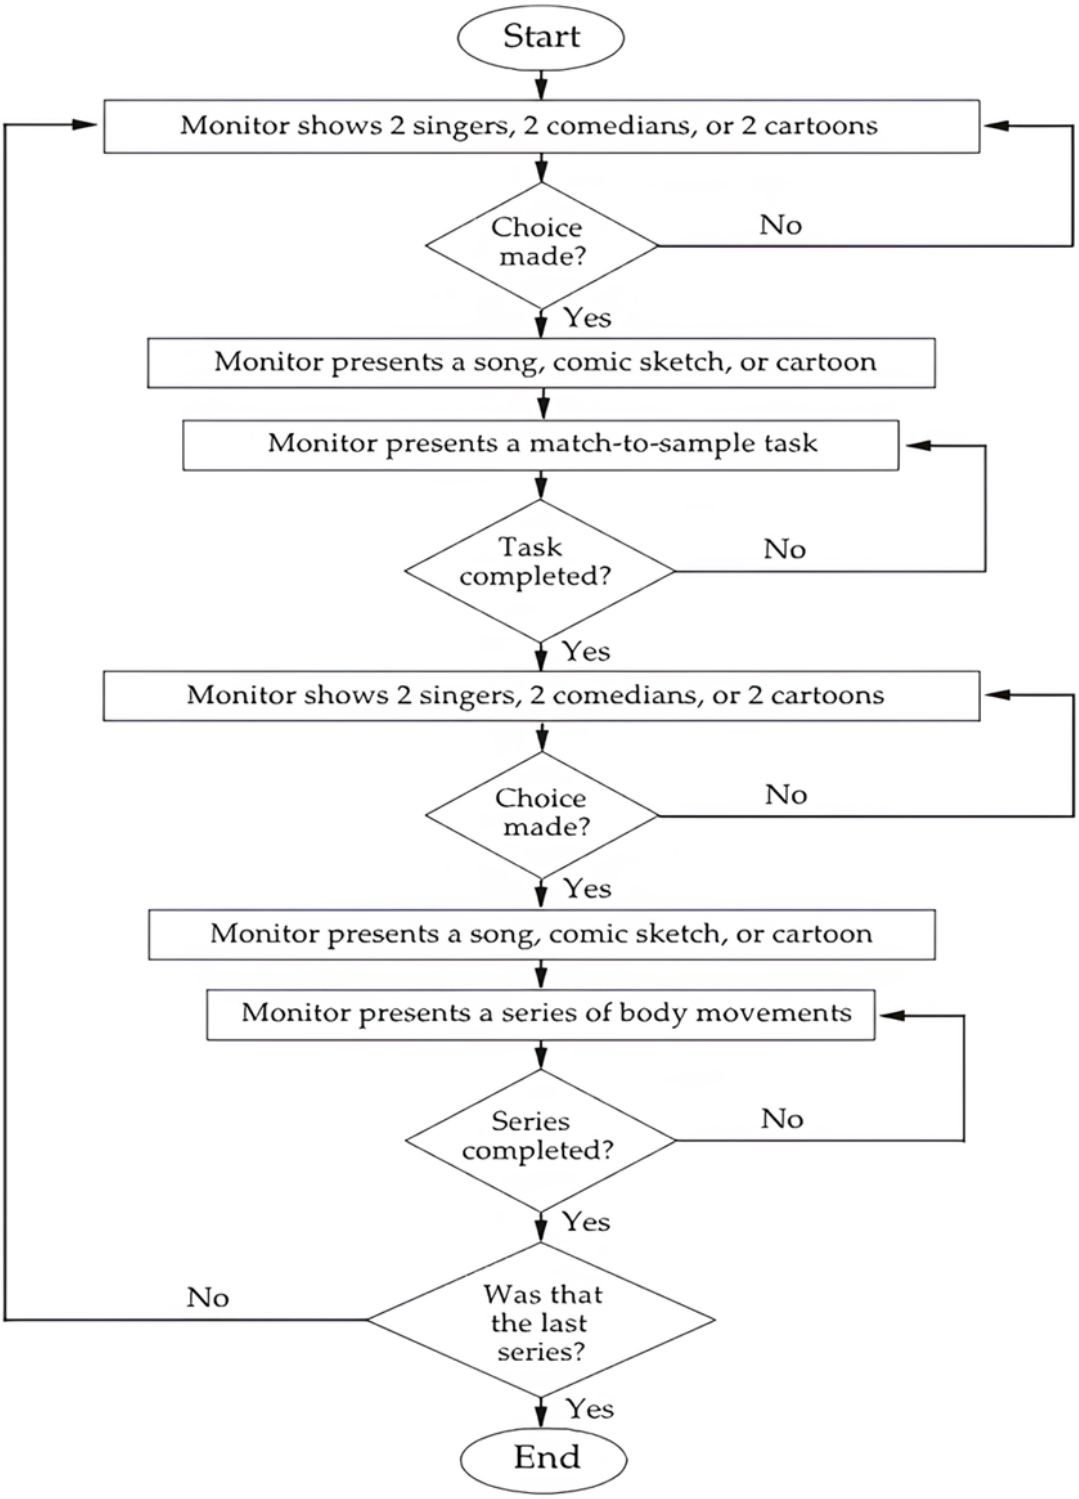
Regular staff members and research assistants showed the participants the technology (ie, touch screen monitor and the options it contained) and asked them whether they would like to use it. Their positive vocal or behavioral (head nodding) response to the question was taken as consent to the study. However, to make their recruitment highly transparent, their legal representatives were involved in the consent process. Specifically, the legal representatives were asked to read and sign a written consent form on the participants' behalf authorizing their inclusion in the study. No compensation was available for the participants whose privacy was protected through de-identification. This study was approved by the ethics committee of the Lega del Filo D'Oro, Osimo, Italy (P031020252). All procedures performed were in accordance with the national and international ethical standards and with the 1964 Declaration of Helsinki and its later amendments or comparable ethical standards.

Setting, Sessions, and Research Assistants

Quiet rooms at the rehabilitation and care centers that the participants attended constituted the setting for this study. This study included baseline and intervention sessions. The baseline sessions were carried out without the use of the technology system developed for this study. The intervention sessions involved the use of the technology system. The sessions were implemented by research assistants, typically once a day, 4 to 6 days a week. Four research assistants were employed to carry out the sessions and collect the data. They held university psychology degrees, had experience applying technology-aided intervention programs with people with disabilities, and were familiar with different data recording methods.

Technology System: Components

The technology system included a touch screen monitor of 27-48 cm, which was linked to a PC. The computer had internet connection, which allowed for the use of a specific web application. This application controlled the presentation of the leisure options (ie, songs, comic sketches, or cartoons), the cognitive activity (ie, match-to-sample tasks), and the physical exercise (ie, body movements) on the touch screen monitor (see the following section). Moreover, the web application enabled the touch screen monitor to (1) recognize different response configurations (eg, standard input responses, heavy touch, prolonged touch, tap or taps, and scrolling movements) and, thus, (2) react to those responses in a manner consistent with the content of the program [53]. The web application is freely available [54].



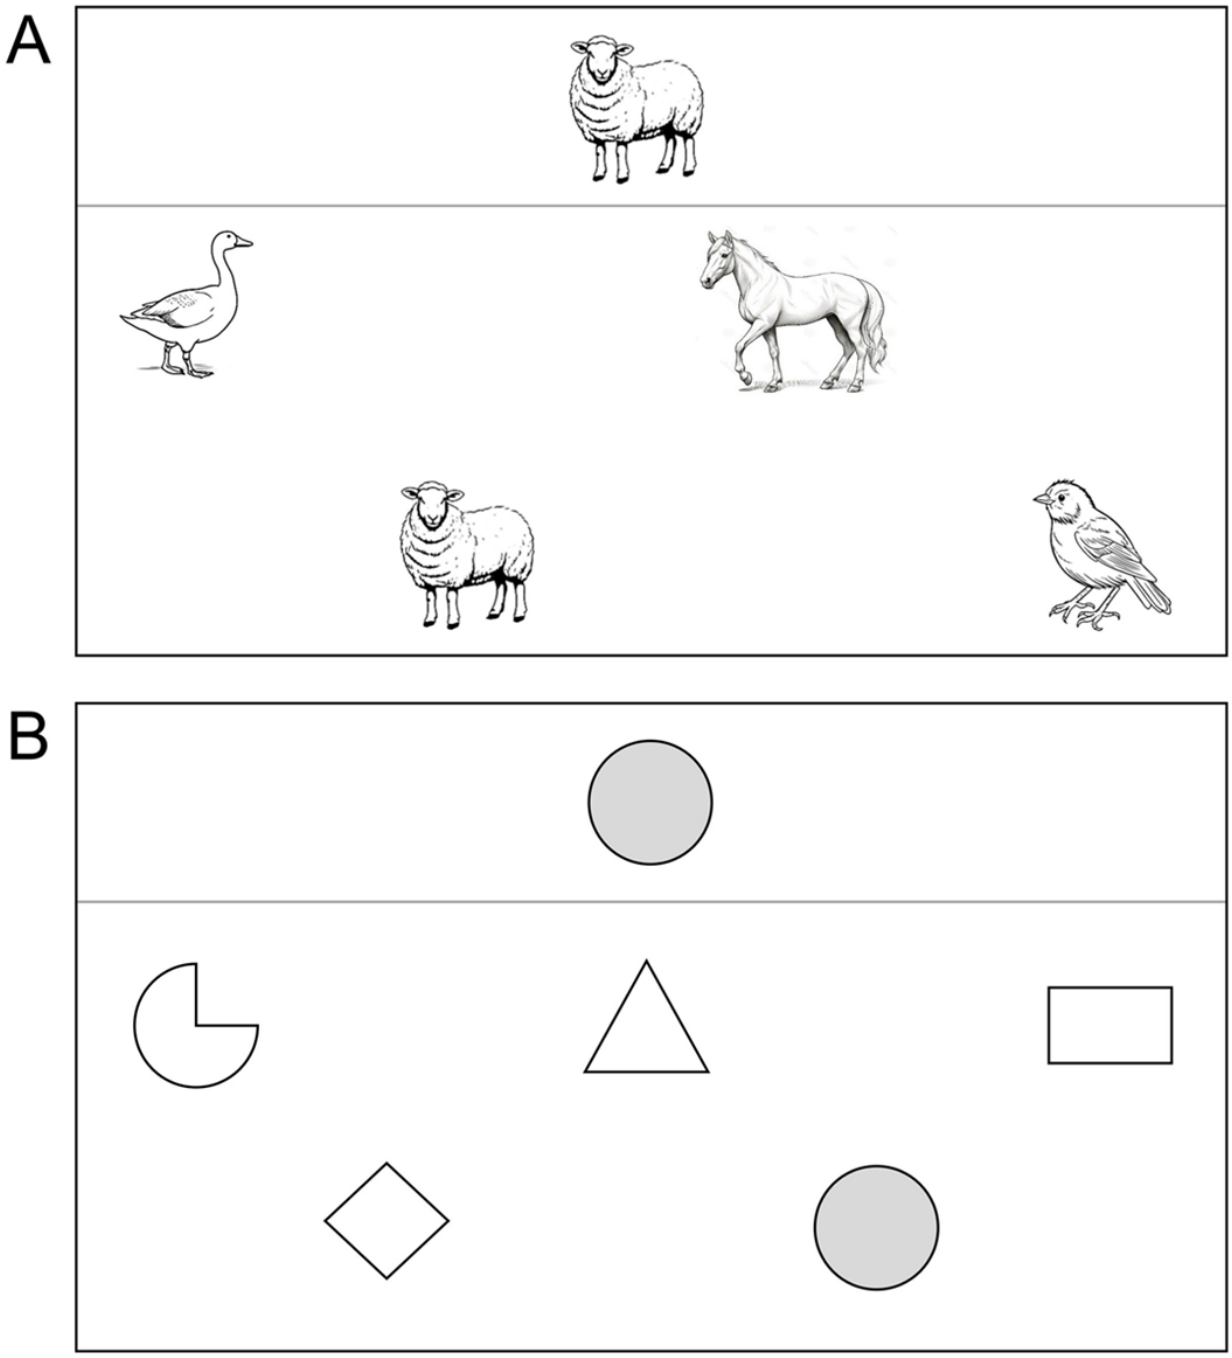
Technology System: Functioning

At the beginning of a session, the touch screen monitor showed 2 leisure options (ie, the images of 2 singers, 2 comedians, or 2 cartoons depending on the participants' preferences and

XSL•FO
RenderX

hearing condition). The participants could choose 1 of the 2 alternatives by touching it. This caused the touch screen monitor to show a 2-minute video of a song, comic sketch, or cartoon consistent with the choice made by the participants. The only exception to this was Lilah, for whom comic sketches or cartoons lasted 1 minute. Observations indicated that her positive attention to those stimuli tended to decrease after 1 minute. Figure 1 provides a summary of the technology system's functioning.

Figure 1. Flowchart summarizing the technology system's functioning.



At the end of the song, sketch, or cartoon, the touch screen monitor presented a match-to-sample task consisting of 5 or 8 different pages (images), each of which represented a sample stimulus (eg, a colored animal or geometric shape) and 4 other colored stimuli, including the correct match (Figure 2A-B). The pages were presented individually so that the participants could see only 1 page at a time. In each of the pages, the participants were to touch the stimulus that correctly matched the sample.

XSL•FO
RenderX

Touching the correct match caused the appearance of a picture showing approval for the response (eg, a woman with thumbs up). This was followed by the appearance of the next page of the task with the next set of stimuli, in which the participants were to identify and touch the correct match. Touching the incorrect match led to the permanence of the same page on the monitor. Progress to the next page occurred only after the participants touched the correct match or a preset interval of 20 to 30 seconds elapsed.

Figure 2. Schematic representation of 2 possible pages (A and B) of a match-to-sample task. Each page shows the sample (top) and the match stimuli available (bottom), which are shown in gray and white in this figure.

Once the match-to-sample task was completed (ie, with answers provided for each of the 5 or 8 pages), the touch screen monitor showed 2 new leisure options (ie, images of 2 singers, 2 comedians, or 2 cartoons), and all conditions were as those described previously. At the end of the song, sketch, or cartoon, the touch screen monitor presented a video in which the research assistants modeled a series of body movements that the participants were to reproduce. For example, the series could consist of the research assistants standing and sitting 10 or more times or raising their arms and bringing them down to their knees for 10 or more times. The research assistants movement modeling was combined with verbal instructions and encouragements to reproduce those movements. Background color changes (eg, red for arms up and white or green for arms

XSL•FO
RenderX

down) could be used for the participants with hearing loss to foster their attention and movement discrimination.

Once the series of body movements had been completed, a new 4-stage sequence (ie, singers, comedians, or cartoons; match-to-sample task; singers, comedians, or cartoons; and body movements) started. The new sequence included different singers, comedians, or cartoons; a different match-to-sample task; and new body movements or new combinations of them. A session included 3 sequences so that the participants had to (1) make 6 choices between singers, comedians, or cartoons (thus accessing 6 songs, 6 comic sketches, or 6 cartoons); (2) complete 3 match-to-sample tasks; and (3) perform 3 series of body movements.

Data Recording

The measures recorded were (1) the songs, comic sketches, or cartoons accessed correctly and independent of research assistants' help; (2) the match-to-sample responses carried out correctly (ie, those targeting the correct match in the first attempt) and independent of research assistants' help; (3) the body movements reproduced correctly and independent of research assistants' help; (4) the instances of research assistants' help; and (5) the length of the sessions. The research assistants recorded all 5 measures during the baseline and intervention sessions.

Interrater agreement was checked in 22.4% (15/67; Adriel) to 26.0% (20/77; Jade) of single-participant sessions through the use of a reliability observer. Agreement on songs, comic sketches, or cartoons accessed; correct match-to-sample responses; and instances of research assistants' help were recorded when the research assistants and the reliability observer had the same scores. Agreement on body movements and session length was recorded when the research assistants and reliability observer had scores that differed by no more than 3 units and 2 minutes, respectively. The percentage of agreement (computed for each participant by dividing the number of sessions in which agreement was reported for all measures by the total number of sessions involving the reliability observer and multiplying this by 100%) was 90% or above for all participants.

Experimental Conditions and Data Analysis

Overview

This study was implemented according to a nonconcurrent multiple baseline design across participants [55,56]. Initially, there was a baseline phase in which the participants were provided with a touch screen monitor that worked in a standard manner. This phase included different numbers of sessions for the participants as required by the design. Two intervention phases were then implemented, during which the participants were provided with the technology system described previously.

To guarantee that the research assistants would implement the sessions accurately (ie, to foster procedural fidelity [57]), familiarization and feedback strategies were used. Familiarization consisted of 2 preliminary meetings in which the research assistants were to practice the baseline and intervention conditions under supervision. Feedback consisted of comments provided to the research assistants after the sessions to inform them as to whether their performance was accurate or needed corrections. Feedback was delivered by a study coordinator who had access to videos of all the sessions.

The baseline and intervention data were reported in graphic format. The percentage of nonoverlapping data (PND), a data analysis method commonly used in single-case experimental research [58], served to determine the impact (effect size) of the intervention on (1) songs, comic sketches, or cartoons accessed; (2) correct match-to-sample responses provided; and (3) body movements reproduced. Specifically, the PND method served to calculate the percentage of intervention sessions with a score higher than the highest baseline score for each measure.

Baseline

The baseline phase included 5 to 11 sessions, during which the technology system described previously was not available and the touch screen monitor worked in a standard manner. Initially, the monitor showed the Google icon. Touching (activating) this icon led the monitor to show a web page with 3 separate folders on the favorites bar: one concerning preferred leisure events (ie, songs, comic sketches, or cartoons), a second one concerning match-to-sample tasks, and a third one concerning body movements. Touching (opening) the first folder led to websites containing videos of preferred songs, comic sketches, or cartoons. Touching (opening) the second folder led to websites containing specific match-to-sample tasks. Touching (opening) the third folder led to websites containing videos of different body movements. Initially, the research assistants modeled the response to access a preferred song, comic sketch, or cartoon (depending on the participants), that is, touching the Google icon; touching (opening) the leisure folder; and touching (opening) the website containing a video with a preferred song, comic sketch, or cartoon. The video was stopped shortly thereafter, and the participants were asked to produce the response on their own. If the participants did not manage to do so for 20 to 30 seconds (ie, an interval considered sufficient for them to produce a response), the research assistants repeated the sequence to allow them to access a song, comic sketch, or cartoon for 2 minutes (1 minute in the case of Lilah).

At the end of the song, sketch, or cartoon, the research assistants modeled the response to access a match-to-sample task (ie, cognitive activity). The response consisted of (1) touching the Google icon, which led to the appearance of the leisure, match-to-sample, and body movement folders; (2) touching (opening) the match-to-sample folder, which led to websites containing match-to-sample tasks; and (3) touching (opening) one of these websites showing a specific match-to-sample task. The task remained visible only briefly. The participants were then asked to proceed on their own. If they did not manage to do so for 20 to 30 seconds, the research assistants repeated the sequence to allow them to access a task and helped them (if needed) to provide match-to-sample responses.

After the match-to-sample responses, the research assistants modeled the response for accessing a song, comic sketch, or cartoon. All steps and conditions were identical to those described previously. Once the song, comic sketch, or cartoon had ended, the research assistants modeled the response for accessing the body movement (ie, physical activity) option. The

XSL•FO
RenderX

sequence involved (1) touching the Google icon; (2) touching (opening) the body movement folder; and (3) touching (opening) one of the websites, in which a video with 10 repetitions of specific body movements (eg, moving arms up and down) was presented. The video was soon halted, and the participants were asked to proceed on their own. Conditions for research assistants' help in case of participant failure were as described previously.

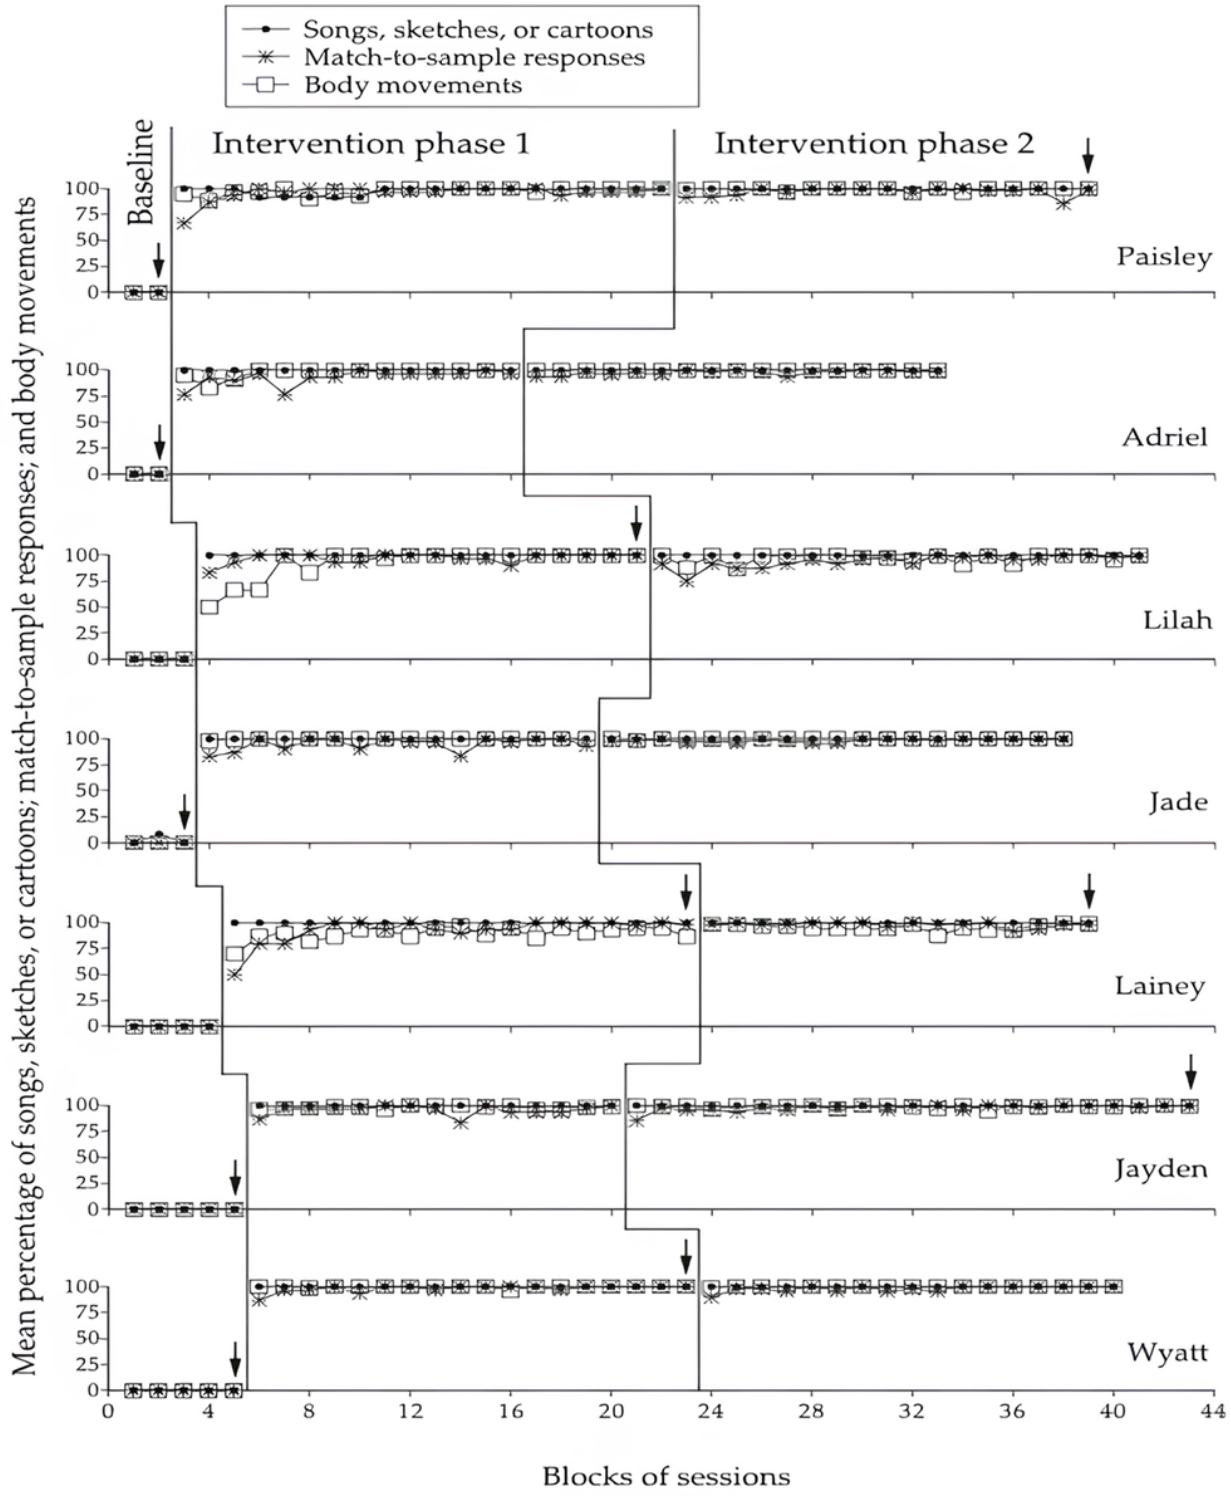
The session was interrupted (to reduce frustration) once the participants had received 4 instances of research assistants' help for opening the websites and accessing songs, comic sketches, or cartoons; match-to-sample tasks; and body movements. The scoring for songs, sketches, or cartoons accessed; match-to-sample responses provided; and body movements performed was negative if the participants required research assistants' help to open the websites leading to them. Negative scoring was also used in relation to the songs, sketches, or cartoons; match-to-sample responses; and body movements missed due to session interruption.

Intervention Phase 1

During the first intervention phase (including 28-40 sessions), the participants were provided with the technology system that worked as described in the Technology System: Functioning section and Figure 1. At the start of a session, the touch screen monitor showed the pictures of 2 leisure stimuli, and the participants were to touch one of them to start a song, comic sketch, or cartoon depending on the pictures displayed. A song, comic sketch, or cartoon lasted 2 minutes (1 minute in the case of Lilah). Thereafter, the touch screen monitor showed (one at a time) the 5 pages of the first match-to-sample task available. For each page, the participants were to touch the stimulus that matched the sample. Once the participants had completed the match-to-sample task, the touch screen monitor presented 2 new leisure stimuli. The participants were to choose one of them as mentioned previously. At the end of the leisure event (ie, song, comic sketch, or cartoon), the touch screen monitor presented a video with the research assistants showing a series of 10 to 18 body movements. The participants were to imitate (reproduce) those movements. Completion of the body movement series led to the beginning of a new 4-stage sequence (ie, leisure stimuli, match-to-sample task, leisure stimuli, and body movements). A session included 3 of those sequences, which differed in terms of the leisure events, match-to-sample tasks, and body movements presented.

The phase was introduced by 4 to 6 practice sessions in which the participants were provided with research assistants' help to manage their access to leisure events, responses to the match-to-sample tasks, and imitation (reproduction) of body movements. During the regular sessions that followed, research assistants' help would only be available if the participants failed to access a leisure event for 20 to 30 seconds.

Intervention Phase 2



During the second intervention phase (including 33-47 sessions), all conditions were as in intervention phase 1 except that (1) the match-to-sample tasks included 8 (rather than 5) pages and (2) the series of body movements included 14 to 30 (rather than 10-18) movements.

Results

Figure 3 summarizes the baseline and intervention data for the 7 participants. The dots represent the mean percentage of songs, comic sketches, or cartoons accessed independent of research assistants' help per session over blocks of 2 sessions. The asterisks and the empty squares represent the mean percentage of correct match-to-sample responses provided and correct body movements performed per session over the same blocks of sessions, respectively. The arrows mark blocks of 3 sessions that took place at the end of the baseline and intervention phases. The practice (familiarization) sessions preceding the start of intervention phase 1 do not appear in the figure.

XSL•FO
RenderX

Figure 3. Dots, asterisks, and empty squares represent the mean percentage of songs, comic sketches, or cartoons accessed; match-to-sample responses provided; and body movements performed over blocks of 2 sessions, respectively. Blocks of 3 sessions are marked with an arrow.

During the baseline phase, the mean percentage of songs, comic sketches, or cartoons accessed; match-to-sample responses provided; and body movements performed correctly and independent of research assistants' help was 0% for all participants except Jade. She managed to access 1 song throughout the 7 baseline sessions available to her. Participants were largely characterized by inactivity and failed to produce effective touch screen responses on those occasions in which they took the initiative to follow the research assistants' modeling on how to activate the Google icon and open the 3 basic folders and the related websites. The aforementioned inactivity and difficulties (causing dependence on research assistants' help) led to the interruption of all baseline sessions. The length of those sessions was always below 15 minutes.

During intervention phase 1, the mean percentage for songs, comic sketches, or cartoons accessed correctly and independent of research assistants' help per session was 100% for all participants except Paisley, whose mean percentage was 97.9%

XSL•FO
RenderX

(SD 3.7%). The mean percentage of correct match-to-sample responses provided and correct body movements performed independent of the research assistants' help ranged between 92.7% (SD 12.1%; Lainey) and 98.2% (SD 3.5%; Wyatt) and between 90.1% (SD 6.5%; Lainey) and 99.9% (SD 0.4%; Jade), respectively. The mean session length varied between slightly over 15 minutes (Lilah) and 23 minutes (Lainey).

During intervention phase 2, the mean percentage for songs, comic sketches, or cartoons accessed correctly and independent of the research assistants' help per session was 100% for all participants. The mean percentage for correct match-to-sample responses provided and correct body movements performed independent of the research assistants' help ranged between 94.2% (SD 6.0%; Lilah) and 98.6% (SD 1.7%; Jade) and between 95.6% (SD 3.1%; Lainey) and 100% (SD 0%; Adriel), respectively. The mean session length varied between approximately 16.5 minutes (Lilah) and 27.5 minutes (Lainey).

The PND method showed an index of 1 on each of the aforementioned 3 measures for all participants. Indeed, the data values of the intervention sessions were always higher than the baseline data values on each of the measures. This evidence confirms the strong impact of the intervention with the technology system across participants and measures.

Discussion

Principal Findings

The results suggest that participants with intellectual or intellectual and sensory-motor disabilities could use the technology system introduced in this study to access songs, comic sketches, or cartoons; provide correct match-to-sample responses; and perform correct body movements independent of research assistants' help. These results confirm previous findings showing that technology-aided programs can be set up to help people with intellectual and multiple disabilities engage in functional activities independent of staff [3,7,11,41]. These results also extend previous evidence. In fact, this study (1) included a form of cognitive (match-to-sample) activity and basic physical exercise adjustable to people with intellectual and multiple disabilities and (2) introduced a new, modified touch screen system. In light of the aforementioned results, several considerations may be in order.

First, enabling people with intellectual and multiple disabilities to remain constructively busy for practically relevant time periods independent of staff supervision may be considered a meaningful achievement for the participants and their rehabilitation context. Indeed, participants can develop and strengthen self-determination and initiative, reach a higher (more satisfactory) level of functioning, and experience a better quality of life in line with their rights [59-64]. The rehabilitation context may be able to include extra opportunities for constructive engagement in the participants' daily schedules without significant investment of staff time [7,65,66].

Second, access to preferred leisure stimuli may be considered important for the participants' enjoyment and possibly their level of satisfaction with the sessions [50,67]. Engaging in cognitive activity and physical exercise may be important for the participants' intellectual and physical stimulation and contribute to their rehabilitation progress and well-being [11,14,68,69]. Combining (interspersing) access to preferred leisure stimuli with cognitive and physical activities, as was done in this study, might help (motivate) the participants to constructively engage in the latter types of activities as well irrespective of the fact that these activities may not necessarily be preferred by them [49,50]. While no formal data are available to confirm the accuracy of the aforementioned statement, the participants' positive and stable performance throughout the intervention sessions may be taken to suggest that they remained motivated to engage in each of the activities available, thus making their involvement in the study constructive and profitable.

Third, the participants' motivation and positive performance during the intervention phase may be ascribed not only to the presence of preferred leisure events among the options available but also to other factors. For example, the cognitive (match-to-sample) tasks and physical exercises (body movements) were tailored (adjusted) to their skill level in terms of the stimuli and movements included, thus minimizing difficulties, failures, and frustration. The participants received positive feedback for the cognitive (match-to-sample) responses completed, and it is possible that such feedback represented a mild form of reinforcement [50]. The body movements were supported by instructions and encouragements for the participants with typical hearing and were cued (emphasized) through background color changes for the participants with hearing loss. The touch screen monitor reacted promptly and consistently to the participants' touch responses, minimizing any risk of failures.

Fourth, the web application included in the technology system ensured that the participants could make their touch responses successful (ie, choosing and activating a preferred leisure stimulus and selecting a matching stimulus) regardless of the accuracy (quality) of their contact with the touch screen monitor. Specifically, they could be successful irrespective of whether their contact consisted of a standard input touch, a heavy touch, a prolonged touch, taps, or scrolling movements. The use of such an application was considered critically important (necessary) based on the preliminary assessment of the participants' response characteristics and their baseline performance. Whether the application was still strictly necessary for all participants by the end of the study is not clear as no data were collected on that. Informal observations seemed to suggest that the participants' response schemes did not show particular changes over time.

Limitations and Future Research

The 3 main limitations of this study involve the lack of assessment of participants' satisfaction with the touch screen technology system and the intervention sessions, the lack of social validation of the program and the related technology, and the absence of maintenance and generalization data on the effects of the program. Regarding the participants' satisfaction, 2 basic points can be made. First, the fact that the participants remained constructively engaged throughout the intervention sessions seems to suggest that they were comfortable (and

XSL•FO
RenderX

possibly satisfied) with the sessions and their content [49,50,67]. Moreover, anecdotal reports provided additional support for this view. Second, future studies are expected to include a formal assessment of participant satisfaction. The assessment could involve two approaches: (1) measuring the participants' indices of happiness during and outside of the sessions and (2) having the participants choose between the sessions and other types of daily occupation [70,71].

The lack of social validation of the program and the technology used can be amended by future studies through surveys of staff and caregivers on these points. In practice, staff and caregivers could be (1) shown videos of the program (intervention) sessions with the participants using the technology and (2) asked to rate the program and technology in terms of impact, user-friendliness, and usability [72-74]. The lack of maintenance and generalization data can be amended by (1) extending the data collection period to verify whether the participants' performance remains stable over time and (2) implementing the program across different settings to ascertain whether the participants continue to be successful irrespective of the context [50,75].

The lack of assessment of whether the cognitive activity and physical exercise had an impact on the participants' functioning in those areas may be considered a fourth limitation of this study. Future research may need to address this limitation and find ways (ie, identify appropriate measures) to carry out such an assessment. The relatively small number of participants might not be considered an additional limitation as far as the internal validity of the data reported is concerned. In fact, the single-case research design used in this study is admittedly adequate to ensure such validity [55,56,76]. To test the external validity of those data, one would need to implement single-case replication studies and possibly group studies including experimental and control conditions [77-79].

Conclusions

The results suggest that the intervention program with the support of the technology system was effective in enabling participants with intellectual and multiple disabilities to independently access leisure events, manage match-to-sample tasks, and perform series of body movements. These findings can be considered encouraging as to the possibility of helping people with serious disabilities reach relevant levels of independent occupation through technology-aided programs. However, no conclusions about their implications can be drawn given the limitations of this study discussed previously. New research will need to counter those limitations and assess the generality and robustness of these data. New research might also seek to upgrade the technology system to make it simpler and more easily available.

Acknowledgments

This research received no external funding.

Data Availability

The datasets generated during this study are available on OneDrive repository [80]

Authors' Contributions

GEL was responsible for setting up the study, acquiring and analyzing the data, and writing the manuscript. GA and CF collaborated in setting up the study and the technology system and contributed to acquiring and analyzing the data and editing the manuscript. NNS, MFO, and JS collaborated in setting up the study, analyzing the data, and writing and editing the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: Socially assistive robots (SARs) are robotic technology platforms equipped with sensing (eg, through audio or visual) and acting (eg, speech and movement) capabilities to interact socially with users. SARs are increasingly adopted in physiotherapy to aid patients in their rehabilitation journey by providing feedback, motivation, and encouragement. However, while many studies have explored SAR implementation in physiotherapy, research involving clinical populations remains scarce, and the overall state of SAR deployment is unclear.

Objective: This scoping review aimed to explore the use of SARs in physiotherapy with clinical populations, how the effectiveness of these interventions has been evaluated, and identify limitations and new areas of application and future work.

Methods: Following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-analyses for Scoping Review) reporting guideline extension, comprehensive searches based on SARs and physiotherapy were conducted in various databases. Title and abstract screening were performed by 1 reviewer, with full-text screening conducted by 2 reviewers. Data extraction, synthesis, and analysis were completed by 1 reviewer. Data on SAR roles were categorized and synthesized using content analysis. Other descriptive texts were summarized to improve readability.

Results: Our findings suggest that SARs are commonly used in rehabilitation clinics and hospital inpatient settings, primarily for neurological conditions. In these interventions, SARs typically serve roles, such as coaching, demonstration, monitoring, and peer support. Their effectiveness is generally evaluated through clinical outcomes, user performance, functional measures, and metrics assessing the robots' acceptability, usability, and perception.

Conclusions: This scoping review highlighted SARs' potential to address challenges faced by human therapists due to the demands of time-extending coaching and monitoring and the limited availability of therapists. Future research should focus on addressing the limitations identified in this scoping review, including small sample sizes, technical issues in both the robot and intervention design, sufficient involvement of key stakeholders in the design and development of SAR-based interventions, and conducting more clinical trials to investigate SAR intervention effectiveness.

KEYWORDS

socially assistive robots; robotics; physical therapy modalities; rehabilitation; human-robot interaction

Introduction

Socially assistive robots (SARs) are designed to provide support to users primarily through social interaction and engagement. SARs were first defined and introduced in the field of physiotherapy in a foundational publication by Feil-Seifer and Mataric [1]. Unlike physically assistive robotic systems, SARs can achieve their primary function without performing any physical work or physically interacting with the environment or the intended user [2]. SARs are endowed with unique capabilities in human-social interactions, such as recognizing patterns of human interactions and engaging users through various forms of communication, including verbal and nonverbal cues, such as motion, and visual or tactile aids [1,3]. By emphasizing noncontact social interaction, SARs have shown promise in enhancing patient adherence, motivation, and engagement in rehabilitation exercises [4]. These merits in SAR application are the key to assisting physiotherapists in fostering active participation in health care programs [5].

In rehabilitation, where time spent engaging in interventions is a key dosage parameter, SARs play an important role by offering verbal encouragement, coaching, feedback, reminders, and continuous monitoring to enhance the overall therapeutic intervention or self-directed therapy [5,6]. For instance, for

XSL•FO
RenderX

children diagnosed with cerebral palsy (CP), conventional therapy approaches may benefit from novel strategies to increase motivation and thus achieve optimal outcomes [7]. A previous review has found that children and young adolescents with CP generally interact positively with SARs, leading to improved motivation and engagement [8]. Furthermore, SARs can be tailored to conduct gamified motor training sessions, capturing the attention of children with CP and encouraging active participation [9]. SARs' ability to address barriers to participation in therapy, such as motivation and self-efficacy, aligns with goals recognized by the International Classification of Functioning, Disabilities and Health (ICF) [10] developed by the World Health Organization (WHO), which serves as the most encompassing taxonomic model to describe an individual's functioning and disability [11].

While existing literature indicates that SARs show promise for improving outcomes across health and social care settings for diverse populations, their specific applications in physiotherapy remain poorly characterized [12]. Despite the growing interest in integrating SARs into rehabilitation settings, the full breadth of usage in physiotherapy practice remains unclear, partly due to a current lack of literature summarizing SAR-assisted physiotherapy studies directly involving clinical populations. Existing reviews of SAR-assisted therapy in physiotherapy have primarily focused on interventions for children living with CP, providing valuable yet constrained perspectives on the potentially broader usage of SARs in physiotherapy practice [9,13,14]. A scoping review exploring the use of robot-assisted therapy for upper limb impairments in children with CP identified 1 type of SAR (CosmoBot) [14]. This SAR was used in a small sample size (n=6) study investigating effects on functional movement quality, thus providing a limited view of the state of SAR deployment in physiotherapy practice.

This paper aims to fill this gap and advance the field by presenting a scoping review of the current state of the art of SAR deployment in physiotherapy with clinical populations [15]. Specifically, this scoping review seeks to identify how SAR systems are implemented and operationally integrated into interventions and activities reported in physiotherapy contexts and describe the methods used to evaluate the effectiveness of interventions that integrate the use of SARs. In addition, the review aims to identify current limitations to SAR integration within physiotherapy interventions and explore new potential application areas suggested in research to date. The findings of the scoping review will guide future interdisciplinary collaboration between physiotherapy, roboticists, and human-robot interaction researchers interested in investigating SAR applications in clinical populations.

Methods

Study Design

This review was a systematic scoping review that followed the methodological steps first described by Arskey and O'Malley [16] and subsequently refined by Levac et al [17], Peters et al [18] and Pollock et al [19]. A scoping review was determined to be the most appropriate review methodology given the paucity of clinical trials investigating the effectiveness of SAR interventions in clinical physiotherapy, which precludes the conduct of a systematic review [20]. As such, our review question was "What is known about the use of SARs within physiotherapy interventions and activities with clinical populations?"

The advantages of a scoping review approach are the development of a systematic and reproducible search strategy, with clear inclusion and exclusion criteria to comprehensively identify and chart existing evidence related to our review question and identify gaps and potential avenues for future research. This scoping review report follows the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-analyses for Scoping Review) [21]. Given the nature of the scoping review being a type of systematic review, no ethical approval was needed.

Search Strategy

The scoping review search terms were structured using the population, concept, context (PCC) framework [18]. For this review, the population was any clinical population, the concept of interest was SARs, and the context of interest was the conduct of physiotherapy interventions or activities. To ensure a balanced and comprehensive yield of existing publications related to robotics in physiotherapy, a combination of health and engineering literature databases was systematically searched. The engineering databases searched for this scoping review were the Association of Computing Machinery (ACM) and the Institute of Electrical and Electronics Engineers (IEEE) databases. The health databases searched were Ovid MEDLINE, Ovid Emcare, Ovid EMBASE, Ovid Cochrane Library, Scopus, and the CINAHL.

A primary database search string was developed in consultation with an academic librarian as recommended for scoping reviews [18]. The first search was constructed for execution in MEDLINE using Medical Subject Headings (MeSH), database-specific thesaurus equivalent words and keywords for SAR (eg, "social* assist* robot") and physiotherapy (eg, "physiotherapy"). Details of complete syntax are listed in (Multimedia Appendix 1).

The primary search string was then adapted for use in all other electronic databases by modifying syntax and using database-specific subject headings (ie, MeSH). In cases where a database did not use subject headings (such as Scopus, ACM, and IEEE), only keywords were used. A study date limit filter was applied to restrict the search for publications since the foundational 2005 publication of Feil-Seifer and Mataric [1]. All databases were searched up to November 23, 2023. Complete search strings for all databases searched are presented in (Multimedia Appendix 2).

Identified records from all databases were uploaded to reference manager software Endnote (Clarivate; [22]) and imported into systematic review software Covidence (Veritas Health Innovation; [23]) for screening. Records were automatically deduplicated in Covidence before conducting title, abstract, and full-text screening. Further manual identification and removal of duplicates were conducted during the screening stages to ensure no duplicate records appeared in the final yield.

Inclusion and Exclusion Criteria

Population

All studies involving clinical populations interacting with SARs were included.

Concept

Only studies reporting on SARs as an intervention, a medium to deliver an intervention, or both were considered. As defined in the introduction, the SARs reported must be capable of providing noncontact social interaction with users. Therefore, studies involving surgical or physically assistive robotics, artificial intelligence software, and virtual intervention without focusing on SARs were excluded.

Context

Studies conducted using physiotherapy as an intervention or cotherapy in various settings, such as hospitals, clinics, community health care centers, and residential aged care facilities, were included.

Types of Studies

Only full-text peer-reviewed primary studies written in English and published from 2005 to the present were included. Peer-reviewed conference papers and proceedings reporting completed studies were considered for inclusion, as in the engineering literature, these undergo a peer review process akin to that of journal papers in the medical field. Any unfinished studies and gray literature, including short technical reports and workshop papers, were excluded. Only studies that reported clinical studies were considered. Publications that solely described robot design and development or evaluated system feasibility, system features, or user perception were excluded.

Selection of Relevant Publications

All references were imported into Covidence [23]. One reviewer (JH) screened all records at the title and abstract stage against the eligibility. To confirm reviewer accuracy in applying the eligibility criteria, a subset of 25 studies was randomly selected for independent evaluation by all 3 review team members. The outcome of the 3 independent reviews of the 25 studies was compared and agreement on the screening outcome was confirmed.

Two reviewers independently screened all papers at the full-text screening stage. One reviewer (JH) screened all papers while the second independent review was conducted by either MF or PCM. Meetings between all 3 reviewers occurred at regular intervals during all screening stages, ensuring close supervision of JH's screening progress and a unified and consistent interpretation of the criteria. Conflicts identified at the full-text screening stage were resolved by an initial discussion between the reviewing pair (JH and MF or JH and PCM) until a consensus was reached. If a consensus could not be reached by the reviewing pair, the third reviewer was consulted and discussion continued until a consensus was reached. Included studies advanced to data extraction, while exclusion reasons were documented for excluded studies.

Data Extraction

A data-charting form was developed in Covidence [23] to extract relevant data from the included studies [4,24-35] . The types of data extracted are shown in (Table 1). The review team piloted the data-charting form with the first 2 records and revised it before charting the data from the rest of the included studies [4,24-35].

One of the reviewers (JH) completed the remaining data extraction process to ensure data extraction consistency. Two reviewers (MF and PCM) audited the extracted data from 4 included studies [26,30,34,35] (approximately 30% of the final yield) and identified negligible errors in the data extracted. Extracted data were then exported from Covidence [23] to a spreadsheet for synthesis.

Table . Template for extracting information from the included studies.

Topic	Extraction details
Study	Title, author name, publication year, country, study duration, study design, study aim, and sample size.
Population	Age and condition or diagnosis.
Concept	Physiotherapy setting, physiotherapy goal, type of training, specific exercise prescribed to patients, length of each session in minutes, number of sessions, and intensity of training.
Context	Name of the robot, level of autonomy, if the robot was being controlled during the intervention, technical support presence during the intervention, area of physiotherapist and patient or client involvement in the protocol or robot design phase, robot model, the function of robot, the behavior of the robot, the communication channels between robot and users, presence of physiotherapist during the intervention, role of physiotherapist and presence of a control group.
Outcome and finding	Construct investigated and associated outcome measure, key finding, study and robotic limitation, and area of application.

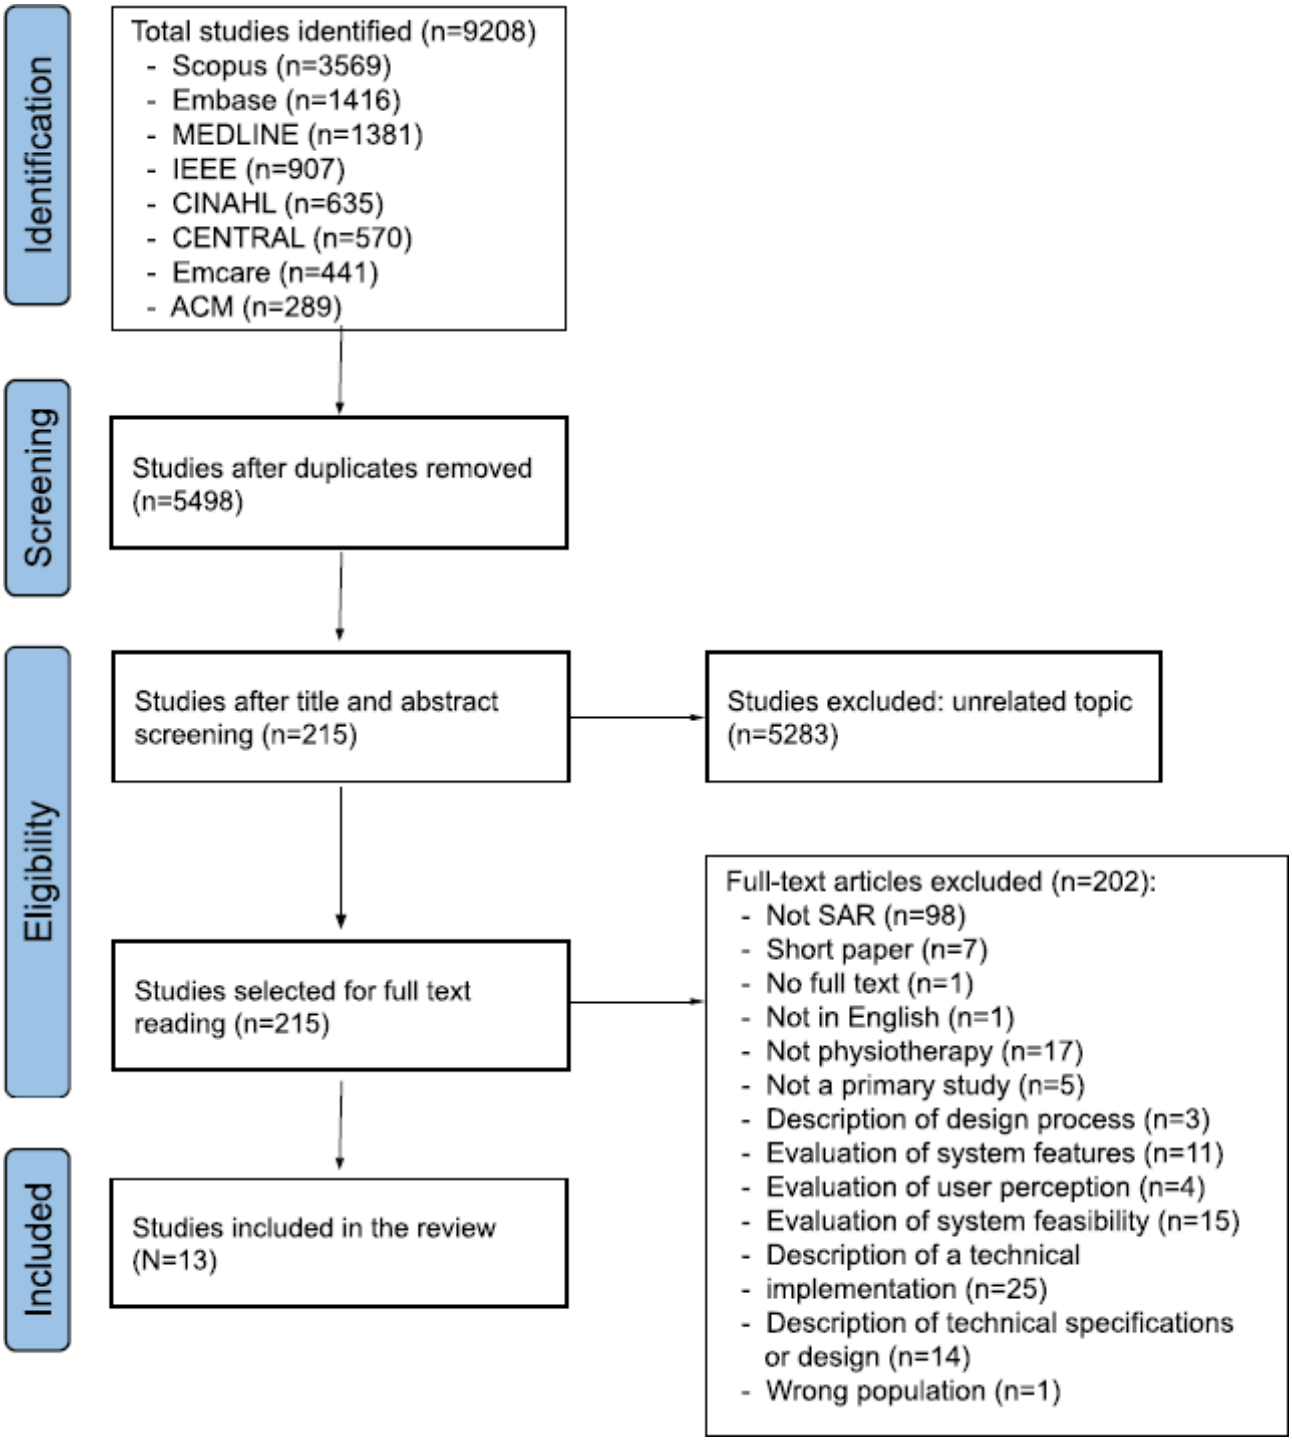
Data Analysis and Synthesis

Data synthesis and analysis was led by JH with regular review meetings with MF and PCM to confirm the accuracy of the synthesis process and devise a shared interpretation of the data synthesized. Charted data were first categorized into groups related to the scoping review questions: study and participant

XSL•FO
RenderX

characteristics (population), features of physiotherapy (context), features of SARs (concept) used in interventions, robot design features, evaluation methods, key findings, limitations, and areas of application. Patterns were identified within each group and categorized, which aided the comparison and interpretation of data.

Subsequently, a more detailed analysis of the data extracted from included studies [4,24-35] by applying content analysis [36] was performed. Descriptive text extracted from studies relating to robot function and behavior was condensed, and patterns related to robot functions were coded and grouped into categories. Similarly, descriptive text concerning the role of physiotherapists, physiotherapists, and patient or client involvement in the protocol and robot design phase, key findings, limitations, and application areas were condensed, coded, and categorized. Throughout the data analysis process, all data were directly linked to the source material, and where necessary, the original text was revisited to confirm context or meaning if extracted data segments were ambiguous when being analyzed in isolation.



Results

Description of Included Studies

The database searches identified 9208 studies. After removing duplicates (3710 studies) and title and abstract screening, 215 studies were included for full-text screening. Of those, 202 studies were excluded with main reasons shown in Figure 1. Seven short papers related to our review question were identified at the full-text screening stage. A citation linkage search using Google Scholar was conducted to establish if any subsequent full-text reports had been published. No additional records meeting the inclusion criteria were identified by citation tracking of the studies included at the full-text stage. A final yield of 13 studies [4,24-35] met the criteria for inclusion in the review (Figure 1).

XSL•FO
RenderX

Figure 1. Flowchart of study selection process adapted from the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-analyses for Scoping Review) flowchart for this review.

SAR-Related Interventions and Activities in Physiotherapy

In this section, we begin by summarizing the general characteristics and demographic details of the selected studies. Following that, we provide an overview of the specific physiotherapy interventions, including prescribed exercises, dosage, and objectives.

Physiotherapy Settings and Participant Groups

Table 2 lists the main characteristics, demographic details, and countries where the SAR interventions took place. For studies that did not explicitly report their country of implementation, we derived the location from the institutional affiliation of the first or corresponding author, treating this as the proxy country of study. Among the included studies, the geographical distribution was as follows: Colombia hosted the largest number (3/13, 23%) [24-26], followed by 2 studies each in Spain [27,28], Israel [29,30], and Australia [4,31]. Single studies were reported from Belgium [32], France [33], and Saudi Arabia [34].

XSL•FO

XSL•FO
RenderX

Article and Year	Country	Study duration	Study design	Sample size	Study group (s) and age in years (mean, SD)	Diagnosis or Condition
Al-Shahry and Al-Shehri [34], 2020	Saudi Arabia	5 trials on different days	Not reported	5	• 20-65	Patients with musculoskeletal conditions diagnosed with pain in muscles or joints or both
Private nursing home						
Bäck et al [35], 2013	Finland	7 months	Not reported	34	Median age greater than 85	Residents of the nursing home

SAR interventions were implemented across various physiotherapy settings, with the most common being rehabilitation clinics [4,24-26,29,33-35] (8/13, 62%) and hospital inpatient settings [27,28,32] (3/13, 23%). One study [31] reported rehabilitation in both inpatient and outpatient settings (1/13, 8%). Inpatient physiotherapy takes place when the patient is admitted to the hospital, while outpatient physiotherapy occurs outside of hospital admission, typically in outpatient departments of hospitals, rehabilitation centers, or private clinics. In addition, 1 study reported SAR interventions in a private nursing home [35].

Regarding the context of application, we found that the reported SAR interventions were predominantly applied in the treatment of neurological conditions, such as CP, obstetric brachial plexus palsy, spinal cord injury, hemispherectomy, hereditary spastic paresis, stroke, and Guillain-Barre syndrome [4,24,25,27,29-32] (8/13, 62%). Musculoskeletal conditions (eg, low back pain, muscle or joint pain) were next in frequency [33,34] (2/13, 16%), followed by cancer [32] (1/13, 8%) and cardiovascular conditions (eg, myocardial infarction) [26] (1/13, 8%). One study's participants were residents in an older care facility [35].

The age range of SAR intervention recipients varied from 3 years old to more than 85 years. Specifically, 4 studies [24,27,28,32] targeted children (younger than 18 years of age), including those in early childhood and adolescence. Notably, 7 studies [25,26,29,30,33-35] focused on adults (18 years and older), encompassing a broad range of ages within this group. Overall, 1 study [31] included both children and parents in the intervention. In addition, 1 study [4] did not report the age of the intervention recipients.

Out of 13 included studies [4,24-35], only 5 studies [27,28,30,32,33] reported using a control group. This distinction is important, as control groups are critical to determining whether the observed effects are truly due to the inclusion of SARs.

Features of Physiotherapy Intervention

Table 3 lists all the physiotherapy interventions extracted from the studies. Interventions encompassed various types of training, specific exercises or programs, frequency, timings, and intensities of training, as well as physiotherapy goals tailored to specific patient populations.

XSL•FO
RenderX

Table . Description of physiotherapy intervention with information is categorized by the type of physiotherapy training.

Author and year	Specific exercises	Physiotherapy goals	Frequency and time	Intensity
Endurance training				
Irfan et al [26], 2020	Warm-up (stretching), exercises on a treadmill, and cool-down (low-intensity exercises)	Accelerate recovery and reduce the risk of recurrent events.	35×20 - 30-minute sessions for 18 weeks.	Relative intensity of the sessions, determined by the treadmill speed and inclination, was progressively increased over time.
Salas-Monedero et al [28], 2023	Warm up, seated upper extremity muscle exercises (shoulder abduction, shoulder flexion-extension, elbow flexion-extension, and elbow elevation), and cool down	Enhance strength and endurance requirements in preparation for repetitive movements, such as those used in neurorehabilitation to acquire movement patterns for activities of daily living.	30-minute sessions, 2-3 times per week for a maximum of 5 weeks (10 sessions in total).	Not reported
Carrillo et al [4], 2018	Sit-to-stand exercise, exercise from a lying down position, and toy relay game	Delivery and participation in exercise programs in pediatric rehabilitation.	1 session of up to 30 minutes per participant.	Not reported
Strength training				
Bäck et al [35], 2013	Arm and leg exercise in sitting	Delivery and participation in a group exercise program.	4 sessions of 10-20 minutes each.	Not reported
Al-Shahry and Al-Shehri [34], 2020	Strengthening exercise	Improve back strength.	5 sessions of 30 minutes each.	Not reported
Butchart et al [31], 2021	Strengthening exercises in supine (such as bridges) and side-lying (such as hip abduction), relay games with obstacles	Delivery and participation of exercise programs in pediatric rehabilitation.	Up to 3 sessions, average session length of 33 minutes.	Not reported
Functional task training				
Feingold-Polak et al [30], 2021	Reach-grasp-and-place, or reach-grasp-and-manipulate movements, using real everyday objects, such as cups, jars, keys, wallets, and drawers.	Use functional task training to practice force regulation and retraining coordination.	30-50 minutes per session, 2-3 times per week for 5-7 weeks (15 sessions in total).	Not reported
Feingold Polak and Tzedek [29], 2020	Kitchen game (arrange jars on shelves at 3 different heights), cup game (ordering a set of colored cups in a row according), target game (ordering a set of colored cups in a circle), keys game (ordering a set of colored keys on a board), drawer game (take objects out of drawers located at different heights), card game (manipulation of cards), and wallet game (take the keys out of zipped wallets)	Retraining coordination of reach-to-grasp movements.	40-60 minutes per session, 2-3 times per week for 5-7 weeks (15 sessions in total).	Not reported
Gait training				
Cespedes et al [25], 2020	Walking using Lokomat	Promote functional locomotor recovery; retrain gait through neuroplasticity stimulation.	SAR[a]-assisted therapy: 1x45-minute session; conventional therapy: 1x 45-minute session	Not reported
Gross motor and motor control training				

XSL•FO
RenderX

Author and year	Specific exercises	Physiotherapy goals	Frequency and time	Intensity
Meyns et al [32], 2019	Gross motor movement exercises, such as raising arms, squats, lunges, and walking forwards and backwards	Participating in physical exercises.	1-minute set of exercise, 1-3 sets for each of the 4 conditions (each participant was asked to perform in all 4 conditions).	Not reported
Buitrago et al [24], 2020	Walking	Improve functional movement and cognitive skills.	16×45-minute sessions over 8 weeks.	Not reported
Flexibility and proprioception training				
Pulido et al [27], 2019	Mirror game (imitate different poses) and imitation game (imitate a sequence of poses in a specific order)	Training proprioception and improving joint mobility ranges	SAR-based therapy: 30 minute session, twice per week for 2 months, maximum of 15 sessions for each participant; traditional therapy: same as above	Not reported
Blanchard et al [33], 2022	Stretching	Promote participation and adherence to long-term exercise therapy for people with chronic low back pain	30-minute sessions, 5 times per week for 3 weeks (15 sessions)	Not reported

[a]SAR: socially assistive robotic.

SARs were used across a range of training modalities, including endurance training [4,26,28] (3/13, 23%), which focused on improving cardiovascular fitness; strength training [31,34,35] (3/13, 23%), aimed at increasing muscle strength; functional task training [29,30] (2/13, 15%), which helped patients practice real-life activities; gait training [25] (1/13, 8%), targeting walking ability and balance; gross motor and motor control [24,32] (2/13, 16%), which improved muscle movement and coordination; and flexibility and proprioception training [27,33] (2/13, 16%), aimed at enhancing joint range of motion and the body's ability to sense movement and position.

The specific exercises described in the interventions varied based on the targeted condition and goals. Setting clear goals is crucial for guiding interventions toward desired outcomes and requires a thorough understanding of the patient's activities, needs, limitations, and strengths [37]. The goals in SARs interventions can be grouped into 2 main categories: increasing activity and participation, as seen in studies by Carrillo et al [4], Back et al [35], Butchart et al [31], Meyns et al [32], and Blanchard et al [33]; and targeting underlying impairments in patients' physical function, such as improving strength and endurance [28], enhancing back strength [34], and retraining coordination [29,30], gait [25], and proprioception [33].

In addition to the conventional therapeutic exercises (eg, treadmill exercise, robot-assisted gait training, and stretching) reported in the majority of the studies [4,24-26,28,32,34,35], SARs were also involved in gamification programs, as reported in 3 studies [27,29,30]. While all studies provided sufficient details on the exercise programs' frequency and time parameters, only 1 study [26] specified exercise intensity. Reporting on these parameters, such as frequency, duration, and intensity is crucial, as it helps track progress and ensures that programs are tailored to the individual's needs and capabilities.

Furthermore, 7 studies [24,26-30,33] implemented relatively long-term physiotherapy interventions, with session numbers ranging from 10 to 35 and total duration spanning from 3 to 18 weeks. In contrast, 3 studies [31,34,35] conducted 5 or fewer sessions, and 3 studies [4,25,32] administered only 1 therapy session per participant.

Finding on SARs Characteristics

To answer the question of how SARs are integrated into physiotherapy contexts, we categorized the information on SARs characteristics based on 4 subquestions.

1. What SAR platforms are most used in physiotherapy?

2. How do SARs and users interact with each other?

3. What roles do these robots serve within physiotherapy contexts?

4. What was the involvement of key stakeholders in the design and development process of SARs and intervention protocols, as well as the presence of technical support and the role of physiotherapists during interventions?

This information aims to provide insights into the relationship we seek to build between robots and users, and how to ensure that SAR interventions are designed with the needs of target users in mind, thereby promoting broader community adoption.

Types and Levels of Autonomy of SARs in Physiotherapy

All reported SARs were humanoid robots, designed to mimic the human body in shape and capable of precise movements for tasks, such as demonstration. Among these, NAO was the most frequently used robot platform (10/13) [4,24-28,31,32,34,35]. NAO is a programmable humanoid robot developed by Aldebaran Robotics (SoftBank Robotics) [27]. Pepper, also developed by Aldebaran Robotics (SoftBank Robotics), was the second most commonly used robot [29,30]. One study [33] used Poppy, an open-source humanoid robot developed based on the Poppy project [38].

XSL•FO
RenderX

Using the classification by Beer et al [39], we identified 3 categories of robot autonomy from the included studies: "fully autonomous," "semiautonomous," and "tele-operated." One study [26] reported that the SAR was "fully autonomous," indicating that the robot operated independently without human intervention. In contrast, 2 studies [29,30] reported that the SAR was "semi-autonomous," as the robot required some degree of human input or supervision during the intervention. However, the majority of studies [4,24,25,27,28,31-35] (10/13, 77%) did not provide a specific description of the level of autonomy or how the robot was operated.

Interaction Between SARs and Users

Eleven studies [4,24-27,29-31,33-35] reported several communication channels from robots to users during the physiotherapy interventions and activities. The use of speech or verbal feedback was the most commonly reported communication method [4,24-27,29,31,33-35] (11/13, 85%). In most studies, the robot used audible phrases with a synthetic voice or prerecorded instructions to engage patients, communicate with the physiotherapist, or provide verbal feedback on the timing or success of tasks [25,29,35]. Motion or gesture was also commonly used, reported in 10 studies [4,24-27,29,31,33-35] (10/13, 77%). For instance, the robot could bow to demonstrate correct spinal posture [25], imitate the patient's movements to demonstrate exercises [27], or perform physical gestures, such as hand clapping or head nodding, to motivate patients [29]. In addition, visual feedback was provided by displaying messages or images on the robot's tablet screen [30,33], and LED outputs were used to prompt inputs [4].

Users were able to command the robots through various methods, including touching the robot's head-based tactile sensors [4,24,26], using voice commands to stop, resume, and restart the exercise program [34], pressing a physical button on a table to indicate completion of exercises [29,30], and interacting with a tablet interface [26]. However, 7 studies [25,27,28,31-33,35] did not specify the communication channels used by users to interact with the robots.

Functions and Roles of SARS

Content analysis identified and categorized 4 functions of SARs in physiotherapy interventions and activities: coaching, demonstration, peer support, and monitoring. However, this was based on data from the 12 included studies [4,24-31,33-35], as 1 study did not explicitly report the function of the SARs [32].

Coaching was identified as a prominent function of SARs in physiotherapy interventions, emphasizing their capacity to provide instructions and feedback. For example, in the study by Buitrago et al [24], the coaching role of SARs was as "[robot] gives feedback to the child by saying positive sentences for having completed the task' and '[robot] verbally indicated him [user] extending an arm that he had to go to where the therapist was to bring another toy." In some studies, the robots delivered game instruction and feedback to users using both verbal and visual feedback, encouraging users to improve their performance [29]. In other studies, the robot encouraged users during sessions using motivational phrases such as "Let's go! You can do it!" [26].

Demonstration was identified as the second most common function reported (6/13, 46%), highlighting the role of SARs in physically showing or modeling exercises, techniques, and movements. This function was often described as leveraging the robot's humanoid embodiment to demonstrate gestures and motions. In 5 studies [4,27,31,33,34], SARs like NAO or Poppy demonstrated exercises or performed them alongside patients. In a study by Cespedes et al [25], the robot provided posture feedback to a patient during gait training and demonstrated corrective cervical or thoracic posture techniques.

Monitoring, 2 studies [25,26] highlighted the role of SARs in monitoring and assessing safety warnings and reporting emergencies to human therapists. In the study by Irfan et al [26], NAO could request the study participant report their level of physical exertion using the Borg scale [40], a numerical scale that measures perceived exertion during physical activity, and issue warnings about a high heart rate during treadmill exercises for patients with a history of myocardial infarction. Similarly, Cespedes et al [25] reported that when a heart rate alert was detected, NAO verbally confirmed the patient's condition and alerted the therapist promptly.

The role of peer support provided by SARs involves the robot engaging with the patient as a supportive companion during therapy sessions, often providing positive reinforcement and encouragement. Most studies described this role through various forms of motivational feedback, such as verbal motivation or encouragement and positive feedback [25,31]. Examples of supportive messages included phrases like "I'm so happy to see you again" and "It is so nice that you came back" [30]. Irfan et al [26] also personalized feedback by including the patient's name in supportive statements aiming to enhance the robot's perceived sociability. In addition, Carrillo et al [4] reported that NAO incorporated humor and preprogrammed dialogue to build rapport with patients.

Key Stakeholder Involvement in SAR Design and Development

Out of the 13 studies [4,24-35] reviewed, 7 (54%) studies [4,26,27,29,31,33,34] reported involving physiotherapists or other health care professionals in the design of SARs or intervention protocols. Physiotherapists specifically contributed to designing exercise programs [27,31,34], patient selection [34], and robot vocal feedback messages [33]. Feingold-Polak and Levy-Tzedek [29] reported system improvements based on recommendations from a focus group of expert clinicians who work with stroke survivors, the intended target users of the SARs. Carrillo et al [4] highlighted the active engagement of therapists in both the design and development phases of the robot, allowing them to critique and explore the system's physical and clinical capabilities and limitations.

Only 2 studies [4,35] involved clinical populations in the design of SARs or intervention protocols. Back et al [35] mentioned the continuous development of an exercise program based on user feedback. Carrillo et al [4] described several early robot-patient interactions during the design and development

XSL•FO
RenderX

to obtain structured feedback for protocol refinement. However, most included studies either did not report clinical population involvement [24,25,27-33](9/13, 69%) or did not include clinical populations in the design process [26,34](2/13, 15%).

Involvement of Technical Support and Physiotherapist During the Intervention

Three studies [4,30,35] reported providing technical support during interventions. In the study by Back et al [35], a therapist was present to ensure the robot functioned properly. In Feingold-Polak et al's study [30], a clinician was present during the intervention to address technical problems, such as replacing a malfunctioning tag reader. Carrillo et al's study [4] required engineer intervention to restart the system due to battery drainage. While 1 study [27] explicitly reported no technical support, 9 studies [24-26,28,29,31-34] did not provide any information regarding technical support required during the SAR intervention.

Eleven studies [4,24-31,33,35] identified various roles of physiotherapists and medical staff during physiotherapy sessions. In some instances, physiotherapists directly participated in therapy by coordinating activities with the robots [24,25] or providing physical support to patients with neurological impairments [31]. Five studies [4,28,30,33,35] explicitly mentioned physiotherapists ensuring the proper operation of SARs [30,35], setting parameters [28,30,33], or arranging the environment to facilitate smooth sessions [4,30]. In the study by Pulido et al [27], the therapist configured personalized exercises based on patient profiles and monitored sessions via a graphical interface. Similarly, Salas-Monedero et al [28] described monitoring through sensors to facilitate timely interventions. In the study by Irfan et al [26], medical staff present during cardiovascular rehabilitation sessions provided immediate assistance during emergencies, monitored vital signs, and interacted with the robot. In another study, physiotherapists played an educational role by introducing patients to robots and explaining system capabilities and interactions before sessions [33].

Methods of Evaluation and Outcome

Table 4 summarizes the evaluation methods for treatment effectiveness reported in the included studies [4,24-35]. The outcomes are categorized into 2 groups. The first group includes clinical outcomes, user performance, or functional measures, which assess the direct impact of interventions on the user's health and functional abilities, as well as their ability to perform tasks related to their functional goals. For example, Buitrago et al [24] used Goal Attainment Scaling [41] to evaluate the extent to which the patient with CP achieved his goals, with positive results indicating that the user successfully met the objectives during robotic training. Salas-Monedero et al [28] assessed upper extremity dexterity in patients with tetraplegia and paraplegia using metrics like the Box and Block Test [42]. Irfan et al [26] monitored physiological parameters, such as heart rate, the Borg scale [40], and blood pressure in a patient with a history of heart attack to observe the intervention's effects.

The second group encompasses metrics that evaluate the acceptance, usability, and perception of robots. Among these, acceptance was the most frequently assessed construct, typically measured through subjective evaluations, such as interviews and questionnaires, with reports indicating a positive trend toward acceptance of SARs [4,26,29-31,33]. In addition, studies focusing on user perception reported positive feedback regarding the overall robot experience [35], usability [27], and increased user motivation and adherence to therapy [4,26,27,32]. However, 1 study found no improvement in adherence [33].

Although most of the included studies assessed the acceptance, usability, and perception of robots, 7 studies [4,29-32,34,35] did not report any clinical outcomes, user performance, or functional measures. This may limit the understanding of the actual therapeutic benefits of the robotic interventions.

XSL•FO
RenderX

Table . Methods of evaluation and key findings from included studies.

Author and year	Measures (clinical outcomes, user performance, or functional measures)	Measures (acceptance, usability, or perception of robots)	Key findings
Meyns et al [32], 2019	• Not applicable	• Motivation: Fun Toolkit (the Again table, the Smileyometer, and the Fun Sorter)	• Humanoid robot instructors, like using music, enhance children's initial motivation for physical activity programs.
Bäck et al [35], 2013	• Not applicable	• Feedback on robot experience: Survey questions	• Positive feedback supports using NAO robots as exercise trainers and in nursing home rehabilitation for older adults.
Al-Shahry and Al-Shehri [34], 2020	• Not applicable	• Robot-patient performance: Clarity, therapy sequences, interaction, voice, timing, independence, operation and technical performance, and degree of freedom	• Robot therapy shows highly satisfactory performance with good patient acceptance.
Butchart et al [31], 2021	• Not applicable	• Perceptions of acceptability and therapeutic value: Semistructured in-depth interview	• NAO robot is an acceptable complement to rehabilitation therapies. • NAO robots have perceived therapeutic value through their potential to enhance engagement and rehabilitation program delivery, particularly in the absence of a physiotherapist.
Feingold-Polak et al [30], 2021	• Not applicable	• User acceptance of the novel system: User satisfaction evaluation questionnaire and open-ended questionnaire • Evaluation of technical limitations: Custom-made questionnaire	• Long-term stroke rehabilitation with robotic platforms in clinical settings is feasible and shows strong acceptance among patients with post-stroke.
Feingold Polak and Tzedek [29], 2020	• Not applicable	• Acceptance: Robot Acceptance Survey (RAS), a custom-made user-acceptance questionnaire based on the User Satisfaction Evaluation Questionnaire (USEQ)	• Patients with poststroke demonstrate acceptance trends toward SAR after long-term interaction.
Martí Carrillo et al [4], 2018	• Not applicable	• Acceptance: Robot acceptance questionnaire from physiotherapists, acceptance questionnaire for guardians	• Despite its limited capabilities, NAO's robust minimalist system deployment provides valuable patient engagement insights for ongoing clinical deployment, especially for a formal clinical evaluation.
Buitrago et al [24], 2020	• Effectiveness of intervention: Objective evaluation of intervention using the Goal Attainment Scale (GAS)	• Not applicable	• Participant showed increased continuous steps during training with a humanoid robot.

XSL•FO
RenderX

Author and year	Measures (clinical outcomes, user performance, or functional measures)	Measures (acceptance, usability, or perception of robots)	Key findings
Salas-Monedero et al [28], 2023	• User performance: Length of the hand trajectory (mm), peak number detected in the velocity profile of hand during the execution of the task (units), Box and Block Test (blocks)	• Compliance: Record the number of sessions for each participant	• Intervention benefited patients with tetraplegia by improving hand motor accuracy and dexterity. However, patients with paraplegia showed no improvement with intensive short-term training.
Irfan et al [26], 2020	• Physiological parameters: Heart rate, Borg scale, gait parameters (step length, cadence, and speed), cervical posture, systolic blood pressure	• Social interaction: Gaze and patient's verbal and nonverbal feedback • Technology use and acceptance: Unified Theory of Acceptance and Use of Technology (UTAUT) questionnaire	• Improved physiological progress observed. • Patient adherence to the cardiac rehabilitation program may have been enhanced with personalized robot attendance.
Cespedes et al [25], 2020	• Patient performance: Heart rate, Borg scale • Poor posture time (cervical and thoracic): The total time during the session when the posture inclination overcomes the good posture threshold	• User perception: Questionnaire to the patient and the therapist	• SAR[a] had a positive effect on patient encouragement, intrinsic motivation, and adherence to the therapy and was well-received by patients and therapists, with reported benefits in gait rehabilitation sessions.
Pulido et al [27], 2019	• Motor performance: Manual Ability Classification System (MACS), Motor scale of Mallet, Quality of Upper Extremity Skills Test (QUEST) scale	• Usability and compliance: Record the number of sessions for each participant • User perception on satisfaction and usability: Questionnaires for patients, relatives, and clinical staff, Likert scale (5 items), open questions	• Patients showed slight motor skill improvement with robotic platform training compared to conventional therapy (where no improvements were detected) • Deemed useful and easy to operate by patients, relatives, and health care professionals.
Blanchard et al [33], 2022	• Change in lumbar pain: Visual analog scale (VAS) • Change in disability: Roland Morris Questionnaires (RMQ), the Dallas Pain (DPQ) Questionnaires • Adverse events: Reported by physiotherapists during therapy sessions and by investigators during evaluation visits	• Adherence: Record number of movements performed by the participants during each robot-led session • Change in fears and beliefs: Fear-Avoidance Beliefs Questionnaire (FABQ) • Usability: System Usability Scale (SUS) • Therapist's acceptance of robot: Unified Theory of Acceptance and Use of Technology (UTAUT) questionnaire	• Adherence to robot sessions declined over time, limiting physical activity supervision. • No negative impact is shown on clinical outcomes, but the system was deemed not yet ready for rehabilitation applications.

[a]SAR: socially assistive robotic.

Reported Limitations and Areas of Improvement

Overall, 4/13 (31%) included studies [28,29,31,35] reported a limitation related to small sample sizes, thus limiting the generalizability of their findings. Selection bias was identified as a potential limitation in 1 study [31], where researchers may have been inclined to select participants they had previous positive interactions with. Other study limitations identified included slow recruitment rates due to strict inclusion criteria [33] and the homogeneity of participants from the same facility [29]. Technical issues and limitations in robot design were reported in 3/13 (23%) studies [33-35], such as system readiness issues and malfunctions leading to missed robot sessions [33], pelvic movement readiness and system heating concerns [34], and limited exercise variety due to robot size constraints [35].

In addition, 3/13 (23%) studies [4,24,34] highlighted limitations in intervention design. For instance, Buitrago et al [24] noted that, although the objective measured by the Goal Attainment Scaling was achieved during the training, neither the robot nor the therapist adjusted the task or the environment to reflect the

XSL•FO
RenderX

new goal. Carrillo et al [4] reported that the therapist performed tasks for the robot as they were not informed of the robot's capabilities. Other reported limitations included a limited range of friendly interactions, the need for refreshment breaks, and limited flexibility in exercise sequences [34].

Other identified limitations included robotic technology expenses [35] and uncertainty regarding the impact of color blindness in users [30]. Identified limitations in evaluation methodologies included difficulty in measuring motivation in very young children [32], a lack of assessment of the robot's impact on physical health [33,35], and the absence of cognitive ability data to indicate acceptability [31]. Three studies [25-27] did not report any limitations.

The areas of application proposed by the authors of the included studies spanned the domains of rehabilitation, such as cardiac rehabilitation [26], pediatric oncology, and neurorehabilitation [24,28,30,32], and applications in older adult care facilities [35]. Other identified applications included supporting exercise, progress monitoring, and maintaining motivation and adherence [26]. In addition, studies' authors suggested integrating SARs into existing robot-assisted gait rehabilitation [25], using SARs to address gaps in telehealth care by enabling real-time program adjustment based on robot-patient interactions [34], and supporting long-term home exercise programs for people with chronic conditions who may not have access or resources for prolonged therapist contact to assist with managing their condition [33]. One study [29] did not propose any specific areas of application.

Discussion

Main Findings

This scoping review aimed to explore the usage of SARs in physiotherapy contexts with clinical populations. Across the 13 studies [4,24-35] identified, SARs' roles and functions were tailored to suit the specific needs of patients and the objectives of physiotherapy interventions. These findings indicate that, in current applications, the primary objective of integrating SARs into health care is therapeutic augmentation [43].

Numerous studies reported that the use of SARs led to repetitive exercises and sessions [44]. This issue may stem from simplistic programming or a lack of personalized adaptation, which can result in a loss of user interest [44]. To address this, efforts have increasingly focused on complementing SAR interventions with devices like Lokomat or incorporating more advanced gamified exercises [4,25,27,29,30]. This review identified several SAR capabilities, including coaching, demonstration, monitoring, and peer support. Currently, SARs seem to be prioritized for roles, such as time-extending coaching and monitoring, functions that are considered unfeasible for human therapists due to the mismatch between the number of available therapists and the size of clinical populations [43].

Robots Used

The dynamics of socially assistive interaction are elucidated through the roles that SARs take on and the communication channels used between robots and users. In all but 2 studies [28,32], where communication methods were not reported, verbal communication channels were used to deliver feedback, encouragement, or instructions (along with visual and motion-related communication). Verbal praise to users is considered positive feedback and thus has the potential to enhance users' intrinsic motivation for task performance [43].

Of the SAR models discussed in the review, the humanoid robot NAO is the most frequently used. Although there is limited evidence guiding the selection of the most suitable SAR model for physiotherapy applications, NAO has been commonly adopted in aged care and pediatric rehabilitation contexts, noted for its good acceptance by users and physiotherapists and movement capabilities [13,45]. The prevalent use of NAO in clinical settings may stem from its perceived usefulness in prior feasibility tests [46], its commercial availability and its well-established functional and technical capabilities [47].

Stakeholder Involvement in the Design of SARs and Intervention Protocols

The involvement of domain experts (physiotherapists) and end users (clinical populations) in the design of the SAR system and the intervention protocols was investigated, with a focus on understanding whether the systems adequately meet the needs of important stakeholders. The findings show a lack of participation from key stakeholders in both processes. Among the 13 included studies [4,24-35], only 2 studies [4,35] appeared to have involved end users in the design and development phase, while the remaining studies either did not report or did not engage stakeholders during these stages. In Back et al's study [35], participants provided feedback on exercise programs to improve their effectiveness. In Carrillo et al's study [4], the authors emphasized the early engagement of patients and physiotherapists in the design and development of SARs, highlighting the benefits of overcoming technological limitations, fostering effective engagement with end users, and facilitating the development of the robot's demonstration function. A previous study has identified the value of stakeholder input in robot development, as it aids in identifying potential uses for developers, pinpointing flaws in current robot designs to avoid, and suggesting improvements to ensure usability, particularly in health care settings [48].

Limitations in the Current Deployment of SARs With Clinical Population

The majority of studies reported limitations within their findings, particularly regarding small sample size [28,29,31,35], challenges in patient recruitment [31,33], the robot's design and technical capabilities [33-35], intervention protocol design [4,24], and evaluation methods [24,32,33]. Meanwhile, despite significant efforts in the application of SARs in physiotherapy, many of the studies are primarily pilot studies intended to pave the way to clinical trials with end users. However, they often fail to progress into larger studies due to the various limitations highlighted in Lo's [49] paper, such as the inappropriate selection of control groups to assess therapeutic benefits, the absence of power calculations to detect minimally clinically important differences, and insufficient detail in robot rehabilitation protocols, hindering reproducibility. The current included studies have flaws, such as slow patient recruitment processes [31,33] and small sample size [28,29,35]. This could

XSL•FO
RenderX

potentially compromise the validity of these trials and their impact on the clinical evaluation of the effect of SARs on patient outcomes.

Other limitations stem from the shortcomings of the current SAR designs and technological limitations, such as pelvic movement robustness, system overheating [34], robot size that affects exercise variety [35], and system readiness and malfunction [33]. This aligns with a study that investigated NAO-assisted pediatric CP rehabilitation, where most physiotherapists considered system or hardware failures during sessions as crucial features needing improvement [50].

In addition, the personalization of the robots to adapt to the user's mood, fatigue, and performance variations during long-term involvement, such as in rehabilitation, remains a major challenge. In a review analyzing patients' and clinicians' opinions on the use of SARs in rehabilitation, the loss of user interest frequently arose as a concern [51]. This could pose a challenge in applying SARs when working with vulnerable user populations, supporting self-rehabilitation, or long-term exercise programs for chronic conditions [33].

Previous papers have described several barriers to the integration of SARs in clinical settings [44,49]. When recruiting end users (clinical populations) in clinical trials, several ethical issues must be carefully considered regarding patient physical and psychological safety, especially when involving vulnerable clinical populations (eg, children or people with cognitive impairments) [52]. Another significant hurdle is justifying the investment in clinical SAR research without clear economic or clinical evidence of its cost-effectiveness, which may impede the adoption of SARs in clinical settings. In addition, conducting research in the clinical setting can be time-consuming, as it requires multidisciplinary collaboration between robotics and health science experts who are rarely co-located [43]. These factors may indeed contribute to the high budget requirements of robot research in clinical settings.

Strengths and Limitations of This Scoping Review

A strength of this scoping review is the interdisciplinary review team with expertise in the fields of physiotherapy (JH and MF), robotics (PCM), and scoping review methodologies (MF). This interdisciplinary perspective was important for identifying relevant locations to search, terms to use, and knowledge of disciplinary publication conventions. While numerous medical and engineering databases were comprehensively searched, citation tracking was limited to short reports that otherwise met the inclusion criteria for pragmatic reasons. This may have resulted in the omission of potential studies suitable for inclusion, but this risk is considered minimal given that the citation tracking found no further eligible studies for inclusion.

Furthermore, one team member led the majority of title and abstract screening, data extraction, synthesis, and analysis. This approach may introduce bias into the study exclusion, data extraction, and synthesis processes, potentially leading to incomplete data capture due to the risk of overlooking relevant information and nuances [53]. The primary reviewer's limited experience in scoping review methodology may further compound these potential biases [53]. However, this risk was counterbalanced in this review through the auditing of processes and data, the use of collaborative review tools with clear audit trails, and regular meetings for confirmation of decisions and team endorsement to progress after each review stage.

Conclusions

This scoping review identified what is currently known about the usage of SARs in physiotherapy interventions and activities with clinical populations. Despite the limited publications on this topic, the review offers insights into SAR design and application areas in physiotherapy interventions. This review has highlighted the future potential of SARs to be increasingly applied in health care settings. Future research should prioritize addressing the limitations in intervention design and evaluation methods to enhance the quality of evidence in this field. There is a critical need to resolve technical issues associated with SARs, such as system readiness, malfunction, size restriction, and overheating, to enhance the quality of interventions. Engaging key stakeholders, including physiotherapists and clinical populations, at all stages of SAR design and development is essential to overcoming technical challenges and promoting user acceptance. In addition, conducting more clinical trials and using reliable and valid clinical outcome measures are essential steps to investigate the effectiveness of SARs in promoting health outcomes.

Acknowledgments

We would like to express our gratitude to Cassandra Freeman, the academic librarian at Monash University, for her invaluable assistance with the electronic search process. Her expertise and guidance were crucial in identifying and accessing relevant resources for this review.

Authors' Contributions

MF and PCM defined the scope of the review. JH conducted the article search, screening, and data extraction from selected publications. MF and PCM validated the screening and data extraction processes of the selected articles. JH wrote the original draft and MF and PCM reviewed and edited the manuscript.

Abstract

Background: Health care is shifting toward 5 proactive approaches: personalized, participatory, preventive, predictive, and precision-focused services (P5 medicine). This patient-centered care leverages technologies such as artificial intelligence (AI)–powered robots, which can personalize and enhance services for users with disabilities. These advancements are crucial given the World Health Organization's projection of a global shortage of up to 10 million health care workers by 2030.

Objective: This study aimed to investigate the acceptance of a humanoid assistive robot among users with physical disabilities during (1) AI-powered (using a Wizard of Oz methodology) robotic performance of predefined personalized assistance tasks and (2) operator-controlled robotic performance (simulated distant service).

Methods: An explorative qualitative design was used, involving user testing in a simulated home environment and individual interviews. Directed content analysis was based on the Almere model and the model of domestic social robot acceptance.

Results: Nine participants with physical disabilities aged 27 to 78 years engaged in robot interactions. They shared their perceptions across 7 acceptance concepts: hedonic attitudes, utilitarian attitudes, personal norms, social norms, control beliefs, facilitating conditions, and intention to use. Participants valued the robot's usefulness for practical services but not for personal care. They preferred automation but accepted remote control of the robot for some tasks. Privacy concerns were mixed.

Conclusions: This study highlights the complex interplay of functional expectations, technological readiness, and personal and societal norms affecting the acceptance of physically assistive robots. Participants were generally positive about robotic assistance as it increases independence and lessens the need for human caregivers, although they acknowledged some current shortcomings. They were open to trying more home testing if future robots could perform most tasks autonomously. AI-powered robots offer new possibilities for creating more adaptable and personalized assistive technologies, potentially enhancing their effectiveness and viability for individuals with disabilities.

Introduction

Background

Health care is evolving to adopt a more proactive approach through the principles of personalized, participatory, preventive, predictive, and precision-focused services (P5 medicine). This approach to patient-centered care uses technologies such as robots. Artificial intelligence (AI) is central in the development of these robots to enhance care and treatment processes [1]. AI refers to "the application of computer technology to mimic

XSL•FO
RenderX

human intelligence and critical thinking" [2]. Through machine learning, AI systems can autonomously enhance their algorithms by learning from data and cognitive inputs without specific programming. This research field is rapidly expanding and becoming increasingly interdisciplinary, attracting a growing number of researchers.

AI techniques can enhance the management of comprehensive health services by supporting medical professionals such as physicians, nurses, and administrators [3]. For example, AI can provide timely access to medical information, streamline hospital operations, and ensure patient safety by improving medication management and care engagement [4]. Furthermore, AI may optimize logistics, such as the just-in-time delivery of drugs and equipment, and improve training for health care personnel, potentially reducing disparities between urban and rural health care services [3]. Furthermore, AI systems have shown promising results within health care in predicting conditions such as sepsis, cancer, and cardiovascular risk and monitoring vital signs in intensive care units [5-7].

Physical AI (PAI) [8-10] encompasses the application of AI technologies within physical systems, devices, and environments, enabling the performance of tasks that involve physical interaction or manipulation in the real world. In contrast to software-based AI, which functions in digital settings, such as data analysis, natural language processing, and web-based recommendation systems, PAI is evident in concrete, real-world applications. Examples of PAI include robotics, intelligent sensors, autonomous vehicles, and other cyberphysical systems that merge computational intelligence with physical functionalities [8-10].

AI-powered robotics in health care may offer a range of potential benefits that could revolutionize the field [11]. These systems provide precision and consistency in tasks, often surpassing human capabilities. Precision is particularly vital in surgeries to avoid adverse events and harm to patients. AI-powered robotics also facilitate telemedicine, allowing health care professionals to conduct consultations and services remotely, thus extending medical services to underresourced areas [12]. Such developments are crucial as the World Health Organization has highlighted global staffing challenges, projecting a potential shortage of up to 10 million health care workers by 2030 [13]. To address these challenges, the health care sector is increasingly adopting robotics and AI to mitigate workforce shortages. AI-powered robots may not only support complex medical procedures but could also assist in daily care activities, potentially reducing the workload on health care staff. In addition, robots integrated with AI could play a pivotal role in personalizing, adapting, and improving services to users with disabilities [12]. Despite the high initial costs of implementing AI-powered robotics in health care, the long-term benefits, streamlined processes, and overall cost savings could significantly improve the efficiency and accessibility of health care delivery [14].

Related Work

The field of scientific robotics is advancing the development of social assistive robots capable of adapting to local social norms, interpreting human emotions and desires, and learning by emulating human behavior. While these socially assistive robots primarily offer companionship and facilitate basic exercises, their capabilities in carrying out a variety of physical assistance tasks, such as carrying and delivery, are still limited. Robots able to assist people physically (carrying and delivery) include robots such as Care-O-bot, Doro, TIAGo, Lio, EVE, and Hobbit. They can be remotely controlled via home services or preprogrammed to operate autonomously, performing tasks primarily ordered through a tablet [15-17].

Research indicates that older adults generally perceive socially assistive robots as enjoyable, friendly, and safe [18,19]. However, studies by Wu et al [20] and Lee et al [21] highlight that older individuals without functional impairments find little relevance in these robots. The domain of assistive robotics for individuals with physical disabilities, whether young or old, remains nascent. Sørensen et al [22] concluded in their review that robots designed to assist with a variety of physical tasks currently demonstrate an inadequate level of technical readiness for home use, particularly due to their lack of personalization and overall preparedness for everyday assistance. A key challenge for effective assistive robots is managing a wide variety of assistive situations and tailoring robots' interactions to the living contexts and preferences (or habits) of the individuals they assist [23]. So far, assistive robots that provide physical assistance have had limited capabilities for detailed personalization, which is essential for effectively serving their users [15]. However, recent advances in AI may enable these robots to adapt to their users' environments and offer services in a more personalized manner [22].

Previous studies highlight that robot personalization is crucial for user acceptance as it aligns robots with the users' preferences and needs, thereby enhancing their willingness to use them [19,24,25]. Rather than taking over enjoyable activities that contribute to physical activity, robots should assist with challenging or energy-draining tasks, thus allowing users to focus on preferred activities [15]. However, personalization can be costly and time-consuming and requires ongoing technical support as users' needs evolve with their health status. Given these challenges, multidisciplinary research, including participatory design in PAI, is essential [26]. PAI combines insights from technical and human sciences to develop robots that intelligently interact with their physical environment, adapt to malfunctions, and integrate with existing systems. This approach fosters innovation and ensures that robots are practical, safe, and effective in dynamic real-world settings [4].

Currently, there is a lack of knowledge about user acceptance of robots able to assist physically or of PAI among individuals with physical disabilities. In this paper, we present the results of a multidisciplinary study investigating individuals with physical disabilities' acceptance of a humanoid robot (EVE) providing personalized assistance in a simulated home setting.

Theoretical Frameworks for Assessing Acceptance of Technology

In total, 2 models have frequently been used to assess acceptability in users of assistive and social robots: the Almere model [27] and the model of domestic social robot acceptance (DSRA) [28]. The Almere model by Heerink et al [27] extends

XSL•FO
RenderX

the unified theory of acceptance and use of technology [29] by including factors related to social interaction. The model's effectiveness has been evaluated through controlled experiments and longitudinal data collection involving 3 different assistive social robots in older adult care facilities and homes. The findings demonstrated significant support for the model and, thereby, contribute to the understanding of the factors influencing the acceptance of assistive social robots among older users. Heerink et al [27] highlight the importance of considering both functional and social variables in the design and implementation of these technologies.

DSRA [28] is rooted in the theory of planned behavior and extends it by incorporating factors specific to the context of domestic social robotics. These include utilitarian and hedonic attitudes, social and personal normative beliefs, and control beliefs. The study's [28] findings underscore the importance of considering these factors in the design and development of social robots to ensure their acceptance and integration into domestic settings.

In this study, we used these models as frameworks in a qualitative investigation of acceptance in potential future users of humanoid robots that are able to assist their users physically. We use the term *physically assistive robots* in this paper.

Objectives

People with physical disabilities, whether from disease or injury, encounter obstacles in their everyday activities and social participation. Many rely on formal or informal caregivers for assistance with activities of daily living. Upcoming demographic shifts pose significant challenges to the availability of home care services and assistants, potentially affecting individuals' ability to access necessary support [15].

The aim of this study was to investigate the acceptance of the prototype humanoid assistive robot EVE in individuals with physical disabilities during (1) AI-powered (using a Wizard of Oz methodology [30,31]) robotic performance of predefined personalized assistance tasks and (2) operator-controlled robotic performance.

In addition, we explored potential users' perspectives on how physical robotic assistance might impact their independence and autonomy.

On the basis of the models used as frameworks, we also suggested changes to the concepts we found more prominent when investigating acceptance of robots primarily designed for physical assistance rather than social interaction.

Methods

Study Design

This study used an explorative qualitative design, with data collection consisting of user testing in a simulated home environment and individual interviews. We used human-centered design (HCD), a creative approach to problem-solving that starts with understanding the needs of the people one is designing for and ends with solutions tailored to their needs. HCD emphasizes incorporating the end user at the center of the design process, ensuring that products or services are tailored to meet their needs and enhance usability [15,32]. The process is iterative, involving multiple stages of prototypes and tests to refine and validate the service based on user feedback, ensuring that the service is usable in real-world scenarios [33]. As recommended for HCD, we worked iteratively and in a multidisciplinary manner with robot engineers; robot operators; and, most importantly, the potential future users we targeted—individuals with physical disabilities [34]. We define usability as "the extent to which a system, product or service can be used by specified users to achieve specified goals with effectiveness, efficiency and satisfaction in a specified context of use" (ISO9241) [35].

Before the user test, we asked the participants for which tasks they would find it most useful to receive physical assistance from a robot. We then shared these insights with the robot engineers, enabling the robot operators to practice performing these specific tasks and make necessary adjustments to align with the robot's current technical capabilities.

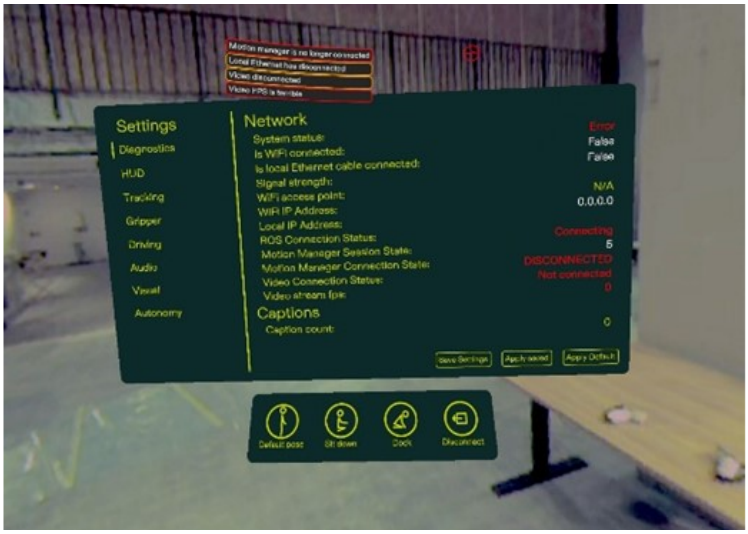
First, user testing [36] of the robot was conducted in a simulated home environment, allowing participants to interact with the robot in a realistic setting. This was followed by video-stimulated interviews with the participants approximately 1 week later, providing them with an opportunity to reflect on their experiences. For data collection and analysis, we used a directed approach [37] based on the 2 theoretical frameworks: the Almere model and the model of DSRA. These frameworks guided the evaluation of how users with disabilities accepted robot home assistance.

The Robot

This project is part of a broader project conducted at the University of Agder focusing on exploring humanoid robotic applications in health care. The university has acquired a state-of-the-art humanoid robot named EVE (Figure 1) specifically for research purposes.

XSL•FO
RenderX

Figure 1. The humanoid robot EVE in the user testing scenario (pictures by LS).



EVE is a full-size humanoid robot designed for research and logistic applications. Standing at a height of 186 cm and weighing 80 kg, EVE maneuvers on 3 wheels, equipped with grippers enabling it to manipulate objects of varying sizes. The robot is equipped with cameras and sensors to perceive and interact with its surroundings. Its mobility, dexterity, and balance allow it to navigate complex environments and manipulate objects effectively [38].

The robots' AI-powered movements are trained using a diverse dataset from 30 EVE robots, enabling it to perform a wide range of tasks, from tidying to social interactions. This base model is then fine-tuned for specific capabilities, such as door manipulation or warehouse tasks. Using data instead of code, robot operators train (using virtual reality glasses and controllers) and expand the robot's abilities to increase flexibility in the robot's functions [38].

In this study, the robot was controlled using Meta Quest 3 glasses. Operators were given a stereoscopic view through 2 fish-eye lenses calibrated to provide depth perception. The Meta Quest 3 controllers were used to manipulate the robot's wrist, whereas an algorithm (self-developed Sync/Robot Control; Figure 2) translated these movements into more complex actions, enabling the robot to mimic human motion based on wrist inputs.

Figure 2. Sync/Robot Control (picture by 1X Technologies, reused with permission).

Recruitment

Participants were recruited through purposive sampling by coordinators of health services at a spinal cord ward at a rehabilitation hospital in the eastern region of Norway and a municipality in the southern region of Norway. The inclusion criteria for this study were individuals aged ≥16 years with physical disabilities, living at home, and receiving formal or informal care.

The coordinators suggested relevant candidates to the researcher based on the inclusion and exclusion criteria (Textbox 1). The first author, LS, then contacted the candidates with information about the study with an invitation to participate. Seven of the participants had previously taken part in a focus group activity [15] where they received information about the robot and saw videos of the robot performing different activities before their interaction with it (although not in the context of health care). The 2 remaining participants received information about the robot and watched the same videos after agreeing to take part in this study.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Aged ≥16 years
- Having physical disabilities requiring physical assistance with personal care or activities of daily living

Exclusion criteria

- Cognitive challenges or language challenges that would make commanding the robot or answering questions in Norwegian difficult

Data Collection and Procedure

The user tests took place in a hospital room designed as an apartment that is used for patients to practice becoming independent before discharge. The apartment has a living room with a table, chair, closet, and television. It also includes an accessible kitchen and bathroom. The control room for controlling the robot through virtual reality was set up in the adjacent room. It included live video feeds displayed on a screen, live audio from the robot, and an additional speaker system (Jabra speakers) to enhance sound quality. The participant-robot interaction was video recorded using 2 cameras in the room (Multimedia Appendix 1). The participants' interaction with the robot had 3 parts (Textbox 2). First, participants watched EVE perform 5 tasks. The tasks were identified as useful in a previous study investigating users with physical disabilities' needs for assistance [15]. We used a Wizard of Oz approach [30,31], in which EVE appeared to perform tasks autonomously while a human operator discreetly controlled the robot behind the scenes unbeknownst to the participants to simulate its functionality. This technique is often used in developing and testing technologies such as health care robots and enables researchers to evaluate interactions, collect user feedback, and identify improvement areas before fully automating the system [30,31,39]. The presence of the operator was revealed to participants at the conclusion of the study.

Second, the participants were instructed to ask the robot to bring a drink of water. Before the user testing, LS had asked each participant how they would need and prefer to have a drink of water served. After the participants had asked the robot to bring the water, the robot nodded for confirmation and went to the kitchen to bring water (Wizard of Oz methodology). Details of the personalized service are described in Textbox 2.

In the third part of the interaction, the participants were instructed to call the operator of the robot to request assistance with a chosen task. This part was designed to simulate a scenario in which a remote operator could control the robot for tasks that were not yet automated (human in the loop). Participants selected tasks that they often needed help with, such as picking up an item from the floor (Textbox 2). The participant first called out "Hallo," prompting the operator to connect to the robot via voice and ask how they could assist. After retrieving the requested item, the operator asked (through the robot) if any further assistance was needed before saying, "just call again if there is anything you need. Have a nice day." The robot then returned to its parking space, which was chosen by the participant. Some preferred the robot to be parked in the living room, whereas others wanted it out of sight, in which case it returned to the kitchen. The user test was facilitated by LS and the second author, DTSJ, in collaboration with the operators of EVE.

Approximately 1 week after the interaction, participants were interviewed at a time and place of their choosing. Seven interviews took place in the participants' homes, whereas 2 were conducted at a hospital due to the participants' short-term admissions. The first author used video-stimulated recall, a retrospective think-aloud interview technique, to help participants recall, discuss, and reflect on their robot interaction [40].

The interviews were conducted by LS, an occupational therapy specialist with knowledge of the participants' functional impairments and daily challenges but no clinical relationship with them. The semistructured interviews were guided by acceptance concepts from the Almere model and the model of DSRA, with additional questions focusing on independence and autonomy (Multimedia Appendix 2).

XSL•FO
RenderX

Textbox 2. The robot-participant interaction in 3 parts.

Demonstration of robot tasks

- Tidying up, including picking up trash from the table and placing it in the garbage bin
- Retrieving a towel from the floor and placing it in the laundry basket in the bathroom
- Pulling down a roller curtain using a string
- Verbally announcing the day's schedule
- Opening a bag of potato chips and pouring them into a bowl

Bringing the participant a drink of water, tailored to each user's specific needs

Four participants received a water bottle that the robot obtained from the fridge:

- For one participant, the robot placed the water bottle on the table (participant 6).
- Three participants received the water bottle in their hand (participants 1, 2, and 7). One participant had paralysis, which required the robot to hold the bottle still for some time until the participant managed to get a grip around the bottle. The robot released the grip as the participant said thank you.
- One participant who also had paralysis had a glass delivered to his hand in a similar way (participant 3).
- Two participants had their glasses placed on a table in front of them. The robot then filled a mug of water in the kitchen, came to the living room, and filled the glass of water. One was a regular glass (participant 4), and the other was a wineglass. This participant preferred a wineglass to be able to grip and hold it by the stem (participant 8).
- One participant who was not able to move their arms had the robot deliver a glass with a straw to a stand in front of their face that was mounted on the electric wheelchair (participant 5).
- One patient was served the drink of water in a bottle with a straw and drank from the straw as the robot held the bottle (participant 9).

A task of the participants' own choosing

- Picking up an object that was dropped on the floor (participants 1, 8, and 9)
- Bringing the participant a newspaper (participant 6)
- Bringing a blanket to lay over the participant's legs (participant 2)
- Taking something out and down from a top cupboard in the kitchen (participant 7)
- Taking out a bag of snacks from a kitchen drawer, opening it, and bringing it to the participant (participant 3)
- Scratching the back of the participant's head using a scratching stick (participant 5)
- Bringing the television remote control and placing it in the participant's lap (participant 4)

Analysis

The interviews were transcribed verbatim by the first author, omitting minor speech hesitations to improve readability. For the analysis, we used the 16-step process described by Assarroudi et al [41] in a combination of deductive and inductive approach [37,42]. First, in the directed approach, the data were coded deductively using a structured categorization matrix [41] based on the predetermined codes from the Almere model and the model of DSRA (Multimedia Appendix 3 [43-51]). According to Hsieh and Shannon [37], directed content analysis is useful when a theory exists about a phenomenon that needs further refinement or development through qualitative research [37]. Second, inductive coding was performed to search for additional concepts that might affect the acceptance of the assistive robot and concepts that needed to be modified or could be excluded. All data analysis was performed using the NVivo software application (version 14; Lumivero). The initial coding was performed by LS. An extract from the coding was then reviewed by and discussed with all authors until an agreement was reached about categories and subcategories. The findings were finally organized into 7 categories with 13 subcategories. Table 1 shows an example from the analysis process.

XSL•FO
RenderX

Table 1. Example of the analysis process.

Participant statement	Codes	Category
"I tend to drop my phone on the floor. If the robot could pick it up, that would definitely be a useful task for me."	• Pick up an item	Usefulness
"...no, giving it verbal commands would not be hard for me, if you have a pet you're quite used to it."	• Voice commanding; not perceived difficult	Ease of use
"I wonder a bit about the monitoring, if people can see and hear what's happening in my house through the robot, I wouldn't like that."	• Distant controlling • Monitoring	Privacy

Ethical Considerations

All methods were carried out in accordance with relevant guidelines (Helsinki Declaration) and national laws. This study was approved by the Research Ethics Committee at the Regional Committees for Medical and Health Research Ethics (467937), the University of Agder- Norway's ethical board, and Sikt—Norwegian Agency for Shared Services in Education and Research (343362). All participants gave their written informed consent to take part in the study, with the possibility to withdraw at any time. To ensure confidentiality and anonymity throughout the analysis, identifiable details in the interviews were anonymized, and participants and other mentioned persons were assigned numbers. As the robot continuously records picture and sound input and stores these data, participants signed an additional consent form for this data collection. All data stored in the robot were deleted 1 week after the robot-participant interaction. Participants were not compensated for participation, but travel expenses were compensated.

Results

Overview

Eleven persons (Table 2) with physical disabilities (3 women, 8 men) agreed to participate in the user tests. Of these 11 individuals, 2 withdrew (1 woman and 1 man), 1 because of illness and 1 because the assistant called in sick that day. The participants were aged between 27 and 78 years, with a median age of 59 years. One participant had muscular dystrophy, 7 had a cervical spinal cord injury (SCI; paralysis to arms and legs), 1 had a thoracic SCI (paralysis to the legs), and all were wheelchair users (full time).

Table 2. Participant characteristics.

Participant ID	Sex	Age (years)	Diagnosis	SCI[a] level	Assistance (h/wk)	Source of assistance
1	Male	69	SCI	C5-6	31.5	Assistants and partner, parents, or children
2	Male	42	SCI	C5-6	3	Home nursing services; assistants; partner, parents, or children; and friends
3	Male	37	SCI	C6-7	45	Home nursing services; assistants; partner, parents, or children; and friends
4	Male	27	SCI	C5	91	Home nursing services; assistants; partner, parents, or children; and friends
5	Male	59	SCI	C3	154	Assistants; partner, parents, or children; and friends
6	Male	78	SCI	Th4-5	31.5	Home nursing services and partner, parents, or children
7	Male	31	SCI	C5	52	Home nursing services; assistants; partner, parents, or children; and friends
8	Female	78	SCI	C6	90.5	Home nursing services; assistants; and partner, parents, or children
9	Female	60	Muscular dystrophy	Lim girdle	168	Assistants; partner, parents, or children; and friends

[a]SCI: spinal cord injury.

Although many of the participants had the same diagnosis, the group was heterogenous in terms of level of independence. Table 3 shows the participants' level of independence according to the Barthel Index for Activities of Daily Living [52], which assesses independence on a summarized scale from 0 to 20, where 20 is independent. All participants received various degrees of assistance with activities of daily living (Table 3). All participants considered themselves above average in being familiar with technology, such as smart house technology, computers, apps, and technical assistance devices. Two participants lived in accessible apartments (one rented and one owned). Seven of the participants lived in private accessible houses that were adapted for their particular needs, with automatic doors or windows, wider doors, ramps, elevators, and no thresholds.

9	0	0	0	0	0	0	0	0	0	0	0

[a]The Barthel Index for Activities of Daily Living assesses the level of independence on a scale from 0 to 20, where 20 is independent.

The extracted main categories based on the concepts from the Almere model and the model of DSRA were hedonic attitudes, utilitarian attitudes, personal norms, social norms, control beliefs, facilitating conditions, and intention to use (definitions can be found in Multimedia Appendix 3). These concepts with subcategories are shown in Table 4. The results related to each category and subcategory will be presented in the following sections. We made some smaller changes to the subcategories from the theory based on the statements from the participants. This is further elaborated on in the Discussion section.

Table 4. Acceptance model categories and subcategories—used, modified, excluded, and added.

Category	Hedonic attitudes	Utilitarian attitudes	Personal norms	Social norms	Control beliefs	Facilitating conditions	Intention to use
Subcategories used	• Enjoyment	• Perceived usefulness • Ease of use • Perceived adaptiveness	• Privacy • Trust	• Social influence • Perceived sociability • Societal impact	• Anxiety • Safety	• No subcategories	• No subcategories
Modified subcategories used	• Attractiveness • Appearance, including animacy	—[a]	—	—	—	—	—
Excluded subcategories	• Social presence • Companionship	—	—	• Status	• Self-efficacy • Cost	—	—
Added subcategories	—	—	• Independence • Autonomy	—	—	—	—

[a]Not applicable.

Altogether, 573 statements were coded from the transcripts. Of these 573 statements, 109 (19%) were used more than once as they fit in more than one subcategory. Of the subcategories, the participants spent most time talking about the robot's functions and how it could assist with their needs. The usefulness category included 123 statements, with the most frequently mentioned tasks being picking up items dropped on the floor and bringing a drink of water. We used the International Classification of Functioning, Disability, and Health (ICF) to organize the findings (Table 5). The ICF is a framework developed by the World Health Organization for measuring health and disability at both the individual and population levels. Other authors have previously used the ICF concerning socially assistive robotics to evaluate assistive technologies' impact on users' lives and group activities that humans perform [15,53,54].

ICF[a]	Useful assistance categories and tasks

Activity and participation	• Bringing items
	  • Water
	  • Snacks
	  • Preheated food
	  • Medication
	  • Blanket
	  • Newspaper
	  • Glasses
	  • Urine drainage bag
	  • Phone
	  • Clothes
	  • Shoes
	  • Remote control
	• Picking up an object dropped to the floor
	• Calendar reminders
	• Assisting with transfers
	• Emergency alerts
	• Housework
	  • Tidying
	  • Wash windows
	  • Putting things in or taking things out of the dishwasher
	• Assisting with technical aids
	  • Moving technical aids; bringing, for example, wheelchair, toilet chair, or walking frame
	  • Putting on tarpaulin
	  • Changing the position of the bed
	  • Controlling the lift and car lift
	• Opening doors
	• Charging phones or tablets

Self care	• Scratching • Putting on or taking off a comforter

[a]ICF: International Classification of Functioning, Disability, and Health.

Hedonic Attitudes

Appearance (Attractiveness) and Animacy

The participants' statements about the robot did not relate to its attractiveness and, thus, did not fit the predefined subcategory of attractiveness from the model of DSRA. However, they were concerned with how the robot should look and its human likeness. Therefore, we named this subcategory Appearance and Animacy. Half of the participants perceived the robot as overly large and described it as bulky and masculine. Others valued the robot's ability to reach levels inaccessible to them, stating that this was particularly beneficial for those using wheelchairs. Participants offered no specific comments about the robot's hands, which featured very mechanical grippers. They did not express a preference against more humanlike fingers, recognizing the functionality of the grippers as paramount. All but 1 participant appreciated the robot's humanlike appearance. They did not desire a greater human likeness, explaining that they preferred it to retain its robotic nature to avoid a "creepy" overly humanlike appearance:

> *They have made a friendly design on it and stylish in relation to color and so you should not make it more human-like than that really. There is something about the fact that with a robot being a robot...you should not pursuit more resemblance to humans, but in relation to meeting a robot it's easier if it looks like a human than not at all. But maybe not too much.* [Participant 2]

However, they were interested in the robot having a humanlike voice and the option to personalize this voice according to their preferences. While some participants appreciated the robot's mobility on wheels, others expressed a preference for a smaller, lighter robot with legs capable of walking in stairs. One participant expressed a wish for the robot to have a humanlike mask and even hair:

> *No, first of all, it could have had completely different colors, been a little neater, smaller, not so dominant in the surroundings and then I think maybe you could also make a more human mask, get hair on the head, more human details, as human as possible for a robot.* [Participant 1]

Enjoyment

As the primary focus of the user interaction was the robot providing practical assistance and not being a social figure, we did not particularly ask about the participants' level of enjoyment. Still, 3 participants mentioned that they enjoyed the encounter and that they believed that it would be fun to have a robot assisting them:

XSL•FO
RenderX

> *I've actually always liked [technology] and I liked it better 10-20 years ago than I do now...I think this is great fun, but it will probably also vary, but I just think it would be fun.* [Participant 9]

Another participant stated the following:

> *...yes, it's very funny this robot helping out, this is the future, but it still seems far ahead...I thought it had come further. It would have been really fun to test the robot when it was fully AI powered. I'm very excited to see how smart it will be to understand its surroundings.* [Participant 2]

Utilitarian Attitudes

Perceived Usefulness

All except 1 participant expressed being impressed by the robot's functionality, particularly as the robot picked up a bag of chips, opened the bag, poured it into a bowl without spilling anything, and then served the bowl to the participants. During this task, the participants could see both finer and grosser movement skills from the robot. The one participant being most skeptical referred to the robot as an early-stage prototype, relating this mainly to its speed:

> *No, putting aside that I found it looking scary, I thought it might be only the second version at best, and its movements were very slow.* [Participant 1]

Another participant stated the following:

> *I was skeptical about what he could pick up...but I was very impressed when he picked up that bag, and no spilling at all, then I was very impressed with it, yes thought it worked really well.* [Participant 6]

All the participants mentioned that tasks such as tidying, bringing them things, and picking up things they dropped on the floor would be particularly beneficial for them. The tasks that they chose for the interaction with the robot were of such character and were personalized to each participant's needs (Textbox 2). The participants appreciated that the robot could serve a drink specifically aligned to their needs and respond to their commands for a particular action. Several of the participants chose for the robot to pick up an item from the floor. Most of the participants were not able to do this if they, for example, accidentally dropped their phone or other items.

The participants mentioned other assistance tasks that would make the robot useful for them: turning lights off and on, answering the door, reading and answering mail, helping write signatures and other notes, scratching when itching, attaching iPads to charging cords, putting cutlery in and out of the dishwasher, serving guests with drinks and snacks, turning on and filling the washing machine, adjusting the comforter if they were too hot or cold, supporting them when transferring to the toilet, and adjusting the electric bed.

The interaction with the robot also led the participants to expect more advanced tasks, including tasks that would require the robot to function outside the home. A few participants mentioned assistance with their technical aids. One expressed that, if the robot could follow him to his car and then roll his walking frame back to the apartment, that would be very useful for him. Taking the tarpaulin off his outdoor electric wheelchair and then putting it back on when he returned would also be highly beneficial. One participant wished for the robot to be her walking partner. She wanted the robot to assist with minor repositioning of her hand so that she could control the joystick of her wheelchair without fear of her hand falling off the armrest. Another participant wanted the robot to control his car lift for more effective boarding, and one suggested that the robot could serve him water outside on his veranda during the summer.

Apart from physical assistance tasks, all but 1 participant appreciated that the robot reminded them of their agenda. They suggested integrating the software with their phones, noting that registering appointments and activities in multiple digital calendars would be cumbersome:

> *That [robot giving reminders] would have been useful for me, just ask my wife (laughter).* [Participant 4]

During the user test, the participants interacted with the robot both in an automated mode (using a Wizard of Oz methodology) and a mode in which the robot was operator controlled, simulated as "municipality services-personnel" controlling the robot. They found the ability to operate the robot remotely to respond to emergencies or perform actions that the robot had not yet learned to be both useful and necessary. However, they preferred the robot to be automated for most tasks. One participant stated the following:

> *It's good to have the opportunity to do that [distant operating], but then, you should be told that "now we can see into your home."* [Participant 4]

Another said the following:

> *Yes, so it has to have that function...well there will always be some challenging tasks, there are no homes or institutions that are the same, so there may be physical things that make it possible for it to mess up.* [Participant 2]

When discussing how the robot could be useful for fulfilling their needs, the participants that received assistance in personal care stated that the robot could never replace their human carers completely. By watching the robot in action, they realized that it could not assist them in tasks such as using a breathing mask or catheterization. One participant stated that, the previous year, she could have benefitted from the practical assistance that was demonstrated by the robot, but as her function had deteriorated, especially her breathing and the risk of having something stuck in her throat, she could only be without her human helpers for very short periods of the day.

Several of the other participants stated that they already had assistants or home services attending to most of their needs. Still, the participants sometimes experienced pressure ulcers or infections, which forced them to bed rest. They suggested having the robot present during these periods to assist in fulfilling the tasks they needed.

However, most participants agreed that such a robot could replace some of their assistants' time and be particularly useful in the gaps when they did not have a human helper:

XSL•FO
RenderX

> *As a backup, they [the assistants] are out driving a lot with the kids to training and so on, and they are shopping for me, it's nice for me to be at home, but during summer I have to drink a lot of water, so then it could be nice [to have a robot assisting].* [Participant 5]

Ease of Use

Through the interviews, it appeared that the participants had above-average technological knowledge. They had advanced wheelchair controls, smart house functions, and different technical aids. None of the participants expressed any worries about being able to control the robot. All agreed that voice control was preferred. Some stated that a combination of voice and gestures and lights would be fine. All agreed that the robot would need to express some kind of confirmation on having received and understood a command, preferably through sound as the robot could be out of its user's sight at the time:

> *But you never know if the robot has confirmed or not...you need to know that it has received...if it repeats what it is supposed to do...that it confirms that it has received, for example when I ask for a glass of water, it should say "yes, it has been received, I will fetch a glass of water.*" [Participant 2]

One participant also commented that the robot's eyes and face should follow its users for more normalized communication. The participants expressed that the speakers and microphone for EVE would need to be of a better quality. All wanted a humanlike voice for the robot and the ability to choose the voice of the robot. One participant expressed that, similarly to his smart home control, he expected the robot to learn his voice and that he would be able to extend commands to the robot and they would learn from each other.

Perceived Adaptiveness

The participants expressed that the robot would need to be adapted to their particular needs. As most of the participants had reduced ability to grip objects, they were concerned with the robot handing over objects and particularly waiting to release the grip until they had managed to get a grip around the item. They mentioned the need for the robot to adapt to be able to navigate around the users' homes. Some were concerned with the robot's ability to understand the different Norwegian dialects:

> *So if...you can go in...and teach it commands, that you can go in and type in commands and then it will execute it, I think in Norway where are so many dialects, you have to find a way that you can override that [the programming]...so that the robot can teach itself.* [Participant 2]

Another participant stated the following:

[About receiving an object from the robot]It worked out really well. I was very unsure about when it would release the grip, because I was unsure if the operators were watching...I would like to have it like...if I said "ok," then it would let go, that it was sort of an agreement. [Participant 3]

Personal Norms

Privacy and Trust

Seven participants stated that they were not concerned at all with any privacy issues regarding having the robot in their homes. Even though they had been informed about how the robots used cameras for navigation and that remote operators would be able to connect through the robot, they did not find this disturbing. However, they did appreciate the idea of a sound or light announcing that someone was connecting from the operating central. Two participants were concerned about the idea that someone "looked" into their house without being informed. They suggested regulations that illegalized this and a log that could be checked for any distant use. One participant stated the following:

> *I haven't thought about privacy at all, because I would never communicate any details to such a machine anyway that I couldn't handle being exposed.* [Participant 1]

Another said the following:

> *It's kind of important that it [the robot] manages to do things automatically in relation to privacy...and so that no one sits looking into your house all the time, yes, because then you're alone, then you know that, this is my place and there's no one else lurking around.* [Participant 4]

All of the participants stated that they would trust the robot. One mentioned that he would trust it if he had a log to check for distant on-logging. They related this both to privacy issues and also physical safety. One participant said the following:

> *It will be the same as an alarm company...I have an alarm here...they can connect to the cameras at any time in theory, but you have to have confidence in it...and if someone abuses this, it must be prosecuted, so it's about trust and that you have legislation if something illegal was going to happen.* [Participant 2]

Autonomy and Independence

The participants had varying views on whether such a robot would increase their independence or autonomy. Most (n=7) believed that the robot could enhance their sense of freedom by assisting with necessary tasks, allowing them to do what they wanted, whenever they wanted, without waiting for assistants, home nurses, or family members. Two participants felt that the absence of a human caregiver and reduced need for constant human interaction would be advantages of robotic assistance. In addition, 2 participants mentioned that having robotic support during times without human assistance would make them feel safer rather than providing a feeling of autonomy:

> *Yes exactly, I think it's very fascinating and it's also a bit...because I get a little tired in my head from having people here all the time because...I cannot help but feel like being at "work" in a way, that I feel I have to be in such a nice positive mode and do some nice things [for and with the assistants]. Because even though I know that it is not in the job role of personal*

XSL•FO
RenderX

> *assistants, it is my life that should be lived the way I want to live it, but I have to practice that extremely much, to completely relax when there are other people in the house. Yeah, I wish I could zero out my head and I think I would have done that easier with a robot than a human in a way.* [Participant 9]

Social Norms

Social Influence

Within this subcategory participants shared how others' opinions on whether they had a robot as an assistant mattered to them. Four participants stated that others' opinions would not affect their decision to have robotic assistants as they did not care about others' opinions. Two participants were concerned about others' opinions, especially on the robot's physical appearance in the room when having visitors:

> *...it matters a little to me if they [guests] feel alright in room.* [Participant 9]

Three participants stated that, somehow, they were often affected by others' opinions, but this was not particularly connected to robotic assistance. They cared about whether others had opinions on having assistance in general and on using technical aids:

> *Yes, it matters to me what people think, whether it's robots or assistants or the wheelchair, so of course you have that in the back of your mind, but from experience, so...knowledge and exposure tend to solve a lot of it.* [Participant 2]

Another participant stated something similar:

> *I've actually thought the same about having assistants...yes that "he's in such a poor condition that he must have assistants," they'd probably think that it was very strange [to have robotic assistance].* [Participant 7]

However, most participants believed that opinions about robotic assistance would not be negative, whereas one participant was concerned that health care employees might worry about losing their jobs.

Societal Impact

In addition to discussing the robot as a potential assistant for themselves, the participants also talked about how the robot could be useful for others. Several of the participants were concerned about the challenges in health care and how this might affect access to help for people in need of assistance and saw robots as a natural part of future health care services. One stated that the home nurses were so busy all the time and it would be good if robots could take some pressure off them, acknowledging that robotic assistance might not involve direct care but could instead focus on meeting practical assistance needs:

> *I am very positive to the idea that health professionals should be relieved of all the running...not necessarily the care...like wound care, but ask if you're okay and so on...and serving breakfast or taking a breakfast order.* [Participant 3]

Sociability

The participants discussed the robot's communication abilities and whether these abilities were important to them. For instance, several of the participants stated that they felt that it was natural to be polite to the robot and thank it for its services. They attributed this to its human likeness. As mentioned previously, one participant expressed dissatisfaction with the robot's inability to make eye contact during communication, suggesting that eye contact would make the interactions feel more natural. Most participants indicated that they did not prefer or need to engage in extensive communication with the robot beyond issuing commands as they preferred to fulfill their social needs with other humans. However, some noted that social interaction with the robot could be beneficial for individuals who live alone or feel isolated.

Control Beliefs

Anxiety

None of the participants reported feeling general anxiety or fear during the interactions. At one point, the robot moved behind the participants to lower a curtain, which they could hear but not see. Despite this, none of the participants expressed feeling uneasy. However, some participants described the robot's appearance and movements as "somewhat frightening," "a little creepy," or "not particularly nice looking." One stated the following:

> *Yes, but it was really only when it came in there and did that stuff, when it took that blanket and bent down it was almost like a snake person...and it doesn't say anything...just completely silent, just some ventilators running that's what was a bit creepy.* [Participant 7]

Another participant said the following:

> *No, it wasn't uncomfortable at all, but I wondered what he was going to do, but then I looked to the side, and I saw the blind coming down, then he pulled it all the way down.* [Participant 6]

Safety

The participants reported feeling safe in the robot's presence, and it was suggested that the robot should be able to alert health services in case of an emergency. The participants who had children in the house did not feel particularly concerned about the robot causing any harm; they simply stated that they expected the robot to be safe before implementation. One participant stated the following:

> *No, not at all [felt unsafe] and it was because I saw that it was so steady on the wheels, I analyzed it before it started driving. Another thing is that if something were to happen that there could have been a connection so that he [the robot] could have notified someone, to call someone at the home-services station: "now you have to come."* [Participant 1]

Facilitating Conditions

Regarding physical facilitating conditions, all participants stated that their home was already wheelchair accessible, so both

XSL•FO
RenderX

placing the robot and the robot moving around was not seen as a problem:

...if people have a wheelchair, then it is very adapted for people who are on wheels, so in that sense, it is almost better that the robot is on wheels than if it should walk. [Participant 2]

This was supported by another participant:

> *Yes, it's good to have houses and apartments for wheelchair users because there are few thresholds, there are open solutions and things are kind of in such a way that it's easily accessible...I have my technical room around the corner there [I would have placed it there], but then it's a bit far away, so then it would take 20 seconds before he came into place, but if there are some automatic tasks, then it's ok.* [Participant 3]

Three participants expressed that they would prefer to have the robot placed in a separate room—to keep it out of sight—just as they did with other technical aids. Some participants were curious about the organization of a robot service. They expressed concerns that, if each robot required a separate remote operator, it would affect the possible societal impact.

Intention to Use

Although the participants were impressed by the robot's functions and its ability to perform tasks aligned to their needs, they did not see the robot as ready for implementation. However, they were willing to test the robot in their own home and were positive to using it when the technical readiness had progressed to a point at which the robot could perform most assistance tasks they needed autonomously. All participants saw the robot as a service to be combined with other assistance, and they would accept someone operating the robot from a distance if it was necessary. The mistakes that the robot made during the interactions, such as dropping an object or the fan being very loud at times, did not affect their willingness to have the robot at home. Some participants said the following:

> *...as long as it correct its mistakes.* [Participants 3, 4, and 6]

Another stated the following:

> *I can do that, I would be willing to try [the robot as a home service]...but of course I wouldn't have it instead of the care that the home care service comes with, I wouldn't replace that, no. So, care in the bathroom and care with inserts and things like that, I wouldn't have wanted to use a robot for those kind of tasks.* [Participant 6]

Discussion

Principal Findings

The aim of this study was to investigate the usefulness, ease of use, and acceptance of the prototype humanoid assistive robot EVE among users with physical disabilities, framed around key concepts from the Almere model and the model of DSRA: hedonic attitudes, utilitarian attitudes, personal norms, social norms, control beliefs, and facilitating conditions [27,28].

Our methodology used directed content analysis, initially applying a deductive approach to analyzing statements from participant interactions with the robot EVE. Subsequently, we adopted an inductive strategy, anticipating the discovery of statements misaligned with concepts from the Almere and DSRA models given their focus on assistive and domestic social robots for users without disabilities. Contrary to our expectations, the frameworks by Heerink et al [27] and de Graaf et al [28] aligned quite well with participant feedback, underscoring the relevance of these models even in contexts involving assistive robots for individuals with physical disabilities. However, we modified the subcategory Attractiveness to encompass the subcategories Appearance and Animacy. Participants were less concerned with the robot's attractiveness but more with its appearance, discussing issues such as size, speed, design, and anthropomorphism. Opinions on the robot's size varied among participants. Some felt that the robot was too large and appeared masculine, whereas others appreciated its ability to reach objects at higher levels. Most of the participants emphasized its humanlike appearance without it being unsettling. They preferred functional aspects over a fully humanlike appearance to avoid a "creepy" effect. This sense of discomfort has been termed the "uncanny valley" by Mori et al [55]. They noted that robots with humanlike features are generally more appealing to people but only to a certain extent. Beyond the uncanny valley, people's attraction turns into unease and a propensity to feel frightened.

While participants primarily valued the robot's assistive capabilities over its potential for entertainment, several noted that interacting with the robot was enjoyable and anticipated that having it at home would be fun. Hedonic factors such as appearance and enjoyment are crucial for acceptance and have been shown to directly influence the intention to use a robot [27,56]. Although robots designed for physical assistance are primarily utilitarian, they also incorporate hedonic aspects. Even if these hedonic elements are only partial, enjoyment remains a critical construct in any acceptance model for robotic technology.

The functionality of the robot impressed nearly all participants, especially its ability to perform precise tasks such as picking up and handling objects without spillage. Participants valued the robot's potential to assist with personalized tasks, although they recognized that it could not replace their human caregivers for more sensitive tasks. Participants also expressed ideas about how others might use the robot and noted that its deployment could potentially alleviate the burden on health care staff, highlighting its societal impact. Most participants in this interaction study had previously participated in a focus group that explored user needs and requirements after viewing videos of the robot EVE [15]. Although their identified tasks that would make the robot useful were similar to those mentioned in the focus group study and fell within the "Activity and Participation" category of the ICF framework [15,53,54], we observed that their expectations of the robot significantly increased after seeing it in real life. Studies on this issue present mixed results, revealing that users' expectations can either differ or remain consistent across virtual and real-life encounters with robots [57-59]. Real interaction may demystify a technology,

XSL•FO
RenderX

making it more approachable and less intimidating. Once participants witnessed firsthand what the robot could do, their comfort with the technology may have grown, consequently raising their expectations. Direct interaction exposes users to the robot's practical applications and capabilities, potentially surpassing their initial assumptions based on mere descriptions or videos. This exposure could shift their expectations as they begin to envision more ways in which the robot could be beneficial in their daily lives. Moreover, after experiencing the robot's assistance, participants might recognize that it can perform tasks more effectively or efficiently than anticipated. This realization leads them to expect more from future interactions, seeing the robot's potential more clearly and imagining broader or more sophisticated applications for its use. In addition, the fact that the tasks performed by the robot were personalized specifically to meet their needs and executed exactly as the participants had described may have enhanced the overall experience.

Participants familiar with various technologies expressed confidence in their ability to operate (ease of use) the robot, favoring voice control as the primary mode of interaction. Although the robot made some mistakes, such as freezing for some seconds or dropping an object, the participants did not react negatively to this, stating that this would be expected of novel technology. This finding is different from those of other studies whose participants became frustrated with the robots' errors [60,61]. It is likely that this could be related to age or previous experiences with technology. This highlights the importance of designing robots with effective error management and recovery strategies to minimize frustration and enhance user interaction.

The consensus on the necessity for robots to adapt to specific user needs highlights a critical area of development in assistive robotics [22]. This adaptation is particularly crucial in tasks such as handling objects with care and effectively navigating home environments. Traditionally, the capacity for robots to adapt to the unique needs of individual users has been seen as overly complex and cost prohibitive. The challenges stemmed from the need for sophisticated sensing technologies and algorithms capable of understanding and responding to a diverse range of human behaviors and environmental contexts. However, recent advances in AI have begun to shift this perspective. AI technologies, particularly those involving machine learning and deep learning, have made significant strides in enabling robots to learn from interactions and adapt their behaviors over time. It will now be possible to analyze vast amounts of data generated from user interactions to continually refine and improve robot performance according to specific user preferences and needs. The integration of AI allows for greater personalization in robotic systems, which has been highlighted as crucial for adoption in several studies [22]. This can include adjusting the grip strength when handling objects or enhancing the robot's ability to operate in complex environments, such as typical home settings where every space is unique.

To our surprise, privacy concerns were minimal among most participants despite their awareness of the robot's data collection capabilities. They expressed a prominent level of trust in the robot, equating its use to that of other everyday technologies such as smartphones and home alarm systems. Participants also indicated that they were accustomed to the frequent presence of visitors in their homes, which may have contributed to their relaxed attitude toward privacy. During discussions about remote operation, participants preferred the robot to handle tasks autonomously. However, they acknowledged the necessity for remote intervention in situations in which the robot had not yet learned a specific task or during emergencies. de Graaf et al [28] discovered that lower levels of privacy concerns were associated with a higher likelihood of using a robot.

Although robots may be a means to solve some of the future health care challenges, we believe that the primary goal of using a physically assistive robot is to support the user's sense of autonomy and independence. Therefore, we included questions on this topic in our interviews despite its absence as an influential factor in existing literature on the acceptance of social robots. Previous studies have emphasized the importance of being able to act independently, doing what one wants, when one wants [15]. Participants have also highlighted the significance of not feeling like a burden to caregivers and the value of experiencing freedom from human carers occasionally [15]. We suggest including concepts on independence and autonomy when investigating the acceptance of robots assisting with daily activities.

Participants expressed varied opinions on the significance of others' perceptions regarding their use of robots as home assistants. Some were indifferent, whereas others cared to a degree similar to the degree to which they cared about others' reactions to other forms of assistance or technical aids. When interacting with the robot, participants were polite, stating that this behavior came naturally; however, they emphasized that their primary expectation of the robot was for physical assistance, not for engaging in conversation. Social norms play a crucial role in shaping individuals' attitudes toward robots by setting expectations for their behavior and societal acceptance [28]. These norms both directly and indirectly affect one's willingness to adopt and integrate robots into daily life. In addition, the degree to which robot use is viewed as normal or endorsed by one's social circle significantly influences an individual's decision to use robots [28].

Although participants noted that the robot appeared large and masculine, they felt safe around it and experienced no anxiety during their interactions. They also expressed no concern about the facilitating conditions as their living facilities were already adapted for wheelchair use.

Methodological Strengths and Limitations

The acceptance models developed by Heerink et al [27] and de Graaf et al [28] have predominantly been applied to quantitatively assess the acceptance of robots, particularly among older populations. In our study, we adapted concepts from these models to guide a qualitative investigation. We contend that using qualitative methods is particularly advantageous when seeking deeper, more nuanced insights into the reception of novel technologies, such as the humanoid robot EVE used in this research. This approach allows us to capture the rich, detailed user experiences and perceptions that quantitative methods might overlook, providing a comprehensive

XSL•FO
RenderX

understanding of how individuals interact with and react to advanced robotic technologies in real-world settings.

The use of purposive sampling in this study might have introduced bias by including participants particularly interested in robotic assistance, which could have influenced their generally positive attitudes toward the technology [15]. We recognize that the small sample size of 9 participants may be seen as a limitation. However, we believe that the information power was sufficient, as defined by Malterud et al [62], who suggest that such power is achieved when participants actively share their experiences, thereby fulfilling the study's objectives. Our participants, all of whom had physical disabilities and varied levels of dependency on assistance, were engaged and provided rich, insightful discussions about the potential of the robot as a novel health care service. This depth of qualitative data bolstered the study's information power. In addition, our findings were rigorously analyzed through a 16-step process described by Assarroudi et al [41], resulting in categories that align with existing theories on robotic acceptance, directly addressing the research questions and aims of the study [27,28,41].

A significant number of participants had experienced an SCI, which could have introduced a specific bias in our results. Despite this, the needs expressed were strikingly consistent across different disabilities, focusing on functionality over the nature of the disability, such as impaired upper-limb function. Moreover, the sample included more male participants, mirroring the demographic trends observed in stroke and SCIs. Despite this gender imbalance, there were no notable differences in the needs or acceptance between male and female participants [63,64].

Using the Wizard of Oz approach raises an ethical concern due to the element of deception as participants are often unaware that a human operator is controlling the robot. This lack of transparency can raise issues related to trust and honesty in human-robot interactions. However, a study by Nasir et al [65] explored the impact of revealing the "wizard" behind the robot and found that participants' perceptions of the robot's autonomy remained largely unchanged even after the deception was disclosed. While the Wizard of Oz method remains a valuable tool for simulating and testing robot behavior, managing deception carefully is crucial, particularly in long-term human-robot interaction studies.

Conclusions

The results of our study reveal a complex interplay of functional expectations, technological readiness, and personal and societal norms influencing the acceptance and intended use of a physically assistive robot among individuals with physical disabilities. Participants were generally positive about the potential of robotic assistance to enhance their independence and reduce reliance on human caregivers for certain tasks, albeit recognizing the robot's current limitations and future potential. While the robot was not deemed ready for immediate full-scale implementation, participants were open to further testing in their homes, with the condition that the robot could perform most tasks autonomously in the future.

For developers, this study underscores the importance of a human-centered, iterative design process. The feedback collected has already informed improvements, leading to the development of a smaller, more functional robot with humanlike fingers and enhanced automation, better tailored to individual user needs. Health care managers, on the other hand, should recognize that, while robotic assistance is progressing, its integration into care settings will require significant adjustments to existing services. This includes rethinking care delivery models, staff training, and the balance between human and robotic caregivers.

As we move closer to successfully integrating robotic assistance into users' homes, both developers and health care managers should prepare for future implementation. This preparation includes addressing system maintenance, remote operation, and service delivery. The next steps should involve larger-scale studies to evaluate these aspects in real-world care environments.

Overall, the application of AI in robotics opens up new possibilities for creating more adaptable and personalized assistive technologies. This progress could reduce the costs associated with personalized adaptations but also enhance the effectiveness of assistive robots, making them a more viable and helpful option for individuals with disabilities.

Acknowledgments

The authors thank the participants, the coordinators assisting in the recruitment of participants, and the operators of EVE from 1X Technologies. This paper is part of a PhD project funded by the Ministry of Education and Research in Norway. The funding body has had no influence on the design of the study; data collection, analysis, and interpretation; or writing of the manuscript. Open access funding was provided by the University of Agder.

Authors' Contributions

LS, DTSJ, HM, and HMJ all participated in the planning and design of the study and the analysis and interpretation of the data. LS performed the data collection assisted by DTSJ. All authors contributed to writing, reviewing, and approval of the final manuscript.

Abstract

Background: Robotic lower limb exoskeletons have emerged as promising tools in the clinical rehabilitation of patients with lower limb paralysis due to neurological disease, stroke, or spinal cord injury. Identified benefits in gait function rehabilitation include improved gait function, cardiovascular effects, enhanced training quality, patient motivation, and reduced physical and psychological workload for therapists. Despite the identified benefits, the successful adoption of this technology largely depends on therapists' user acceptance.

Objective: This study aims to explore physiotherapists' perceptions of using robot-assisted lower-limb gait training in specialized neurological rehabilitation using the unified theory of acceptance and use of technology framework.

Methods: A qualitative, exploratory research design with a deductive approach was used. Semistructured interviews were conducted with 7 expert physiotherapists in a Norwegian specialized rehabilitation hospital. Data collection and analysis were guided by the unified theory of acceptance and use of technology framework.

Results: The physiotherapists' use of lower limb exoskeletons was greatly influenced by perceived benefits for patients or challenges, such as usability issues, the time required for adjustment to each patient, and the lack of personnel resources to facilitate their use. Thus, perceived usefulness and facilitating conditions (or lack thereof) had a great influence on the physiotherapists' intentions to use and the actual use of the exoskeleton.

Conclusions: This study identified several factors influencing the physiotherapists' acceptance and integration of the lower limb exoskeleton. Available resources, such as time and personnel, were emphasized as important factors to increase the use of the exoskeleton in specialized rehabilitation. Our findings may inform service providers and engineers in specialized neurological rehabilitation settings.

Introduction

Background

The use of robot-assisted gait training (RAGT) for patients with lower-limb paralysis due to neurological disease, stroke, or spinal cord injury has seen a global increase over the past 15 years [1-3]. The appeal of this technology in gait function rehabilitation is manifold, including improved gait function, cardiovascular benefits, enhanced training quality, objective measurements, patient motivation, and reduced physical and psychological workload for therapists [2,4-6].

Traditionally, treatment aimed at improving gait function requires frequent and meticulous follow-up several times a day by at least 1 physiotherapist to have a significant impact [7,8], which imposes significant resource burdens. To mitigate these challenges, lower limb exoskeletons have emerged as promising tools in clinical rehabilitation to allow intensive, high repetition of the gait cycle in individuals with locomotor disability, with reduced therapist effort [9]. Among health care professionals who interact directly with this technology, physiotherapists are expected to play a crucial role due to their specialized expertise. Their experiences and perceptions are likely to significantly impact the integration of exoskeletons into clinical practice because of both their academic competencies and hands-on experience in the rehabilitation of gait function. Physiotherapists are also proficient in the application of different modalities and new technology in clinical practice. Therefore, physiotherapists' perspectives are likely to be fundamental in the successful implementation of this technology.

The literature provides valuable insights into the experiences of physiotherapists regarding benefits, disadvantages, and practical considerations with RAGT [2,3,10-14]. Studies have explored physiotherapists' experiences with a diverse array of robotic exoskeletons in different treatment settings. Most studies have revealed a complex interplay of benefits and disadvantages. For example, using RAGT compared to traditional rehabilitation, physiotherapists have observed similar benefits to those experienced by patients, including increased training volume within a single session, improved gait, and better balance [2,12]. They also report that benefits include reduced physical strain and fatigue, improved gait patterns, the ability to stand upright, experiencing greater control and safety, and expansion of where rehabilitation can take place [2,10]. Studies have also reported challenges related to the use of robotic exoskeletons, such as the time required to calibrate the equipment, the time needed for training in its use, user-friendliness, adaptability to patients with various physical adaptations, and ensuring patient comfort and safety [3,10,13]. Physiotherapists have also expressed concerns about the technology's clinical integration, addressing resource requirements, overcoming equipment-specific challenges, and managing expectations of the technology [10,11,14].

While physiotherapists remain optimistic about the technology's ongoing evolution, the existing literature lacks a focus on the end user's perspective. Studies stress that this viewpoint is vital in the development and deployment of robot-assisted training tools [3]. They also assert that the successful implementation of these tools largely depends on therapists' perceived usefulness and user acceptance [15,16].

Knowing that the successful adoption of robot assistive technology largely depends on therapists' user acceptance, there are still gaps in fully comprehending the nuances of physiotherapists' perspectives. Therefore, this study aims to explore physiotherapists' perceptions of using robot-assisted lower-limb gait training in specialized neurological rehabilitation, using the unified theory of acceptance and use of technology (UTAUT) framework [17]. UTAUT is among the most used frameworks in explaining which determinants affect the acceptance of various health care technologies through different user groups, settings, and countries [18]. UTAUT has also proven to be valid for assessing technology acceptance among therapists in rehabilitation [19,20]. We foresee that the findings could potentially inform exoskeleton engineering, clinicians, researchers, and service providers while also contributing to the body of knowledge on RAGT in specialized neurological rehabilitation settings in Norway and beyond.

The Rehabilitative Robotic Exoskeleton

Robotic technology for gait training can be divided into 2 main categories: end effector and exoskeleton, with lower limb robotic exoskeletons further classified as "static" or "overground," where movement around the environment is possible [1]. This paper focuses on overground exoskeletons, which are of 2 main types: assistive and rehabilitative [21]. Assistive robotic exoskeletons aim to serve as aids in daily life, while rehabilitative robotic exoskeletons aim to restore gait function in patients, particularly those with neurological conditions. There are several manufacturers of this type, but this paper refers to the Ekso GT model (Ekso Bionics Holdings Inc) [5], which is shown in Figure 1.

XSL•FO
RenderX

Figure 1. Overground exoskeleton, Ekso GT (Ekso Bionics Holdings Inc).

Gait rehabilitation robots commonly feature an external motorized exoskeleton that follows the legs on both sides. Movements are triggered by the physiotherapist with hand control or by the patient herself or himself using leg movement or upper body momentum. An actuator in the knee and hip joint then initiates movement. Gait robots require support from the upper body or a therapist to maintain balance [1]. Furthermore, we will refer to the Ekso GT by the term “exoskeleton” in this paper.

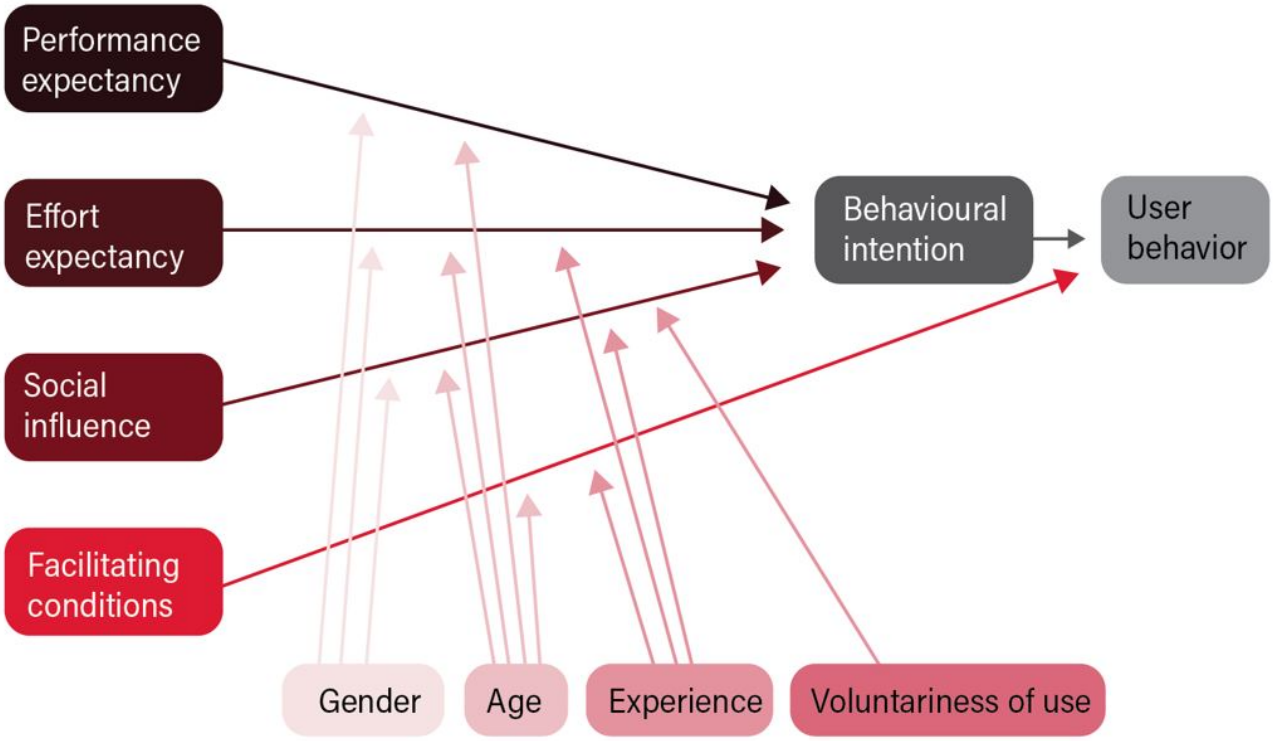
Methods

Study Design and Method

A qualitative exploratory research design with a deductive approach was used along with individual semistructured interviews [22].

Participants and Recruitment

A purposive sampling of physiotherapists was undertaken at a Norwegian specialized rehabilitation hospital based on the following inclusion criteria: physiotherapists with clinical experience using the exoskeleton, holding a minimum of 50% position, and having ≥2 years of experience in traditional gait rehabilitation. The head of the technological intervention center at the hospital assisted in disseminating invitations to physiotherapists who met the inclusion criteria. Initially, all 9 eligible physiotherapists responded with interest and were given a study information letter emphasizing confidentiality and voluntary participation. A total of 2 of the recruited participants chose to withdraw before the interview. Thus, our final sample consisted of 7 physiotherapists.



All included informants worked at Norway’s largest and most advanced rehabilitation hospital for individuals who have experienced severe illness or injury. The institution undertakes nationwide tasks and responsibilities and functions as a university-affiliated institution. The hospital is accredited according to the international standards of the Commission on Accreditation of Rehabilitation Facilities.

Data Collection

Individual interviews were chosen as they are suitable for capturing diverse experiences and subjective perceptions while preserving unbiased responses from the informants [22]. A semistructured interview guide was developed by the first author (AOH) and was based on the UTAUT framework (Figure 2 [17]).

XSL•FO
RenderX

Figure 2. The unified theory of acceptance and use of technology framework.

UTAUT posits 3 determinants directly influencing behavioral intention (performance expectancy, effort expectancy, and social influence) and 2 determinants directly impacting use behavior (facilitating conditions and behavioral intention). Together, these 5 determinants, along with use behavior itself, comprise the 6 main constructs of user acceptance according to the UTAUT. In addition, the framework includes 4 moderators (gender, age, technology experience, and voluntariness of use). Table 1 shows how the main constructs of the UTAUT framework were applied in the development of the interview guide.

Table 1. Interview questions guided by the unified theory of acceptance and use of technology (UTAUT) framework.

Main constructs of the UTAUT framework	Interview questions
Performance expectancy	• How do you perceive the usefulness of the exoskeleton in treatment? • How does its usefulness compare to other or traditional gait training methods?
Effort expectancy	• How do you experience the user-friendliness of the exoskeleton? • What do you think are important factors for the technology to be perceived as more user-friendly in gait training?
Social influence	• In what ways are your use of the exoskeleton influenced by colleagues' or the management's attitude towards the exoskeleton? • In what way do you feel that having knowledge and skills in using this technology provides any benefits for you as an employee?
Facilitating conditions	• How is use of the exoskeleton organized in the department? (time, resources, etc) • What type of training have you received in using the exoskeleton?
Use behavior	• How often do you use the exoskeleton? • Do you choose the exoskeleton over other treatment methods?
Behavioral intention	• What are your intentions for future use of the exoskeleton? • What possibly promotes or hinders your use of the exoskeleton?

The interview guide was pilot-tested by a physiotherapy researcher at the specialized rehabilitation hospital who was familiar with RAGT and qualitative research. The pilot testing led to changes to a couple of questions; one of the questions proved to be leading, and the other was a yes or no type of question.

In the semistructured interview setting, the open-ended questions were based on the main constructs of the UTAUT framework (Table 1). These questions were followed up with probing

XSL•FO
RenderX

questions to further explore responses and the topic of interest [22]. The first author (AOH) conducted all the interviews. Due to the COVID-19 pandemic and physical distancing requirements, all the interviews were conducted digitally using Microsoft Teams (version 1.5.00.9163) or Zoom (version 5.10.1; Zoom Communications Inc). The interviews lasted from 35 to 70 minutes, with a mean of 60 minutes. The interviews were audio recorded for transcription purposes using a digital recorder (web form) with approval from the data protection officer at the University of Agder.

Data Analysis

The first author (AOH) transcribed all the interviews and conducted the initial analysis combining deductive and inductive approaches [23]. First, the transcripts were read through to identify units of meaning that were relevant to the research question. Second, the units of meaning were placed under appropriate main categories aligned with the UTAUT constructs in an analysis matrix, representing the deductive part of the content analysis. Five of the 6 main constructs of the UTAUT were viewed as predetermined main categories and served as the deductive framework as follows: performance expectancy, effort expectancy, social influence, facilitating conditions, and behavioral intention (Table 1). Data concerning use behavior were not included in the content analysis but were considered demographic data regarding the actual use of the exoskeleton. Thus, the deductive analysis was used based on 5 of the 6 predetermined main categories of the UTAUT framework.

Next, all meaning units sorted under each category were reread inductively to identify possible subcategories. Furthermore, the units of meaning were condensed, coded, abstracted, and grouped into subcategories. The final part of the analysis process, as described in Table 2, represented the inductive part of the content analysis, and it allowed for the emergence of unanticipated subcategories. The first author (AOH) discussed all the findings of the deductive and inductive analyses with the last author (HMJ) until a consensus was achieved. Furthermore, the identified subcategories were discussed, and a consensus was reached among the 3 authors. The analysis was partly conducted with NVivo Pro 12 software (Lumivero).

In alignment with reporting qualitative research, the prevalence of participants' responses is generally presented using descriptors, such as "most," "many," and other equivalent terms. The manuscript preparation adhered to the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist.

Table 2. Example of the inductive part of the content analysis.

Main category	Subcategory	Code	Meaning unit (participant statement)
Performance expectancy	Advantages of using the exoskeleton	The exoskeleton contributes to controlled and focused working conditions.	"What can be nice is that it's [the exoskeleton] slow and you can correct and have more focus on quality in gait training. I worked with stroke patients who don't use the affected side much without the robot. When using the robot, you can work on focusing on not letting them compensate with a shorter stance phase on the affected side."

Ethical Considerations

Ethics approval for this study was granted from the Norwegian Agency for Shared Services in Education and Research (578944) and the ethics committee at the faculty of health and sport sciences at the University of Agder. All participants received written and oral information about the project, and written informed consent was secured from all participants via email before the scheduled interviews. The first author (AOH), who conducted the interviews, had not physically met the participants before the actual interviews. The participants did not receive any compensation for their contribution in the study.

To secure confidentiality, study IDs were assigned to each participant that replaced their names in transcripts. Names and participant numbers were stored separately in a secure location. In addition, direct personally identifiable data, such as age, gender, and experience, were not directly reported in this paper but summarized under demographic data in the Results section because all the participants resided in the same unit at an identified hospital. Furthermore, participant numbers were not displayed in presenting direct quotations (translated from Norwegian into English by AOH) from the interviews in order to ensure the anonymity of the participants.

Results

Participants

A total of 7 physiotherapists participated in this study, 1 man and 6 women between the age of 38 and 71 (mean 39) years. They had worked in rehabilitation between 8 and 37 (median 15) years. The participants were physiotherapists with advanced expertise in rehabilitation. Education levels varied from bachelor's and master's to doctoral degrees in physiotherapy; however, all had completed courses and further education within the field to be titled specialist physiotherapist. In total, 5 physiotherapists had been certified to either level 1 or level 2 of the supplier's required training, which involves using the robot with more advanced settings. Each had between 8 and 37 years of clinical experience, with several serving in senior or leadership positions within specialized rehabilitation centers. This level of expertise provided an in-depth understanding of the factors influencing user acceptance of technology in a clinical setting. The level of experience using the exoskeleton varied from weekly use to almost no use in the past year. All the participants had started using the exoskeleton in the hospital's implementation project 3 years before data collection.

XSL•FO

Results From Content Analysis

Overview

Table 3 presents the findings based on the main categories of the UTAUT framework. Findings related to subcategories are described in the text, illustrated with citations representing all informants.

Table 3. Summary of the study findings. Main categories and subcategories aligned with the constructs of the unified theory of acceptance and use of technology framework.

Main category	Subcategories
Performance expectancy	• Perceived benefits of using the robot • Perceived disadvantages of using the robot
Effort expectancy	• Robot design and functionality • Customization and personalization of the robot
Social influence	• Managers' influence on use behavior • Peers' influence on use behavior
Facilitating conditions	• Available resources • Training and expertise
Behavioral intention	• Intentions to adopt the robot • Intentions not to adopt the robot

Performance Expectancy

Perceived Benefits of Using the Robot

The exoskeleton was described as a good supplement to existing walking training and its usefulness lay in the possibilities it added. All the participants described the benefits of using the robot, such as the ability for a patient to stand up, facilitating an increased number of steps, or symmetrical loading of the body in treatment. The usefulness for patients varied depending on the individual's functional abilities and diagnosis. For example, the exoskeleton offered new opportunities, especially for patients with complete spinal cord injuries:

> *If you have a complete spinal cord injury, you don't have the ability to walk. For these patients, it's been a great opportunity to be able to stand up straight and walk. Using the exoskeleton may also facilitate secondary treatment benefits such has cardiovascular effects which are also achieved by mobilization.*

Furthermore, the increased number of steps was considered particularly beneficial in spinal cord injury training that focused on neuroplasticity:

> *The patients can focus more on performing an increased number of steps. It [the robot] is stable, I control the balance. The patients can work on weight transfer. The steps come on their own or on impulse from the patients. So, they get a lot more repetitions by using the robot, because it's automatically possible to do more repetitions. That's clearly an advantage in using a walking robot.*

Participants who described benefits, such as symmetrical loading, mostly worked with patients who had experienced a stroke. One of the benefits they described was related to the possibility of "disconnecting" one of the exoskeleton's legs to allow the good leg to move freely. Other benefits described were related to the fact that the exoskeleton stabilized the patient quite well, and this simplified the work of the physiotherapists and freed up their hands so they could focus on other aspects of the treatment.

Furthermore, several participants stated that it was an advantage that the speed of the exoskeleton was slow, which made it easier to focus on the execution of movements and thus increased the quality of the treatment. It was also considered an advantage that the robot did not let patients compensate with a shorter stance phase on the affected side; rather, it supported the full weight transfer of their whole body.

Several participants also talked about the benefit of being able to help patients feel safer by creating safe and stable frameworks, which meant that patients dared to challenge themselves more. Furthermore, the experience of standing upright also seemed very motivating for the patients and, in that way, contributed to something beyond traditional walking training for certain patient groups.

Perceived Disadvantages of Using the Robot

Using the exoskeleton was quite time consuming, which was described by all the participants as a significant disadvantage. The initial treatment was perceived as particularly time consuming due to all the preparations, adjustments, and measurements that needed to be made. When the exoskeleton was used on different patients, the disadvantage related to time consumption was amplified. The time required for adjustments both before and after the training session made the disadvantages outweigh the benefits, as the time that could have been saved in terms of quantity and quality of treatment was consumed by preparation and adjustments. Some participants described it as taking time away from effective treatment time. However, participants reported reduced time consumption during subsequent training sessions in comparison to the first one.

Several participants mentioned that the exoskeleton could negatively affect patients' self-effort and expectations. For example, some participants described how the patient was

XSL•FO
RenderX

confined within the "skeleton" of the exoskeleton, which made it difficult to assess the patient's own effort. This resulted in uncertainty about the effectiveness of treatment for several patients. Some participants explained this by describing how the exoskeleton could function as a crutch. One informant stated the following:

> *When they [patients] started getting better, it became apparent that they relied more on the robot's support to a greater extent than I had hoped...because something unconscious happens when you are so encapsulated that you automatically rely a bit more on the robot, and then it becomes difficult to challenge yourselves enough.*

Similarly, some physiotherapists described a downside to the benefits of the technology that dealt with the challenge of managing patient expectations, for example, for patients with spinal cord injury who could have high hopes or hopes of regaining function beyond what was realistic. Finally, it was mentioned that sometimes, patients used the robot for such a brief period that it was not effectively used. As a result, the physiotherapists did not experience any of the mentioned benefits of its use.

Effort Expectancy

Robot Design and Functionality

Certain physiotherapists said that the exoskeleton was large and heavy to handle. One suggested that it could have been made from completely different materials. The size and weight of the exoskeleton were perceived as particularly challenging when mobilizing patients from a chair and onto the exoskeleton and when supporting activity during walking training itself. Due to its weight, moving the equipment to other locations was out of the question. Few participants said that a ceiling rail had been installed to assist with this problem.

Most of the participants perceived that it was easy to learn how to use the exoskeleton. One described it as follows:

> *It [the robot] is easy to use in the sense that it can be learned by reading an instruction manual.*

At the same time, most of the participants thought the robot was very comprehensive and time consuming to use. This was partly explained by the fact that the physiotherapists had to conduct manual adjustments and programming of the robotics before using it. Some said that they had some kind of checklist they went through, which made it easy to get the basic settings right. Furthermore, many experienced the user interface on the exoskeleton as "old-fashioned" and not very user-friendly. It was pointed out that the menu system had many setting options, but there were few buttons for selecting settings. Finding the setting they wanted to use required several operations, which was exacerbated when using the technology's most advanced settings. As a result, most of the participants did not use the advanced settings. One of the informants summarized this as follows:

> *It's not user-friendly at all, I feel, because there are far too many possibilities on too few buttons, I think, so you have to scroll forever to find what you're looking for, even then you have to kind of learn by heart which functions are under which in the menu—so in relation to using a smartphone, it was in a way so far back in relation to those systems, you felt in a way that you were using an old personal computer.*

Some participants also mentioned that the technology felt "unnecessarily complex." One of the informants described it as follows:

> *We have a lot of technical aids here in the facility, but the Ekso is clearly the most comprehensive of them all.*

Customization and Personalization of the Robot

Some participants experienced that the robot device had physical limitations, which meant that some patients were too tall, too short, too wide, or too narrow to fit it. There was no solution to this, and several participants described this as a major limitation. One of the informants said the following:

> *It was a big limitation, especially on this issue of hip width, we were often adamant about it. There were several patients where we thought it would fit, but then they were too wide over their bum, it also happened that they were too small for it to fit. Or too tall or short.*

The physiotherapists described that if the exoskeleton was used frequently with different patients, there was no quick way to use the settings that had been used on the patient during a previous treatment. All settings had to be replotted. Challenges surrounding the need for manual adjustments to the device, such as adaptation and adjustment of the ankles, knees, and hips, were described by several of the participants. Some expressed that this was a matter of training and that one got better at adjustments when one had done it enough times. Some of the participants also described a fear of tightening the straps too tightly or making incorrect settings that could make it uncomfortable or create fear in the patients.

The participants were asked what could make the robot easier to use. Several said that ease of use for them in relation to the robot concerned whether it was quick to prepare for use, that it required few work operations, and that the user interface was clear and intuitive.

Social Influence

Managers' Influence on Use Behavior

The participants experienced that the management's commitment to and willingness in the implementation of the exoskeleton influenced their use of it to a large extent. The management's wish and plans to adopt the exoskeleton were communicated clearly, and this was followed by resources and goodwill to facilitate its implementation. The participants said that the management encouraged the inclusion of patients whose treatment could fit the use of the exoskeleton. These calls were followed up by the physiotherapists in many different treatment settings, which led to frequent use of the exoskeleton.

XSL•FO
RenderX

Some participants suggested that the hospital management's aim and vision of being at the forefront of new technology and innovation played a role in why they chose to adopt the technology. They had also experienced that when other, and sometimes conflicting, innovation projects related to gait training came along, the enthusiasm and follow-up had somewhat decreased. One of the informants said the following:

> *We're supposed to do a lot of cool projects, but there's perhaps too little holistic thinking around walk training.*

Some participants also proposed that when the need for certain technology has not come "from the therapists," it may be difficult to follow calls that come from the management. One participant said the following:

> *You could say that the desire to use [the exoskeleton] did not come from the therapists. It has come from the top management, and it's a slightly unnatural way to approach a product—a bit like: Now you have it, so now you have to figure it out.*

Because the implementation of the exoskeleton had not been triggered by the needs of the therapists, some participants felt it was a form of forced use.

Peers' Influence on Use Behavior

Most participants said that the attitudes of their colleagues toward the exoskeleton did not matter much in relation to their own choice to use it. One stated that they had not experienced any negative attitudes toward using such a robot. Some participants shared that one could be influenced to use it if colleagues brought it up in plenary meetings, that is, asking for possible candidates for using the exoskeleton. Other participants proposed that professional discussions about the exoskeleton influenced their choice to adopt the technology. One participant said the following:

> *We had colleagues who were quite positive about it. At the same time, people wondered a little whether it would work for the patients we were going to use it for.*

Facilitating Conditions

Available Resources

Many participants described organization-related challenges in using the exoskeleton. Several mentioned that its use was perceived as resource intensive, as it required 2 people to be involved in the treatment and its use and thus needed to be coordinated with other staff. One explained it as follows:

> *It's a problem in the healthcare system in general that we don't have an abundance of staff. So, it became quite cumbersome to arrange it, to schedule the use of the exoskeleton, and to find someone to assist during the same time slot and manage the logistics so that it could work.*

Due to this, the use of the robot was perceived as vulnerable in case one of the therapists was absent from work. One participant stated the following:

> *I think the resources are not there in terms of personnel.*

Several participants mentioned that the use of the exoskeleton worked better during certain periods when they had a porter available to prepare the equipment before use. At the same time, some noted that if staff had to be reassigned to other tasks, they had to cancel the exoskeleton treatment due to staffing needs. Furthermore, most participants mentioned that when they needed to use the exoskeleton, they sometimes had to deprioritize something else that was already scheduled. This affected not only their own time allocation but also that of the other therapists who had to participate. Because the use of the exoskeleton was so time consuming, several of the participants who worked with patients with spinal cord injuries perceived that the exoskeleton was not suitable for the interdisciplinary program that patients went through during their stay.

The location of the exoskeleton in the gym was considered appropriate and well suited to its use. This was partly explained by the fact that it felt safe that there were more people available in the room. In addition, a rail with suspension from the ceiling had been added, which reduced the need for personnel. Other participants felt that the location in the gym made the exoskeleton less relevant for some patients because some patients had challenges that made it difficult if there were too many other people in the same room.

Several of the physiotherapists said that a large part of the resource needs would be solved if it were organized as a "lab" and that this could solve several of the challenges related to time and personnel resources. One participant said the following:

> *There should be a separate laboratory where one uses such technology, where there are staff who do this job. If we had such lab, [the exoskeleton] would probably have been used more because people would then be able to try it out, while they received other training and treatment, which they needed in addition. That more patients could be offered to try the Ekso.*

Regarding technology support, participants knew whom to ask if they were unsure about something regarding the device. They had superusers for support if needed.

Training and Expertise

All the participants perceived the training on using the exoskeleton as very useful. Some said that the training provided the skills needed to put it into use, and several described the training as having a good balance between theoretical and practical exercises. Some of the participants stated that the training was "very extensive," especially in order to be certified to level 2, which was required for being responsible for treatment with the use of the robot. The extensive part of the treatment was described as time consuming due to the need for an instructor from the robot supplier to be there for 1 week, in addition to several hours required afterward to be certified. Others described it as extensive due to the fact that their daily schedule was very tight, and they had to be replaced by other therapists.

The participants were satisfied with the training they had received, but, at the same time, they asserted that one had to

XSL•FO
RenderX

practice a lot to become really good at using the exoskeleton and its advanced settings. One participant proposed the following:

> *Like with all new things, time must be set aside for someone to become very good at it.*

It was suggested by several participants that it could be an advantage to organize the use of the robot within a laboratory and engage certain physiotherapists to gain and maintain good competence in using the robot.

Behavioral Intention

Intentions to Not Adopt the Robot

The physiotherapists' biggest reasons for choosing not to use the exoskeleton referred to the time consumption and disadvantages of use, as described in the Performance Expectancy section, and to overly extensive planning, as described in the Facilitating Conditions section. Other reasons were their own professional judgment and the lack of evidence-based knowledge about the effects of using such a robot. One of the informants described some of this as follows:

> *For me, it's important that there's a professional foundation. It's not enough that it's technological and cool, or that we have to show off. The most important thing for me is what benefits the patient or not.*

Furthermore, several of the physiotherapists described how the acquisition of a walking robot was not triggered by a need from the therapists in the clinic. Some also found it difficult to know when and what to use it for. One of the informants said the following:

> *It must be said that this is also where a bit of our opposition lies—without having any good professional arguments for using it—the managers overlook our professional judgements on what is reasonable treatment and use of resources.*

All the participants expressed that the possible benefits that could be achieved in one treatment session using the exoskeleton were eaten up by the time spent on rigging it and the several operations related to its use. Several said that the need for 2 physiotherapists when using it was one big reason for choosing not to use the exoskeleton. It could be challenging to coordinate with another physiotherapist's timetable, or this could result in a second physiotherapist prioritizing to assist before conducting other valuable treatments. Both the planning and the logistics related to the exoskeleton treatment session were so time consuming and difficult to achieve that it could be perceived as easier to choose not to use the exoskeleton.

Intentions to Adopt the Robot

What the physiotherapists described as the biggest reason for choosing to use the exoskeleton was that it offered advantages for some patients, such as new opportunities to be able to stand up straight and walk. These benefits were related to those patients who had some gait function but could not yet practice traditional walking training. Others chose to use the exoskeleton to get people with spinal cord injuries, who otherwise would not be able to do so, to stand. The exoskeleton could provide a safe environment for insecure patients, and it could be used with patients who were motivated by using new technology. Furthermore, several participants described certain criteria for using the exoskeleton, such as consulting the responsible therapist and investigating whether there were contraindications due to specific medical conditions and whether it fitted the patient's physical goals.

Some participants said that the decision to use the exoskeleton initially was made because it was necessary to log hours for certification during the implementation project. Several of the participants who described this used it most frequently in that period. Other participants described that a priority on new technology being used was the reason for choosing to use it.

When asked what would be needed for the technology to be used more frequently in the future, the participants described how more resources and time were needed. Several said that it must "require less energy" for it to be used more frequently. Among other things, some participants pointed out that it will be important to start treatment early as a supplement in order to choose to use it. In addition, it must fit in with the way they work and their needs. For example, several of the participants highlighted the need to gather expertise and resources in a "lab." Here, the exoskeleton could be organized in such a way that one could book an appointment with one's patient, and it would not come at the expense of other treatment for one's other patients.

Several participants called for more evidence-based knowledge about the treatment effects before one could professionally defend using the time and resources needed to use the exoskeleton:

> *It becomes a dilemma in relation to what to invest in using it, when you don't know the actual effects. What we've seen from articles and such has not been very encouraging.*

Other improvement points that the participants described dealt with the development of the exoskeleton technology itself. Some argued that the weight and size of the device should be reduced to expand the range of use and that the control panel should be more intuitive and user-friendly.

Discussion

Principal Findings

Overview

To the best of our knowledge, this study is among the first to investigate the use of a lower limb exoskeleton in specialized neurological rehabilitation using the UTAUT framework, based on the experiences of expert physiotherapists. The physiotherapists predominantly perceived the disadvantages of using the exoskeleton as outweighing the benefits. The use of the exoskeleton was significantly influenced by the perceived benefits for patients, its time and personnel demands, the adequacy of training and support, clinical evidence, and accessibility. A cost-benefit perspective on its use and perceived advantages was decisive in determining how frequently they chose to use the exoskeleton in clinical practice.

XSL•FO
RenderX

The exoskeleton was perceived as beneficial for rehabilitating patients with limited mobility, especially those with spinal cord injuries, by enabling them to stand and walk. It increased the number of steps in training, enhanced neuroplasticity, and promoted symmetrical weight distribution. Its stability allowed physiotherapists to focus on other treatment aspects, and patients felt safer and more motivated.

However, significant drawbacks included the time-consuming setup, especially during initial sessions, which reduced treatment efficiency. The exoskeleton's bulk and outdated user interface also posed challenges, making it cumbersome to handle and adjust. Physiotherapists expressed concerns that patients might rely too heavily on the device, undermining their own efforts. In addition, staffing constraints further limited its use, as 2 physiotherapists were required per session.

The findings are further discussed in accordance with the main categories of the UTAUT framework.

Performance Expectancy

The findings showed that the physiotherapists' perceived usefulness (performance expectancy) of the exoskeleton was primarily related to the possibilities and benefits it offered in treating their patients. They highlighted advantages, such as enabling patients to stand up straight, increasing the number of steps taken, and promoting symmetrical body loading. The experiences described by our participants regarding physical and diagnosis-dependent benefits align with previous studies by Vaughan-Graham et al [3] and Mortenson et al [13].

However, despite the aforementioned advantages, most physiotherapists identified the time required to prepare the exoskeleton for initial treatment as a significant disadvantage, which is consistent with findings from Read et al [2]. Additional perceived disadvantages revolved around the narrow scope of the exoskeleton's utility. The technology was perceived as effective only within a specific clinic area, depending on the diagnosis, and for a limited duration during rehabilitation. As patients' functions significantly improved, conventional gait training was preferred. Conversely, if patients' conditions were poor, adaptations were time consuming and deemed inefficient. This may be related to what several physiotherapists described as a "free ride," where patients were essentially passive, without significant therapeutic effect. This aligns with Turchetti et al [24], who identified this potential downside of robot technology in rehabilitation. One possible explanation for this issue is the difficulty physiotherapists face in assessing patients' exertion and contribution when they are confined within the exoskeleton. Another explanation could be related to the level at which physiotherapists use the exoskeleton. Few reported using it at a "high level" fully exploiting all the device's functionalities.

The physiotherapists predominantly perceived the disadvantages of using the exoskeleton as outweighing the benefits. This cost-benefit perspective is elucidated by Mortenson et al [13], who raised questions regarding the exoskeleton's efficacy and cost-effectiveness relative to other approaches. However, our findings are consistent with those of Liu et al [19], indicating that physiotherapists are likely to adopt new technology if they perceive it as beneficial for their patient-related work. For example, our participants found that the benefit of using the exoskeleton for certain patients was a key motivation for their intention to use it. Thus, our findings are in line with the UTAUT framework [17], showing that performance expectancy, herein perceived usefulness (or lack thereof), is the strongest predictor of user acceptance and intention to use technology.

Similar to participants in other studies [3,11,25], the physiotherapists expressed disappointment regarding their expectations of the potential benefits of using the technology. This may suggest a discrepancy between user needs and the acquired product, a known issue with acquisitions of commercial off-the-shelf solutions, as described by Turchetti et al [24]. Challenges associated with such acquisitions include products not being developed to address the needs they are meant to solve. Physiotherapists find it difficult to understand which requirement the exoskeleton is intended to fulfill. This can be explained, on the one hand, by the nature of the product but also by the absence of user engagement during the implementation process, a phenomenon commonly referred to as the "top-down" approach in the literature [26,27].

Effort Expectancy

The physiotherapists' effort expectancy was related to the design, functionality, customization, and personalization of the exoskeleton for each patient. For example, the exoskeleton was challenging to use due to its size and weight, and its outdated control panel (user interface) with limited options made adjustments unnecessarily complex. However, despite its perceived lack of user-friendliness, most participants found learning how to use it easy.

Effort expectancy in terms of usability is expected to significantly influence the degree of use during the initial phase of implementation when users have not yet learned how to use the technology [17]. Previous studies have demonstrated that the impact on the intention to use decreases the longer the technology has been in use regardless of how difficult it is to learn [17,19]. On the one hand, the findings of this study align with this notion, as the physiotherapists have been using the technology for >3 years, and perceived usability had less influence on their intention to use it. Some participants expressed that "it was a matter of training" and that proficiency improved with practice. On the other hand, several physiotherapists used the technology sparingly over these 3 years, suggesting that perceived usability might be more significant than the results indicate. A possible explanation is that all physiotherapists in this study found the gait robot easy to learn initially.

In this study, perceived usability has been shown to have little influence on physiotherapists' intention to use the gait robot, consistent with the findings of Liu et al [19]. For the exoskeleton to be perceived as more user-friendly, the participants suggested that such technology should be quick to prepare for use, requiring few operational steps, and having an interface that is clear and intuitive.

Social Influence

According to Venkatesh et al [17], social influence from others may directly influence behavioral intention. In addition, a

XSL•FO
RenderX

moderating factor on social influence is the voluntariness of use. The physiotherapists in this study perceived they were influenced by their management, particularly at the onset of the implementation project when it was necessary to log hours to achieve certification. Some also indicated that the exoskeleton was a "top-down" investment not triggered by the physiotherapists' needs. In contrast to Venkatesh et al [17], our findings indicate minimal influence from colleagues on their behavioral intention.

Upon reviewing the literature on the use of rehabilitation robots, no other studies were found that described findings related to social influence.

Facilitating Conditions

According to Venkatesh et al [17], facilitating conditions have a direct impact on user acceptance. This was supported in our findings, as physiotherapists described shortcomings related to available resources, organization, training, and competence related to using the exoskeleton.

The findings of our study largely revolved around the disadvantages that physiotherapists experienced related to organization and resources. This affected physiotherapists' behavioral intention in such a way that they demanded more resources in terms of personnel and time to further use the exoskeleton. This aligns with the challenges described by Read et al [2], Mortenson et al [13], and Reicherzer et al [16]. Furthermore, our findings indicated that facilitating conditions, such as a lack of organization and resources, affected behavioral intention to a greater extent than their use behavior. This is in accordance with the findings of Liu et al [19] who found that physiotherapists who perceive good utility value use the technology regardless but more frequently if facilitating conditions were in place. Liu et al [19] referred to how facilitating conditions are the strongest factor influencing physiotherapists' use of new technology in the rehabilitation setting.

The finding that physiotherapists experience challenges related to planning and providing treatment on a hectic weekday aligns with the experiences of physiotherapists in the study by Mortenson et al [13]. Physiotherapists in our study emphasized the significant resource demands associated with coordinating appointments involving multiple physiotherapists for treatment, particularly in terms of personnel allocation. This was also found in the study by Mortenson et al [13]. Multiple physiotherapists described untapped potential in the current implementation of the technology, a recognized concern based on research in health technology and implementation [26,28].

It is important to note that the implementation of RAGT requires a large investment in training and equipment for most services.

Behavioral Intention

According to Venkatesh et al [17], behavioral intention captures the individual's motivation and intention to use the technology. They also described behavioral intention as a key predictor of actual use behavior when interacting with technology.

Physiotherapists in our study cited the exoskeleton's potential to benefit patients, particularly those with limited function or spinal cord injuries, as a key motivation for adoption. The technology provides new opportunities for patients to stand and walk and fosters a safe, motivating environment. In addition, participants identified specific criteria for use, including consultation with responsible therapists and consideration of patient goals. However, the lack of available resources within the organization, including time and personnel, emerged as a central barrier to adoption. Physiotherapists expressed concerns about the time-consuming nature of using the exoskeleton and the logistical challenges associated with coordinating sessions. In addition, uncertainty surrounding the technology's effectiveness and the need for evidence-based knowledge were highlighted as deterrents to adoption.

Our findings align with previous research by Liu et al [19], which identified performance expectancy and intention to use as key predictors for actual use. Similarly, Heinemann et al [11] and Mortenson et al [13] emphasized the importance of expanding the scope of use scenarios to promote future adoption. This aligns well with our findings in that physiotherapists experienced that for particular patients and particular rehabilitation phases, the robot simply could not be used. This was related to patients who had not obtained enough function to take advantage of the robot yet, but the time frame, between being ready to use the robot and when they were more likely to walk without it, was fairly short, limiting the "window of opportunity" for those particular patients and rehabilitation phases.

Our study uniquely highlights the potential barrier posed by the lack of available resources within the organization, a factor not extensively explored in previous literature. This underscores the need for a comprehensive examination of user acceptance among physiotherapists to guide the implementation of robot-assisted training in clinical practice, as highlighted by Venkatesh et al [17] and our own study.

Strengths and Limitations of This Study

The data and findings in our study are unique, as we applied the validated UTAUT framework in exploring physiotherapists' acceptance of a robotic lower limb exoskeleton in specialized neurological rehabilitation. To increase the validity and reliability of the findings, the main categories of the deductive analysis were based on the dimensions of the UTAUT framework. Knowing that using a deductive or directed content analysis approach may bias the identification of other possible main categories or subcategories in the text [29], the authors remained open minded during the analysis to allow for the emergence of additional themes or subthemes from the data.

The trustworthiness of the study was ensured using the criteria of credibility, dependability, and transferability [30]. Credibility can be understood as maintaining a careful focus on the project. This criterion was met by choosing participants who were most relevant to the aim of this study. Dependability was ensured through rigorous and well-documented data collection techniques and procedures. The interview guide was pretested, and the same questions were used for all the participants. Moreover, all interviews were conducted by the first author, who is a physiotherapist with extensive expertise in the use of technology in health care. The other authors have extensive

XSL•FO
RenderX

expertise in specialized rehabilitation, pedagogics, and qualitative research, which influenced the study design, data collection, and data interpretation throughout the research process.

Although the generalization of findings is not a goal of qualitative research, qualitative researchers strive for the transferability of findings. To address this, we provided a thorough description of the context, participants, and research process. Furthermore, we attempted to present the findings in as much detail as possible while ensuring the deidentification of the informants. Thus, we argue that the qualitative part of the study meets the criteria for trustworthiness.

There are some limitations to this study. Due to the scarcity of physiotherapists certified in the use of the lower limb robotic exoskeleton in a specialized rehabilitation unit, the eligible sample was limited. Even so, despite the small sample size, it can be argued that information power was achieved, as the cohort of expert physiotherapists provided substantial insights relevant to the actual study [31]. The findings reflect the perspectives of physiotherapists at a specialized rehabilitation hospital in Norway. However, we think the findings may be transferable to comparable contexts.

Conclusions

Our findings showed that the participants' intention to use and their actual use of a lower limb exoskeleton in a specialized rehabilitation setting were influenced by perceived benefits (performance expectancy) for patients; challenges, such as usability issues and the time required for adjustment to each patient (effort expectancy); the lack of personnel resources to facilitate its use (facilitating conditions); and deficient evidence-based knowledge about its treatment effects. A cost-benefit perspective was adopted where the perceived advantages were a decisive factor in determining how frequently they chose to use the exoskeleton. The expert physiotherapists predominantly perceived the disadvantages of using the exoskeleton as outweighing the benefits.

This study advances understanding of the factors affecting the user acceptance of lower limb RAGT in specialized rehabilitation from the perspective of physiotherapists. Although the findings are limited by the sample size and the exploratory nature of the study, they provide directions for possible decisive factors for the acceptance and integration of lower limb exoskeletons in specialized rehabilitation. With a growing demand for technology in rehabilitation, our insights on acceptance and integration of the lower limb exoskeleton may inform others who are considering or in the process of integrating exoskeletons into clinical practice. The findings may inform exoskeleton engineering, researchers, and service providers in Norway and beyond.

Further research should focus on gathering evidence on the rehabilitation effectiveness and cost-effectiveness of lower limb exoskeletons. Such evidence can justify their integration into specialized rehabilitation by demonstrating clinical benefits and economic viability.

Acknowledgments
