Abstract

Background: Children with hearing impairments (HIs) have traditionally faced difficulties with language acquisition due to various factors, such as difficulties in accessing early intervention and therapy, among others. There is an opportunity for digital technology to address this problem; however, how different technologies can facilitate language acquisition, as well as the level of evidence, is not well understood.

Objective: This study aimed to explore the types, roles, and outcomes of different digital technologies in supporting language development in children with HIs.

Methods: Following Arksey and O'Malley's framework for conducting a scoping review and the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews), we systematically searched 6 online databases from 2014 to September 2024 for relevant studies on the role of digital technologies in supporting language learning among children with HIs (aged <18 years).

Results: A total of 45 studies met the inclusion criteria. Mobile apps were the most frequently reported technologies, followed by digital books, extended reality, computer-based programs, and tangible or robotic tools. The most commonly used signed-language apps focus on vocabulary development and visual communication. Spoken language tools were less common but included augmentative and alternative communication (AAC) systems and auditory training apps. The efficacy outcomes of 12 studies included in this review showed that AAC-based apps had stronger effects on expressive language, pragmatic communication skills, and vocabulary development. These outcomes occurred when AAC-based apps were used in structured contexts with a therapist or parent. In contrast, signed language apps often reported narrower, word-level outcomes. Notably, relatively few interventions targeted early spoken language development, despite early childhood being a critical period for language acquisition. In addition, limited attention was given to visual design considerations related to user comfort, cultural relevance, and contextual adaptation.

Conclusions: The evidence base reveals 3 structural patterns: the dominance of accessibility-driven mobile technologies; an imbalance between signed and spoken-language interventions, characterized by a greater number of signed-language tools but stronger and more consistent evidence for spoken-language outcomes, particularly in AAC-based interventions; and limited integration of digital technologies across home, school, and clinical contexts. Future research should prioritize the co-design and evaluation of culturally responsive, integrated, developmentally appropriate digital systems that support early spoken-language development and sustained, family-mediated language learning across contexts.

Introduction

Background

Globally, more than 5% of people worldwide, about 430 million, including 34 million children, are living with disabling hearing loss, and this number is expected to rise to more than 700 million by 2050 [1]. Children with hearing impairments (HIs) encounter considerable challenges in acquiring spoken-language skills. HI refers to a reduced ability to hear sounds at normal levels, with varying degrees of severity. In children, hearing loss is typically diagnosed when the pure tone average exceeds 15 dB across key frequencies [2]. The scope of HI ranges from mild to profound. Children with profound hearing loss, who are often referred to as deaf, are unable to hear conversational speech without hearing technology, such as hearing aids or cochlear implants [2,3]. Those with mild to moderately severe hearing loss, commonly referred to as being hard of hearing, can often benefit from hearing aids [4]. In the context of this review, the term "children with HI" is used to refer to children who are deaf, hard of hearing, or have varying levels of hearing loss. Where relevant, cultural terms such as "deaf" have been used as per their application in the literature.

Communication preferences of children with HIs vary based on their access to hearing devices and language training. Some children rely on signed languages, while others use auditory input to develop spoken language through devices such as cochlear implants or hearing aids [5]. However, even with assistive devices, many children experience persistent challenges in developing spoken language due to limited access to early intervention, variability in device effectiveness, and insufficient support at home or school, which can lead to academic, behavioral, and social difficulties [6]. These challenges are compounded by barriers such as limited access to therapy, high costs, and a lack of parental knowledge regarding effective language-learning methods [7-9]. Many parents lack access to appropriate materials and training, leaving them unprepared to support their child's language development [10]. Language learning can be defined as the process by which individuals develop the capacity to understand, create, and use language for communication purposes. This involves the acquisition of listening, speaking, reading, and writing skills, as well as the understanding of grammar, vocabulary, and social use of language [11]. Language learning progresses from basic abilities, which include auditory or visual awareness, to the acquisition of language skills, followed by the use of language for pragmatic purposes [12].

Assistive and digital tools offer a promising solution to address these challenges. According to ISO 9999:2016, assistive products are defined as tools, whether custom-made or commercially available, designed to support people with disabilities. These technologies, including mobile apps and tangible devices, are innovative ways to enhance spoken-language learning for children with HIs. These technologies provide accessible, cost-effective resources that can support both parents and therapists in speech therapy [8,13].

Recent studies have included augmentative and alternative communication (AAC) devices [14], virtual reality (VR) apps such as BEARS (Both Ears) developed by Vickers et al [15], and digital books designed for children with HIs [16]. Despite the potential of these tools, there remains a gap in the development of cost-effective, interactive technologies that children can use independently, with parental support [8,9,13,17]. In particular, mobile technology has tremendous potential for providing home-based auditory training and speech therapy [18].

Recent reviews have explored various digital tools for supporting children with HIs. Herrera et al [13] highlighted that using hearing technology in mobile learning for children was affordable and accessible, although efficacy analyses and attention to visual design were lacking. Frisby et al [19] reviewed 146 studies of mobile hearing health care services across all age groups, with most studies originating in high- and upper-middle-income countries. While the review highlighted a focus on screening, diagnosis, and treatment, it placed limited emphasis on language learning for children with HIs. Hajesmaeel-Gohari et al [20] investigated digital games and found that they could increase motivation; however, their therapeutic impact remains unclear. Similarly, Nanjundaswamy et al [21] reviewed computer-based auditory training programs and acknowledged a range of tools for different age groups, including children, but highlighted a critical lack of evidence proving their efficacy. These findings point to an important gap: despite the increasing presence of digital tools, there is a limited understanding of how they influence the language-learning outcomes of children with HIs, particularly those who rely on spoken language. This scoping review addresses this gap by mapping the landscape of assistive and digital technologies for children with HIs, examining their features, contexts of use, and reported outcomes. In particular, the extent to which these tools support spoken-language development, for which evidence is scarce but is urgently needed, is explored.

Aim

This scoping review seeks to establish the landscape of assistive and digital technologies used to facilitate language learning among children with HIs. The review covers the following areas: (1) types of digital technologies applied, (2) the fundamental design elements and purposes of these technologies in facilitating language learning among children with HIs, and (3) the scope and nature of the reported efficacy outcomes. Although the review focuses on language learning as the core area of analysis, some studies that integrate language technologies with other domains of learning, such as literacy, mathematics, science, and general classroom interaction, are also included if language development remains a core component. The review covers both spoken language and sign language technologies to accommodate the varied communication needs of children with HIs. In this review, we have defined technology-based language learning interventions as digital tools intentionally designed to aid individuals in learning or improving language skills such as vocabulary acquisition, speech production, phonological awareness, listening comprehension, or signed language proficiency. Technologies whose primary purpose was unrelated to language learning, such as general communication aids or educational

XSL•FO
RenderX

games, were included in this review only when the intervention explicitly targeted measurable language-learning outcomes.

Methods

Overview

This scoping review was conducted following the framework proposed by Arksey and O'Malley [22], which posits that scoping studies are useful for mapping key concepts, types of evidence, and gaps in the research within a given field, particularly when the area is complex or has not yet been comprehensively reviewed. In light of the variety of digital technologies as well as the research designs that have been implemented so far, this study does not intend to critically discuss the efficacy of specific interventions. Instead, it maps and summarizes the types of efficacy outcomes across studies. This design enabled the identification of patterns across the literature, highlighted areas with limited evidence, and informed recommendations for future research.

We used the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews; refer to Multimedia Appendix 1 for the complete Checklist 1) to guide the reporting in this scoping review [23] and developed a population, concept, and context framework [24] that is provided in Table 1 below. As this was a scoping review, no formal critical appraisal or statistical synthesis was performed.

Table . Population, concept, and context (PCC) framework.

PCC[a] aspect	Description
Population	Children aged <18 years with HIs[b], including children who are deaf, Deaf, or hard of hearing, as defined by the original studies.
Concept	Assistive and digital technology used to support language learning.
Context	Settings in which digital technology was used in controlled interventions to support the spoken-language learning of children with HIs. In addition to the contexts of intervention (home, school, or clinic), the geographical contexts (high-income countries or low- and middle-income countries) were also explored in descriptive terms under the component of "Context" in the PCC framework. However, this is only to look at the differences in access, scale, or learning environments and not to pose another research question in analytical terms.

[a]PCC: population, concept, and context.

[b]HI: hearing impairment.

Step 1: Identifying the Research Questions (RQs)

This review is based on the following research questions that seek to explore how digital technologies are used in facilitating language learning and academic engagement for children with HIs:

RQ1. What types of digital technologies support language learning for children with HIs?

RQ2. What is the role of digital technology in supporting language learning and language-mediated academic participation among children with HIs?

RQ3. What are the reported efficacy outcomes of these digital technologies in supporting language development for children with HIs?

Step 2: Search Strategy

The authors conducted a comprehensive search strategy to include all relevant literature published between January 2014 and September 2024 across the following databases: Ovid MEDLINE, PsycINFO, Web of Science, Scopus, CINAHL, and Computers and Applied Sciences Complete. An experienced librarian assisted in refining the subject headings and keywords to ensure broad coverage of technology-based interventions and HIs among children. The final search strategies are provided in Multimedia Appendix 1.

Step 3: Study Selection

Studies needed to focus on the identification, implementation, and evaluation of assistive technology and digital technology for children with HIs to be included in this review. Refer to Textbox 1 for details regarding the inclusion and exclusion criteria. Eligible studies were identified using a 3-step process. In step 1, one reviewer (ADS) collected the search results and then removed duplicates. In step 2, two reviewers (ADS and AAM) reviewed the titles and abstracts of the identified studies that appeared to meet the inclusion criteria. In step 3, the same reviewers evaluated the full texts of the remaining publications that were identified in our searches to include potentially relevant publications. Covidence software (Veritas Health Innovation Ltd) was used to facilitate the screening, selection, and data management processes during the scoping review [25].

Eligibility Criteria

Studies needed to focus on the identification, implementation, and evaluation of assistive technology and digital technology for children with HIs to be included in this review. Refer to Textbox 1 for details regarding the inclusion and exclusion criteria. Studies were included if they focused on identifying, implementing, or evaluating assistive or digital technologies for children with HIs. Studies were limited to English-language, peer-reviewed journal studies published between January 2014 and September 2024. Studies of adults, nondigital technologies, or those focusing exclusively on signed language were excluded.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria:

- Studies focused on hearing technology for children with hearing impairments (HIs).
- Studies involving digital technology, mobile apps, or computer-based interventions.
- Studies written in English.
- A study was only included in our review if the technology was specifically intended for language development outcomes such as vocabulary learning, grammar acquisition, speech production, or signed language comprehension.
- Digital tools used by children with HI may indirectly impact language development if they serve as communication aids or educational games. However, this review only included technologies mainly aimed at language learning or those directly measuring language-related outcomes.
- Studies published between 2014 and 2024 were included in this review. This period was chosen because mobile and app-based digital interventions have evolved rapidly since smartphones and tablets became widely used [26]. Earlier studies were largely based on technologies (eg, desktop-based or clinic-bound technologies such as computer-based training programs, CD-ROM–based tools, or fixed web platforms typically used in controlled settings) that are now quite different from the digital tools commonly used today (eg, app-based learning environments that support multimodal interaction and home-based language practice). From around 2014 onward, the growth of mobile learning technologies and app-based learning tools has had a substantial impact on digital environments for language learning, making this timeframe particularly relevant to the aims of our study.
- Journal studies.

Exclusion criteria:

- Studies were excluded from our review if the technology served primarily as a communication aid, accessibility tool, or general educational application without explicit language-learning objectives or language outcome measures.
- Abstract only, conferences and posters, study protocols without the published full-text study, and editorial letters.
- Studies exclusively focused on traditional sign-language instruction without a digital assistive learning component targeting broader communication, literacy, or educational participation outcomes were excluded.
- Studies focused on HIs in adults aged >18 years.
- Studies not written in English.
- Studies published before 2014.
- Nondigital technologies.

Screening and Selection Process

Eligible studies were identified using a 3-step process. In step 1, one reviewer (ADS) collected the search results and then removed duplicates. In step 2, two reviewers (ADS and AAM) reviewed the titles and abstracts of the identified studies that appeared to meet the inclusion criteria. In step 3, the same reviewers evaluated the full texts of the remaining publications that were identified in our searches to include potentially relevant publications. Covidence software (Veritas Health Innovation Ltd) was used to facilitate the screening, selection, and data management processes during the scoping review [25].

Step 4: Data Extraction and Charting the Data

Data from the eligible studies were extracted using standardized data extraction forms developed by the research team (refer to Multimedia Appendix 1). Two separate data extraction tools were used to capture key details about digital technologies, including the type of technology, the communication preference (signed language or spoken language), app settings, app purpose (research-based or commercial), and app functionality (eg, language learning, math learning, literacy, or educational assistance). In addition, the extracted data included study characteristics such as the year of publication, the country in which the study was conducted, and the purpose of the study, as well as participants' demographics, such as age, sex, and degree of HI. Outcome measures were also recorded to assess the impact of the technology.

Step 5: Collating, Summarizing, and Reporting the Results

We grouped the studies based on their technological focus and summarized the key characteristics, including the study design, target populations, settings, research purposes, and reported limitations. We identified and outlined the features of the digital tools used for each group, together with the intended outcomes. This process was intended to highlight existing gaps and to inform future research or intervention designs.

Results

Overview of the Studies

Initially, 2541 studies were imported into Covidence; after duplicate removal, 1783 citations were identified from electronic database searches and study references. After screening the titles and abstracts of these citations, 330 studies were included in the full-text review process. Of these 330 studies, 45 studies met the inclusion criteria, and 285 were excluded (refer to Figure 1). Data extraction was completed for the 45 studies that were considered eligible for this review. The PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart is shown in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart for the selection of the included studies.

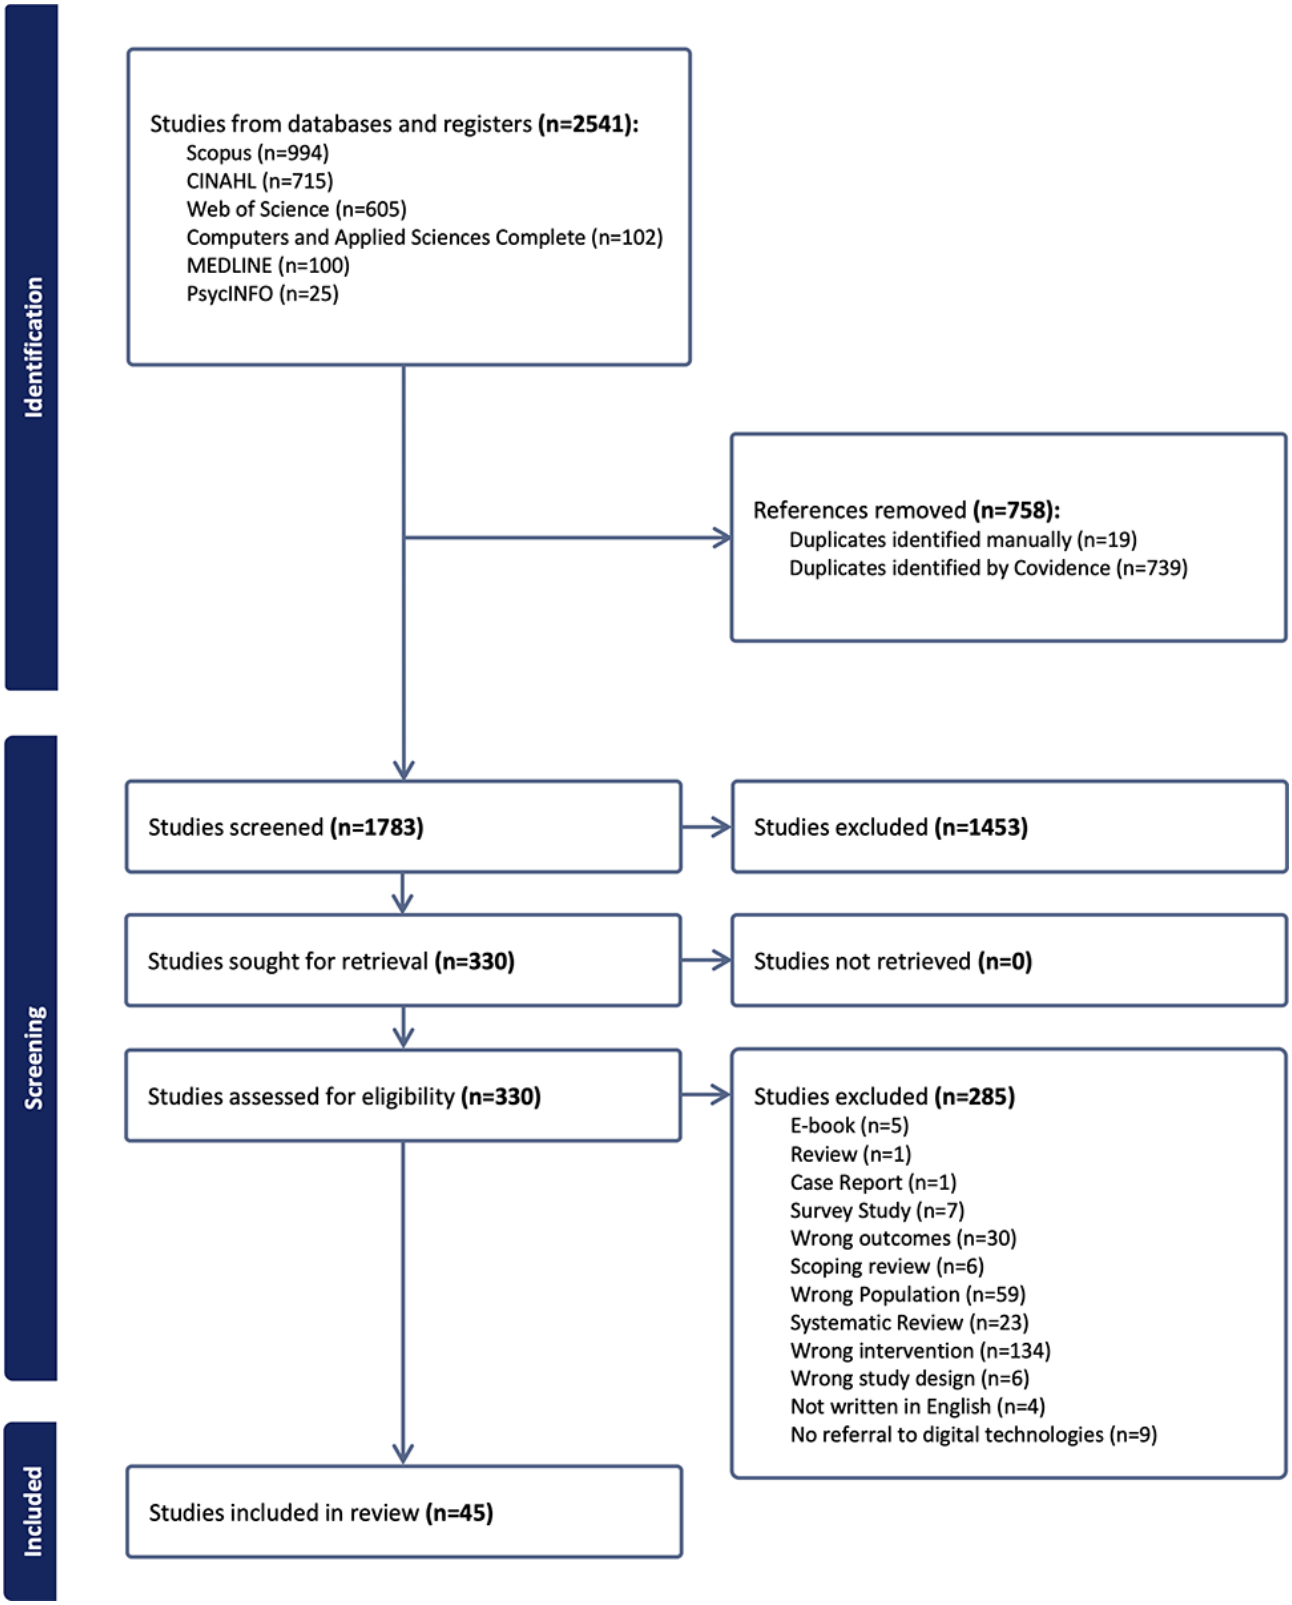

Figure 2 shows the geographical distribution of the included studies. Most studies were conducted in Asia (40%, 18/45), followed by Europe (22%, 10/45), and North America (20%, 9/45). All North American studies originated from the United States, which represented the largest national contribution. South America contributed 13% (6/45), primarily from Colombia (4/45), while Africa accounted for 4% (2/45), represented by Mauritius and Tunisia. Consistent with the population, concept, and context framework, geographical context (high-income vs low- and middle-income countries) is reported descriptively to contextualize access, scalability, and learning environments, rather than as a separate analytical focus.

Among the studies conducted in low- and middle-income countries (n=24), Indonesia and Colombia contributed the

XSL•FO
RenderX

highest number of studies (n=4 each), followed by Pakistan (n=3) (Table 2).

Of the 45 studies, only 18 studies involved parents and experts. Parents mainly supported progress monitoring [27-29] and were most engaged during the design stage [16,30-36]. A few studies also created dedicated interfaces for parents and experts [6,34], highlighting the role of technology in connecting home and professional contexts. In addition, testing was not limited to children, as parents and experts were also part of the evaluation process. Previous studies by Mood et al [30], Meinzen-Derr et al [37], and Shoaib et al [38] highlighted that technology requires the continuous input of parents, therapists, and teachers to maximize its impact.

Figure 2. Distribution of included studies by country, showing the number of studies conducted across different geographical regions.

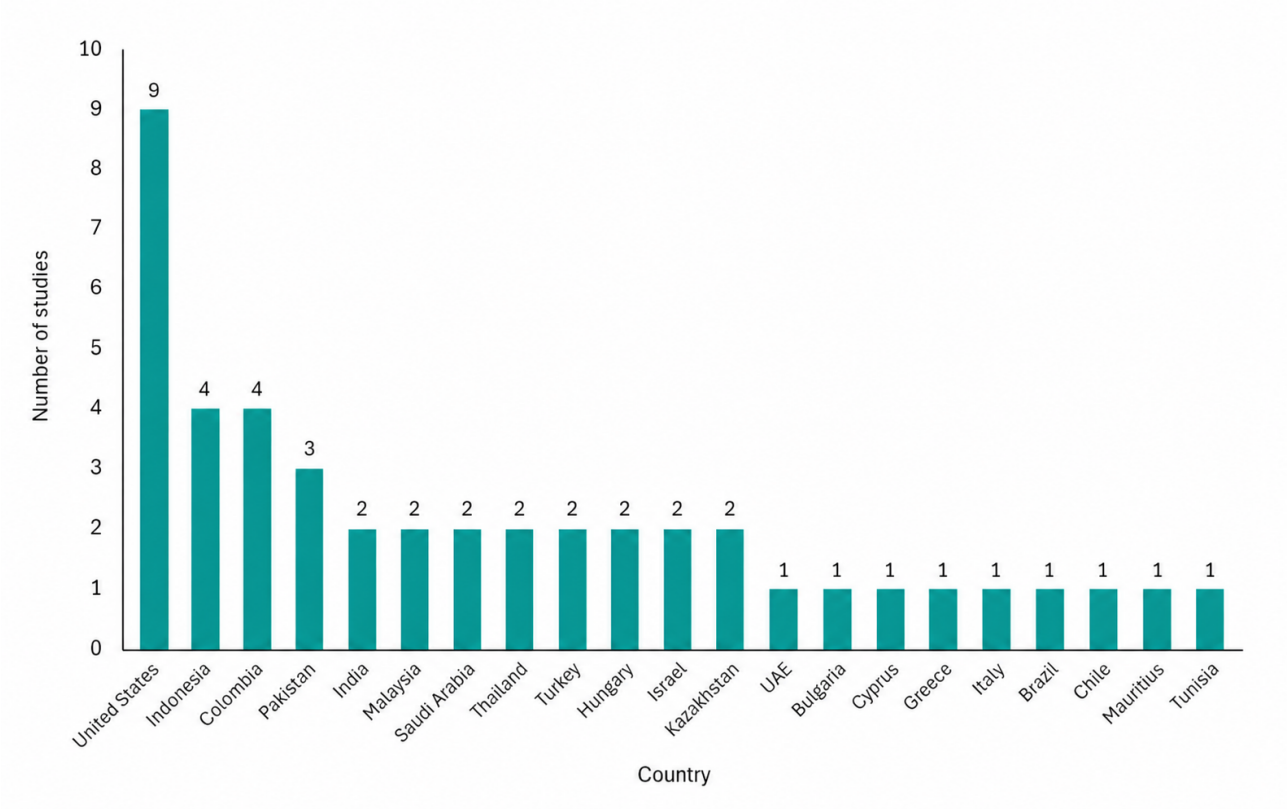

Table . Distribution of studies across low- and middle-income countries (N=24).

Country	Value, n (%)
Colombia	4 (16.7)
Indonesia	4 (16.7)
Pakistan	3 (12.5)
India	2 (8.3)
Kazakhstan	2 (8.3)
Malaysia	2 (8.3)
Thailand	2 (8.3)
Turkey	2 (8.3)
Brazil	1 (4.2)
Mauritius	1 (4.2)
Tunisia	1 (4.2)
Total	24 (100)

Participant Characteristics

The mean sample size across the included studies was relatively small, with an average of 23 participants. Participant ages ranged from 2 to 17 years, with a mean age of 10.6 years. The mean age of children was 11 years, and the mean sample size was 20 participants. Of the 45 included studies in this review, 27 reported participant gender, comprising 778 individuals. Of these individuals, 397 (51%) were male, and 381 (49%) were

XSL•FO
RenderX

female. The remaining 18 studies (221 participants) did not specify gender information. All studies involved participants with HIs; however, only 21 studies provided details on the severity of hearing loss. In total, 8 studies reported profound hearing loss, 1 severe, 5 moderate, and 7 mild. The remaining 24 studies did not provide specific information regarding the extent of hearing loss. There was an inconsistency in the reporting of gender and demographic data; therefore, the aggregate data only reflect studies that reported this information.

Types of Digital Technologies That Support Language Learning for Children With HIs

Five categories of digital technology were identified, namely mobile apps (n=26), digital books (n=6), extended reality, augmented reality, and virtual reality (n=5), computer-based programs (n=3), and other tools such as robots, tangible devices, or cross-platform systems (n=5; refer to Multimedia Appendix 1 and Table 3). Across the range of technologies, mobile apps consistently highlighted the importance of customization, interactivity, and visual reinforcement, whereas XR and tangible systems highlighted the importance of embodied and immersive approaches to learning.

[d]VR: virtual reality.

[e]AAC: augmentative and alternative communication.

Various digital technologies have been developed to support language learning for children with HIs, each offering distinct features and learning approaches. Mobile-based apps, which were the most frequently represented, tended to incorporate diverse interactive elements, such as color, animations, and accessible font styles that were designed to engage young users

XSL•FO
RenderX

[39,40]. Customization features appeared most frequently across all technology types, reflecting the need to accommodate variations in hearing levels and individual progress. Leveling systems were also suggested as essential additions, enabling content to be adapted according to the child's stage of development [41,42]. XR and tangible technologies, such as robots, provided immersive and hands-on experiences, while computer-based and cross-platform software supported more structured or instructional content.

The learning goals that were supported by these technologies typically aligned with either spoken-language or signed-language development. Technologies that were designed to support spoken language, which were frequently delivered through mobile apps or AAC-based platforms, often focused on auditory memory and visual reinforcement [30,37]. These tools included speech-to-text, audio playback, activity logging, and real-time feedback to support receptive and expressive language skills. By contrast, technologies that supported signed-language learning relied heavily on visual modalities and incorporated elements such as video demonstrations of signs, fingerspelling, and articulation animations [43-45].

While mobile-based technologies dominated in frequency and feature integration, each type of technology had unique value depending on the targeted communication mode. Tools that supported spoken languages tended to integrate multimodal input (auditory and visual), whereas those supporting signed language were predominantly visual. These differences highlight the importance of aligning technological features with the sensory needs of children with HIs, as well as with their language preferences [31]. Customization, interactivity, and adaptability remain central to the effectiveness of these digital tools in diverse learning contexts.

The Role of Digital Technology in Supporting Language Learning and Language-Mediated Academic Participation in Children With HIs

While this review focuses on language learning, many of the technologies described incorporate language development into more general learning activities, such as literacy, mathematics, science, and participation. As a result, these areas were also included whenever language comprehension, expression, or communication formed a core component of the learning process. Digital technologies served the following two main functions: (1) assistive and learning support (literacy, math, science, and classroom participation) and (2) language learning (spoken and signed languages).

Assistive and Learning Support

Across the reviewed studies, assistive and learning support technologies for children with HIs consistently featured multimodal, interactive tools that adapted traditional curricula and presented them in more accessible and engaging formats. These technologies span various domains, including literacy, mathematics, science, and classroom participation, with an emphasis on personalized and inclusive learning experiences.

In terms of literacy, the most common tools used are digital storytelling and gamified apps to enhance reading comprehension, vocabulary acquisition, and phonemic awareness. Standard features included animated narratives, interactive feedback, and adaptive content, which not only maintained learner engagement, but also supported comprehension in both signed- and spoken-language contexts [46-52]. Several studies highlighted the role of e-books and storytelling apps in facilitating bilingual or bimodal literacy, reflecting a shift toward culturally and linguistically responsive learning materials.

In terms of math, digital tools often incorporate multimedia elements, such as visual aids, auditory prompts, and gesture-based input, to improve the understanding of mathematical concepts. A shared feature across these tools was their ability to break down abstract mathematical ideas into concrete, interactive tasks. Many platforms also integrated signed language or visual modeling to accommodate different learning styles [32,53-56]. These interventions indicated a common goal of making math education more inclusive and accessible, particularly by addressing language-related barriers that may impede conceptual understanding.

In terms of science and classroom learning, a variety of assistive technologies, such as AR apps and humanoid robots, were used to simulate real-world experiences to foster inquiry-based learning and promote social interaction [43,57-59]. Of note, some of these tools, such as humanoid robots, were designed for classroom use and to support parents and caregivers at home, thereby enabling them to reinforce language and academic skills in informal settings. This highlighted the increasing recognition of the home environment as a crucial context for learning, particularly when access to professional therapy was limited.

Differences among these categories reflected their learning objectives and sensory modalities. Literacy tools often focus on phonemic and vocabulary development through fingerspelling for signed languages and audiovisual storytelling for spoken languages [6,49]. Math tools prioritized logical reasoning and problem-solving through interactive formats [53,54,60], while science-oriented technologies were geared toward experiential learning and stimulating curiosity [61]. Across the domains, most of the tools incorporated multimodal input (visual, auditory, or gestural) and adaptive content features.

Language Learning

A strong trend across spoken-language interventions for children with HIs was the increasing use of technology-enhanced tools that combined visual, auditory, and interactive elements to support diverse aspects of spoken-language development. These tools addressed various communication skills, ranging from auditory-verbal training and lip reading to speech articulation, phonemic awareness, and expressive language production.

One commonality among these interventions was the emphasis on multisensory input. Most apps integrated real-time visual and auditory feedback, allowing users to self-correct and reinforce their learning. For example, tools targeting articulation and auditory training often use game-based interfaces and visual prompts to help learners practice specific speech sounds and patterns in an engaging environment [5,27,33]. Similarly, lip-reading tools focused on visual speech cues, providing

XSL•FO
RenderX

guided repetition and clear visual models to support speech recognition without relying on signed language [28,38].

AAC-based systems were another common strand, particularly for supporting expressive spoken language and pragmatic communication. These tools typically provided audiovisual pairings, customizable vocabularies, and structured sentence construction to support communication across different developmental stages [14,30,37,62]. Longitudinal research has also shown that AAC tools can be adapted to a child's developing language abilities and can remain effective across contexts [63].

Despite these shared features, differences in focus and depth were noted. Some tools were narrowly designed for phoneme-level training or early auditory skills [27], while others provided comprehensive language systems with vocabulary expansion, grammar structuring, and social communication support [14,30]. The level of interaction also varied, ranging from passive repetition tasks to immersive, gamified environments with dynamic feedback loops [64].

Overall, these studies reflected a shift toward personalized, feedback-driven spoken-language learning, with tools tailored to different linguistic profiles, therapy goals, and developmental needs.

34

Efficacy of the Tools for Language Learning

Table 4 summarizes the characteristics, interventions, and key findings of the 12 studies that reported efficacy outcomes. These studies covered spoken-language learning (AAC, phonemic awareness, and prosody) and signed-language learning, with 1 study also reporting academic outcomes. Where available, statistical results are reported descriptively to reflect the outcomes presented in the original studies, rather than to infer comparative effectiveness.

Table . Efficacy of digital technologies.

Study	Aim of the study	Name of the platform	Age of the children (years)	Key results
Mood et al [30]	To evaluate AAC[a] on iPads for language development	AAC on iPad TALI[b]	3 - 12	Over 24 weeks, children aged ≥5 years in the TALI[b] group showed greater gains in pragmatic language (12.7-point increase in CELF-5[c]) vs a 6-point decrease in the TAU[d] group (P=.04). For children under 5, the TALI group improved significantly in VABS[e] Communication (86.7 to 99.1) and Social domains (91.8 to 97.4, P=.01), while the TAU group showed no significant change.
Meinzen-Derr et al [62]	To assess the TALI program's impact on communication skills	TouchChat HD: AAC with WordPower (used in TALI)	3 - 12	Over 24 weeks, children in the TALI group, compared to those in the TAU group, had significantly greater increases in the length of phrases they used to express themselves (β=.91 vs .15, respectively; P<.001). Similar findings were seen with conversational turn-taking and the number of different words spoken.
Meinzen-Derr et al [37]	To implement a language intervention that used AAC technology on iPad VR devices to enhance language development in children who are DHH[g] with language underperformance	AAC software on iPad TouchChat HD	5 - 10	[f]More than 24 weeks, median MLU[f] increased from 2.41 (range 1.09-6.63; mean 2.88) to 3.68 (range 1.97-6.81; mean 3.62; P=.002). Median total words were 251 (range 101-458) and median different words were 100 (range 36-100) at baseline, both increasing significantly over time. Total words: β=26.8 (7.1); P=.001 and different words: β=8.0 (2.7); P=.008. Mean (SD) values increased from 3.15 (2.09) to 3.86 (1.81) for MLU, from 265.4 (130.1) to 357.8 (159.2) for total words, and from 96.6 (44.2) to 125.2 (42.8) for different words; mean turn length showed minimal change.
Meinzen-Derr et al [14]	To determine whether integrating AAC core-word language strategies improves speech-language outcomes in young children who are deaf or hard of hearing	AAC strategies using TouchChat HD with WordPower by Silver Kite	4-11	The study reported high satisfaction with AAC strategies and notable language gains: MLU increased by 38%, NDW by 39%, and the Pragmatic Checklist Score rose from 68.8 to 95.5 (P=.01).

Study	Aim of the study	Name of the platform	Age of the children (years)	Key results
Mohammad et al [34]	To test a game-based mobile app for a signed language	My Sign	6 - 12	The study showed that children using the mobile app scored significantly higher in the post-quiz, with a 60% improvement in Group A. The *t* test (*P*=.01) confirmed the app's positive impact, and the Eta squared (0.585) indicated a strong effect size. The game-based learning approach led to higher engagement and better learning outcomes compared to the traditional method.
Ploylji w and Michel [35]	To use the AR[h] book to teach vocabulary and signs	AR book	5 - 9	The results showed that the efficiency of the lesson in the pretest and the exercise during the study (E1)[i] averaged 85.33%, while the posttest (E2) averaged 87%.
Sztahó et al [65]	To improve prosody using CAPT[j]	CAPT	6 - 10	The CAPT app significantly improved prosody in children with HIs (t_{14}=4.07; *P*<.001), with strong agreement between teachers' and automatic scores (*r*=0.87). Gains were observed across all hearing levels, particularly among children with mild hearing loss.
Vasel and Ragonis [32]	To assess multimedia impact on academic outcomes	Multimedia instruction	7 - 11	The program significantly improved students' language and math skills, with gains in semantics, reading (49.5→60.5), grammar (63.3→66.9; *P*=.001), and math mapping. Morphology showed slight improvement; syntax remained unchanged.
Lawal et al [39]	To evaluate English learning via a digital app	A mobile app named ''Hausar Kurma''	5-7	The study showed that the mobile app significantly improved English learning among Hausa-speaking students with hearing impairment (pretest median = 30; posttest median=90; *z*=2.82; *P*<.05; *r*=0.633; binomial *P*=.01).
Techaraungrong et al [55]	Math learning (counting, addition, and subtraction) with language components through a signed language	Multimedia app for arithmetic learning	7	The study revealed that multimedia-based learning significantly outperformed traditional instruction (*z*=4.545; *P*<.001), improving counting, addition, and subtraction. Students reported better motivation, understanding, and independence, supporting multimedia's effectiveness and the need for inclusive design.

Study	Aim of the study	Name of the platform	Age of the children (years)	Key results
Alsalem and Alzahrani [46]	Language learning (phonemic awareness, vocabulary, writing, and reading comprehension)	Custom-designed e-books	10 - 12	There were statistically significant between-group differences across all outcome measures, with the experimental group demonstrating superior performance in phonemic awareness (t_{39}=11.25; P<.001; d=1.77), writing (t_{39}=12.18; P<.001; d=2.03), vocabulary (t_{39}=7.25; P<.001; d=1.15), and reading comprehension (t_{39}=6.29; P<.001; d=0.99). All observed effects were large.
Joy et al [31]	To develop and evaluate a mobile-based tool for learning sign vocabulary to improve deaf and Deaf children's language acquisition.	SiLearn	School-age children	The SiLearn program significantly improved vocabulary, with higher gains in the experimental group (mean 21.43, SD 7.45) vs the control group (mean 11.07; $t_{22.91}$=2.926; P=.003), confirming its effectiveness.

[a]AAC: augmentative and alternative communication.

[b]TALI: Technology-Assisted Language Intervention.

[c]CELF-5: Clinical Evaluation of Language Fundamentals, Fifth Edition.

[d]TAU: treatment as usual.

[e]VABS: Vineland Adaptive Behavior Scale.

[f]MLU: mean length of utterance.

[g]DHH: deaf and hard of hearing.

[h]AR: augmented reality.

[i]E: efficiency index.

[j]CAPT: computer-aided pronunciation training.

Across the 5 AAC-focused studies, 4 studies [14,30,37,62] reported positive efficacy outcomes in specific language domains, including vocabulary growth, increased utterance length, and improvements in pragmatic communication, while 1 study did not include relevant efficacy data. For instance, in a 24-week study using AAC on iPads, the mean length of utterance increased from 2.41 to 3.68 (P=.002), the total words increased by 26.8 (P=.001), and different words increased by 8 (P=.008) [30]. In the randomized controlled trial of the Technology-Assisted Language Intervention (TALI), children aged ≥5 years showed a 12.7-point increase in Clinical Evaluation of Language Fundamentals, Fifth Edition Pragmatics Profile scores compared to a 6-point decrease in the treatment-as-usual group (P=.04) [62]. For children aged <5 years, significant improvements were observed in the Vineland Adaptive Behavior Scale (VABS) Communication (86.7-99.1) and social domain scores (91.8-97.4; P=.01). In addition, children in the TALI group demonstrated greater gains in the number of different words spoken (82-104) compared to the treatment-as-usual group, which increased from 82 to 87 [14]. This difference was statistically significant (β=11.04 vs β=2.65; P=.007), further emphasizing the more substantial impact of the TALI approach on language development [62]. Preliminary results suggest promise; however, most research designs had small sample sizes, short intervention durations, and heterogeneous outcome measures.

Only 12 studies reported efficacy outcomes; however, they had small sample sizes, short intervention periods, and methodological variability. Thus, the findings should be interpreted as exploratory rather than confirmatory. One study reported on the effectiveness of computer-assisted pronunciation training (CAPT) in supporting speech therapy for children with HIs [65]. Sztahó et al [65] found that, after a 3-month intervention, children using the CAPT app showed significantly improved prosody compared to the control group, with strong agreement between automatic assessments and teachers' ratings. Improvements were most notable in children with mild hearing loss, but were present across all levels [46]. Students in the treatment group showed large improvements in phonemic awareness, writing, vocabulary, and reading (all P<.05) with large effect sizes (d=0.99 - 2.03) [46].

Several studies (n=5) demonstrated the effectiveness of digital tools in enhancing the acquisition and development of signed languages [31,34,35,39,55]. A mobile app significantly improved signed-language learning compared to traditional methods (P=.01; η^2=0.585) because of its engaging, game-based features [34]. Ployjiw et al [35] reported vocabulary gains using

XSL•FO
RenderX

AR books, with scores increasing from 7.20 to 8.70 (P=.01) and instructional efficiency exceeding 85%. High satisfaction was noted, particularly with signed-language videos and parental involvement. The SiLearn app (developed by Joy et al [31]) also showed significant vocabulary improvements, confirming its positive impact. Another study [39] reported a sharp increase in English scores, while Techaraungrong et al [55] found that multimedia instruction outperformed traditional methods in basic math by enhancing motivation and independent learning. One study [32] reported on the efficacy of digital tools in supporting academic outcomes such as language, math, and classroom learning for children with HIs. Significant gains were observed in reading, grammar, and math mapping. Refer to Table 4 for the full results. Although several studies showed statistical significance, the limited number of studies on the efficacy of digital technology makes it difficult to draw conclusions on the comparative effectiveness of the intervention.

Discussion

Principal Findings

In this scoping review, we synthesized evidence regarding how digital technologies were used to support language learning for children with HIs across home, school, and clinical contexts. Of these technologies, mobile apps emerged as the most frequently used tools due to their accessibility, ease of use, and adaptability to different contexts [34,66]. This suggests that the ease of deployment is prioritized over the pedagogical depth and the mechanisms of language learning.

By contrast, other technologies, such as computer-based programs, AR, VR, tangible user interfaces, and social robotics, were implemented less frequently, probably due to higher costs, greater complexity, or limited availability [57,59,67]. The scoping review findings reveal 3 structural patterns in the existing evidence base, which affect the way in which children with HIs acquire languages through the use of digital technologies. These patterns relate to the dominance of mobile technologies, the relative focus on the use of signed-language vs spoken-language interventions, and the use of digital technologies in the classroom, the clinic, and the home.

One of the major findings of this review is that the majority of the mobile apps were created for signed-language learning, with a strong emphasis on enabling children to develop their communication skills through visual language [57,68]. This is also understandable since the relative ease of designing signed-language technologies may also be a factor, since it is much more easily implemented in mobile apps without the need for any complex auditory-processing capabilities. Besides the purpose of signed-language learning, other apps included speech-to-text functionality for general purposes of communication, as well as a variety of assistive learning apps such as literacy, reading, mathematics, and classroom apps [31,35,49].

By contrast, apps focusing on the development of spoken language were relatively limited, particularly for younger children. Existing spoken-language tools typically supported auditory training for children who used hearing aids or cochlear implants by using phoneme recognition, AAC, and interactive exercises to enhance speech, literacy, and pragmatic communication [27,30,48]. While the number of spoken-language apps was relatively small, both types of apps, whether focused on signed or spoken language, shared the same goal of helping children with HIs to communicate more effectively and strengthen their communication skills [30,32]. Despite this imbalance, both sign- and speech-oriented tools shared the overarching goal of improving children's ability to communicate effectively, which is essential for academic achievement, social inclusion, and overall quality of life [69].

There were also a number of studies (n=10) related to the design and development of spoken-language apps that were targeted at young children, which may indicate that there is a relative lack of digital interventions in this area. This has significant analytical connotations, as it has been demonstrated that early childhood is an important period in the development of spoken language, where input is maximally effective [70,71]. There may be several reasons why there is a relative lack of early childhood spoken language tools, including the developmental sensitivity, complexity, and therapy requirements to support early spoken-language development in children with HIs, rather than later ages or signed-language development. Nevertheless, digital interventions for early spoken-language development have the potential to serve as effective and low-cost tools to support therapy in contexts where access to professional support is limited. It is therefore essential to prioritize the development of the body of research on tools to support spoken-language development in association with family-based interventions and therapy in early childhood, as this is the period where interventions are maximally likely to have long-term effects.

An important finding of this study highlighted the value of designing mobile apps that were both interactive and engaging, particularly for children with HIs. Features such as games, modular activities, and visual feedback helped to maintain attention and to support learning [34]. This aligned with theories of multimodal learning, which suggest that combining auditory, visual, and kinesthetic inputs enhances comprehension and retention [72]. Evidence has shown that multimedia-based approaches demonstrated a stronger and more consistent impact on improving math skills compared to conventional teaching methods, as multimedia-based approaches enhanced students' motivation, improved comprehension, and promoted greater independence in learning [55]. Nevertheless, visual design must also take users' comfort and cultural relevance into account. Prolonged screen time may make children with HIs sensitive to harsh colors, such as bright red, which can cause eye strain [35]. In addition, culturally relevant content using familiar visuals, language, and contexts can improve engagement and comprehension [73]. Therefore, while rich interactive features enhance learning, they should be balanced with thoughtful visual and cultural design to ensure accessibility, comfort, and meaningful engagement.

We observed that most of the digital apps remained classroom-oriented and were rarely extended to a therapeutic setting or to home-based practice. With regard to spoken languages, multisensory approaches combining auditory and visual feedback in phoneme training, AAC platforms, or

XSL•FO
RenderX

gamified exercises were common. This approach aligned with evidence showing that pairing auditory training with visual reinforcement strengthened outcomes [74]. Signed-language apps typically emphasized vocabulary building and visual communication, but often relied on drill-based practice, with limited support for family engagement or integration into daily social and classroom interactions. Overall, many of the tools lacked progression, therapist dashboards, and parent-engagement features. Reviews of parent-mediated interventions have raised similar concerns, noting that family involvement and asynchronous support were often underused [75]. This highlights a gap in tools that actively involve families and provide opportunities for sustained, adaptive practice at home.

Most of the available evidence comes from high-income countries. Only a handful of studies examined interventions in low- and middle-income countries, despite these being the settings in which access to therapists and structured educational services is most limited. In these contexts, home-based practice and community-led learning frequently represent the primary pathways for children's communicative development. Addressing this challenge requires adapting and evaluating digital tools in resource-limited settings to ensure that they are relevant, sustainable, and responsive to the needs of both spoken- and signed-language users. Future work should therefore prioritize large-scale trials, long-term follow-up, and the cultural adaptation of digital interventions to ensure sustainability and broader impacts.

In terms of efficacy, AAC interventions demonstrated the strongest and most consistent evidence by improving utterance length, vocabulary, and pragmatic communication [14,37,62]. Signed-language apps, while effective for vocabulary and visual communication, often produced narrower outcomes that were limited to word-level learning [31,76]. Academic-oriented digital tools showed broader benefits in improving reading, writing, and mathematics, although their focus was less specifically on communication outcomes. Furthermore, CAPT interventions provided promising evidence for speech training and prosody, but the findings remain preliminary and were based on small-scale studies. Despite the positive outcomes, the evidence base remains limited. Many studies were short-term, small-scale, or lacked rigorous statistical testing, leaving questions about long-term efficacy and generalizability unanswered [13]. Few tools integrated therapist dashboards, adaptive progression, or structured parental involvement; these features could extend the benefits beyond drill-based practice. This review contributes to the field by providing an understanding of the role of current digital technologies in the facilitation of language learning across spoken-, signed-, and bimodal-language modalities, including the gaps in early spoken-language interventions, parent-mediated interventions, and culturally scalable interventions.

Limitations

This scoping review has several limitations. First, the search was limited to studies published in English, which may have led to the exclusion of relevant studies published in other languages. As a result, the findings may not fully represent global perspectives, particularly in non-English-speaking regions in which important work in this area may take place. Second, while efforts were made to include studies from reputable sources, some relevant interventions were reported in lower-impact journals, which may have affected the overall quality and reliability of the included evidence. Third, restricting the search to studies published after 2014 may have excluded earlier work on computer-assisted language-learning technologies. Nevertheless, the aim was to synthesize evidence relevant to contemporary digital learning environments that are more relevant to current educational and clinical practice. As this study is a scoping review, the purpose was not to evaluate the quality of the included studies; therefore, the results should not be considered indicative of the effectiveness of the interventions. Additionally, the results may have been influenced by publication bias, selective results reporting, and the exclusion of non-English publications, which may have contributed to the lack of representation of certain regions. Moreover, the development of technology may affect the longevity of the tools identified in the study.

Conclusion

This scoping review was intended to synthesize the existing literature concerning the use of digital technology to promote the development of languages among children with HIs in different settings such as the home, school, and clinic. The existing literature concerning the use of digital technology to promote language development among children with HIs indicates that there are 3 patterns that can be used to explain the use of digital technology to promote language development among children with HIs.

Mobile technology was the most widely used digital approach to promote language development among children with HIs due to its accessibility and adaptability across contexts. Among the mobile technologies, the use of signed-language interventions was the most commonly used to promote language development among children with HIs. The use of signed languages was effective in promoting vocabulary development among children with HIs. However, there was no existing literature concerning language development other than vocabulary among children with HIs. On the other hand, spoken-language interventions were less commonly used to promote language development among children with HIs. However, the existing literature concerning the use of AAC was effective in promoting vocabulary and language development among children with HIs in structured contexts and with the assistance of therapists and parents.

Another major gap that we identified is the early development of spoken language. Although it is acknowledged that the period of early childhood is a critical period for the development of language, there are still very few digital interventions for the development of spoken-language skills for young children with HIs. In addition, the interventions that were implemented did not have the essential characteristics of being adaptable, having therapist dashboards, and involving parents.

In conclusion, although digital technology is acknowledged as a potential facilitator of language development for children with HIs, this potential is limited by the imbalance between the 2 modalities and fragmented interventions. Further studies should

XSL•FO
RenderX

aim at the co-design and coevaluation of digital technology for the development of both signed and spoken languages for children with HIs, as well as the facilitation of the continuation of language learning for children both at home and school.

Abstract

Background: Daily activities shape individuals' health and well-being, reflecting functioning and lived health. For people with neurological conditions, these activities are often disrupted, affecting autonomy and quality of life. Traditional assessments miss subtle, real-time fluctuations, whereas ecological momentary assessment (EMA) captures moment-to-moment activity within natural contexts, offering insight into person-environment-occupation interactions. Despite its growing use, it remains unclear how EMA protocols conceptualize daily activities and integrate person-environment-occupation dimensions in applications for neurological populations.

Objective: This scoping review aims to map the existing literature on the use of EMA to capture daily activities, ranging from basic self-care to more complex activities, in individuals with neurological disorders.

Methods: A scoping review was conducted to map studies using EMA to capture daily activities in adults with neurological conditions, with a specific focus on content and practical application. A total of 341 articles were identified.

Results: A total of 20 studies using EMA to assess daily activities in neurological populations were included; most were observational, with 2 longitudinal studies and 2 randomized controlled trials. Daily activity questions and response formats varied, often using multiple-choice lists; only 1 study allowed open-ended responses. In addition to daily activity questions, EMA captured person (physical, affective, and cognitive), environment (physical and social), and occupation domains, as well as motivation and EMA disturbance. Protocols differed in setting, schedule, technology, and adherence, with most reporting completion rates above 70%.

Conclusions: EMA captures daily activities in neurological populations and demonstrates generally high adherence despite variability in study designs, questions, and technologies. The findings suggest that the phrasing of EMA items, the predominance of closed-response formats, and the narrow focus on the verb "doing" limit the depth and nuance of the data collected, often overlooking important aspects of performance, engagement, or both in daily activities.

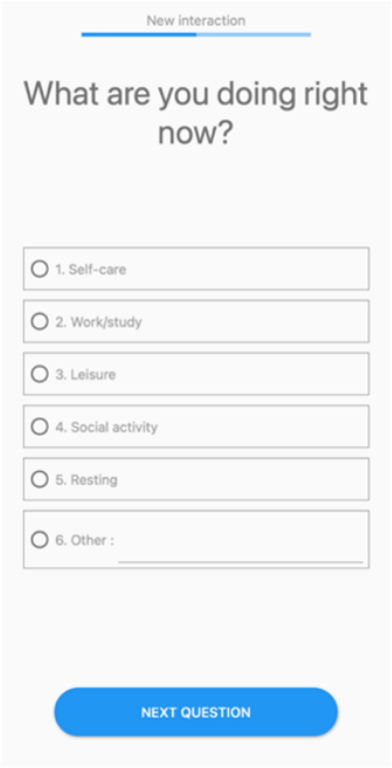
Introduction

Daily life is made up of countless activities that shape how individuals experience their health and well-being. Understanding how people engage in these daily activities offers important insights into the broader concept of functioning, which has gained recognition as a key link between medical conditions and the lived experience of health [1]. The World Health Organization's International Classification of Functioning, Disability and Health (ICF) emphasizes functioning not merely as the absence of disease, but as lived health: the capacity to carry out activities and participate in life situations within real-world contexts [2]. This perspective shifts attention toward what individuals are actually able to do in their environments and how they engage with the world around them. However, while the ICF offers a valuable conceptual framework, it provides limited guidance on how personal, environmental, and activity-related factors interact dynamically in daily life. To address this gap, the Person-Environment-Occupation (PEO) model has been widely applied in occupational science and rehabilitation research [3-5]. This model highlights the complex and evolving relationship among the person, environment, and occupation. Meaningful engagement in daily activities arises at the intersection of these 3 domains [4-8]. Daily activities are context- and role-specific, ranging from basic self-care to more complex activities such as work, leisure, and caregiving. They are central to human identity, autonomy, and connectedness [7,9]. Through these activities, individuals express preferences, fulfill social roles, and structure their everyday lives, making engagement in daily activities a vital expression of functioning and lived health. In this review, the term "daily activities" refers to observable actions and tasks performed in everyday life [10]. Although related, this construct is distinct from broader concepts such as participation (involvement in life situations, as defined in the ICF) and occupation (as conceptualized within the PEO model) [2,4]. To ensure conceptual clarity, these terms are used consistently and are not treated as interchangeable.

However, for individuals living with neurological disorders, engagement in daily activities is frequently challenged or disrupted. Neurological disorders encompass a wide range of conditions, including multiple sclerosis (MS), spinal cord injury, stroke, traumatic brain injury, and neurodegenerative disorders such as Parkinson and Alzheimer disease [11]. Recent global data underscore the magnitude of this issue. A major study published in The Lancet Neurology in collaboration with the World Health Organization, drawing on the Global Burden of Disease 2021 dataset, revealed that more than 3 billion people worldwide were living with a neurological disorder in 2021 [12]. Neurological disorders have become the leading cause of disability worldwide. Since 1990, the burden associated with these disorders, measured in disability-adjusted life years—which combine years lost due to ill health, disability, or premature death—has increased by 18%, highlighting their profound impact on functional independence and quality of life [12]. While clinical symptoms such as motor deficits, cognitive decline, and sensory impairments are well documented, the real-world consequences of these disorders, particularly their effect on engagement in daily activities, remain a critical yet underexplored area in both research and clinical practice. For example, motor impairments, such as paralysis and loss of mobility, can disrupt basic self-care activities [13]. A similar pattern is observed in MS, where 42% of individuals reported a decline in their ability to manage daily life over a 2-year period [14]. These conditions differ substantially in symptom presentation, disease progression, and associated functional limitations, influencing the nature of engagement in daily activities.



To effectively support individuals living with neurological disorders, it is essential to gain a nuanced understanding of how daily activities are experienced and performed. To this end, a range of established assessments and observational tools are used to examine the factors that influence engagement in daily activities, namely, the dynamic interaction among the person, the environment, and the activity itself [15]. Within the ICF, a distinction is made between capacity—what a person is able to do in a standardized or controlled environment—and performance—what a person actually does in their real-life context [2]. Assessments at the activity level, such as the Canadian Occupational Performance Measure [16], the Functional Independence Measure, and the Barthel Index [17], primarily address this domain, often with a focus on performance in everyday tasks. Assessments at the participation level of the ICF—referring to a person's involvement in everyday situations and society—are also limited for individuals with neurological disorders. In addition, diagnosis-specific instruments, such as the Parkinson's Disease Questionnaire, the Barthel Index, and the Quadriplegia Index of Functioning, are frequently used to capture functional status [2]. However, most of these tools rely on retrospective self-reports and structured observations, which have limited capacity to capture the subtle, moment-to-moment fluctuations that shape everyday functioning [18,19]. As they reflect past experiences rather than real-time activity, they are vulnerable to memory bias, social desirability effects, and inaccurate recall [20,21]. As a result, these methods often fail to detect microprocesses—small but meaningful behavioral and cognitive patterns—that play a crucial role in shaping engagement in daily activities [8,20]. One of the main challenges is the lack of assessments that directly measure how people perform their daily activities. In recent years, advances in digital health technologies have enabled more objective approaches to capturing aspects of daily behavior, such as mobility tracking, sensor-based monitoring, and smartphone interaction data [22]. While these methods provide valuable, continuous measurements of observable behavior, they offer limited insight into the subjective experience, meaning, and contextual factors that shape engagement in daily activities [9,20,22]. As a result, they may not fully capture how individuals perceive, interpret, and engage in their daily lives.

To overcome the challenge of accurately capturing daily activities, ecological momentary assessment (EMA) has emerged as a promising approach. EMA typically involves repeated assessments administered multiple times per day over several days or weeks, often delivered via smartphone-based apps or other digital devices. Participants receive prompts at fixed or random intervals and are asked to report on their current experiences, behaviors, or context in real time. This approach

XSL•FO
RenderX

minimizes recall bias and enhances ecological validity by capturing data in natural environments as events unfold. By collecting real-time data on behavior, emotions, and contextual factors in people's natural environments through regular, random prompts covering various topics, EMA offers a dynamic way to understand daily life as it unfolds [20,23,24]. Also referred to as ambulatory assessment or experience sampling methodology, EMA has been widely adopted across the health sciences, psychology, and clinical research. Its applications range from monitoring symptoms and evaluating treatments to designing personalized interventions, such as Just-In-Time Adaptive Interventions and Ecological Momentary Interventions, for individuals with and without disabilities [25-30]. To provide a concrete illustration of how EMA is experienced by participants, an example of an EMA prompt is presented in Figure 1. The illustration was created using the m-Path platform and serves as an example only; it was not derived from an included study. The potential of EMA to provide insight into daily activities was recently highlighted in a bibliometric review, which demonstrated that EMA has been applied across a wide range of domains, including neurological disorders. Notably, individuals with neurological disorders represented the third largest population in which daily activities were assessed using EMA [31]. However, while this review provided an overview of the fields in which EMA has been applied, it did not examine how daily activities are specifically measured or how daily activity–related questions, arising from the dynamic interaction among the person, occupation, and environment, are incorporated into EMA protocols for individuals with neurological disorders [31].

Figure 1. Example of an ecological momentary assessment question.

Note: The illustration was created using the m-Path platform and serves as an example only.

In addition to understanding what is measured, it is equally important to consider how EMA protocols that include questions about daily activities are conducted. Key design characteristics of EMA protocols, such as the sampling schedule, number of assessments, delivery tools (eg, smartphone apps), and participant adherence, play a crucial role in determining feasibility, participant burden, and data quality [20,21,24,32]. For example, a higher sampling frequency may increase ecological validity but also participant burden, potentially reducing adherence [32]. Despite the growing use of EMA in health research, there is currently no clear consensus on how these design characteristics should be optimized when assessing daily activities, particularly in populations with neurological disorders. As a result, substantial variability exists in how EMA protocols are applied, which may influence both the feasibility of implementation and the validity of the data collected.

Therefore, an analysis is needed to understand which aspects of daily activities are captured in EMA studies, particularly in relation to the PEO model. For example, it remains unclear whether current EMA methodologies adequately capture person-, environment-, and occupation-related aspects of daily activities. In addition, it is important to understand how EMA is implemented, including its key design characteristics. Therefore, this scoping review aims to map the existing literature on the use of EMA to capture daily activities, ranging from

XSL•FO
RenderX

basic self-care to more complex activities, in individuals with neurological disorders. Specifically, this review addresses 2 key dimensions:

- Content-related aspects (WHAT): identifying EMA items that directly assess daily activities and analyzing how additional EMA questions relate to daily activities through the lens of the PEO model; and
- Practical application (HOW): examining the key design characteristics of EMA protocols and their potential implications for feasibility and data quality.

Methods

Design

A scoping review was conducted in accordance with the framework of Arksey and O'Malley [33] and reported following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews; see Multimedia Appendix 1) guidelines to map the existing literature on how EMA is used to capture daily activities in individuals with neurological disorders [34].

Search Strategy

The search focused on neurological disorders and included the most prevalent conditions identified in Feigin et al [11]. This restriction was applied to ensure methodological coherence and feasibility. To ensure a comprehensive search, we combined the MeSH term "Nervous System Diseases" with a selection of specific neurological conditions. The MeSH term was used in its exploded form, thereby capturing a wide range of related disorders within the hierarchical MeSH structure (eg, cerebrovascular diseases and spinal cord diseases), including conditions not explicitly listed as separate search terms. Additional specific conditions (eg, tetanus, migraine, and brain neoplasms) were included to increase sensitivity, account for potential variability in indexing and terminology across databases, and capture studies not yet indexed with MeSH terms. This set of disorders was combined with terms related to daily activities and EMA. Daily activities were operationalized broadly to capture activities across different contexts and roles, ranging from basic self-care to more complex activities such as work, leisure, productivity, and caregiving. This approach aligns with an occupational perspective in which daily activities are understood as emerging from the dynamic interaction among the person, environment, and occupations performed, as described in the PEO model [3,4]. EMA was defined as a real-time assessment method, also referred to as ambulatory assessment or experience sampling methodology, designed to capture experiences, behaviors, and activities as they occur in everyday life [20,21,23]. The complete search string is presented in Multimedia Appendix 2.

The search was performed on February 27, 2025, across the following electronic databases: MEDLINE, Scopus, Embase, and Web of Science. These databases were selected to ensure broad coverage of biomedical and interdisciplinary research. The search strategies presented in Multimedia Appendix 2 were adapted to the indexing systems and technical requirements of each database. Although minor adjustments in syntax were made, the underlying search concepts and structure remained consistent across databases. The initial search yielded 341 records. After duplicates were removed, 207 unique articles remained. Following the screening of these 207 articles, an additional search for gray literature was performed using DANS Data Station Social Sciences and Humanities, DANS Data Station Life Sciences, and ProQuest Dissertations & Theses. However, this gray literature search did not identify any additional relevant records.

Data Screening

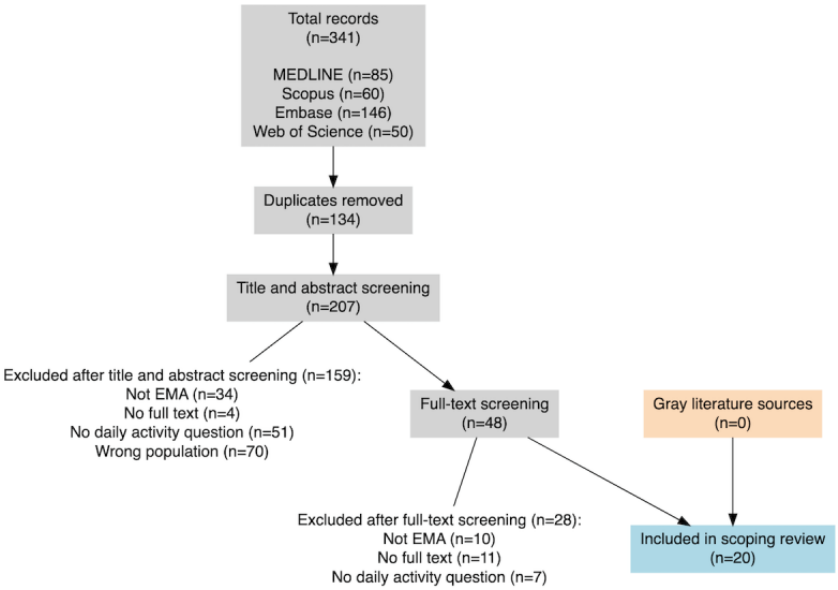
Following the search strategy, the screening process commenced. An initial screening of titles and abstracts was performed using the following inclusion criteria: (1) studies that used EMA, experience sampling method, or ambulatory assessment, or that met the core characteristics of EMA methodology. These characteristics included repeated data collection in real-world environments using prompts delivered at fixed or random intervals, with participants reporting on their current or very recent experiences, behaviors, or context. Given the variability in terminology, studies were not excluded solely based on the terminology used if their methodological characteristics aligned with EMA. (2) Neurological populations defined according to the classification of neurological disorders described in the Global Burden of Disease framework. Studies were included if the sample consisted predominantly of individuals with a neurological condition. Studies including mixed samples were considered only if data from participants with neurological conditions could be clearly identified. (3) At least one item related to daily activities in the EMA protocol, defined as questions explicitly referring to participants' engagement in everyday activities or tasks (eg, what the participant was doing at the moment or during a recent period). Only studies including at least one such item within the EMA protocol were retained. (4) Full-text research reports, regardless of publication type (eg, peer-reviewed articles or gray literature such as theses). The exclusion criteria were (1) poster or conference abstracts and (2) mHealth apps that did not implement EMA methodology.

The screening was performed independently by 2 reviewers. Two members of the research group each served as the first reviewer, while the lead researcher (ED) served as the second reviewer. Discrepancies were discussed during regular meetings until consensus was reached. After the initial title and abstract screening, 159 articles were excluded. Subsequently, a full-text screening was conducted, again using independent duplicate review. After this stage, an additional 28 articles were excluded. The final selection comprised 20 articles included for data analysis. The entire screening process was managed using Rayyan software.

Data Extraction and Analysis

Following screening, the included articles were systematically analyzed based on their full texts. Data analysis was conducted using structured extraction tables developed for this review. Data extraction and coding were performed independently by 2 reviewers, following the same approach used during screening. Any uncertainties or discrepancies regarding extracted variables (eg, PEO categorization, setting, or study type) were discussed

XSL•FO
RenderX



during regular meetings until consensus was reached. Three main domains were extracted to address the research question. First, general study characteristics were recorded for each included study, including article information, setting, study design, and population. Second, content-related aspects focused on how daily activities were assessed using EMA. All EMA items directly assessing daily activities were extracted, together with their response formats. In addition, supplementary EMA items were coded according to the components of the PEO model, distinguishing among person-, environment-, and occupation-related constructs. The categorization of EMA variables into the PEO domains was guided by the theoretical definitions of the PEO model [4]. Each item was assigned to the domain that best reflected its primary focus, based on predefined subdimensions (eg, physical, affective, and cognitive aspects for the person domain). Third, practical application aspects addressed key design characteristics of EMA protocols and their potential implications for feasibility and data quality. These data were summarized in a separate extraction table and included the EMA schedule, number and timing of assessments, and reported adherence rates. To explore broader trends in EMA design characteristics, exploratory simple linear regression analyses were conducted using RStudio (version 2024.12.0+467; Posit PBC). Three simple linear regression analyses were performed: (1) regressing the number of assessments per day on study duration (days), (2) regressing adherence on the total number of EMA assessments, and (3) regressing adherence on EMA schedule. Given the limited number of included studies and incomplete reporting of adherence data, the regression analyses were conducted in an exploratory manner to identify potential trends rather than establish confirmatory associations. The analyses were not weighted by sample size. For visualization purposes, study sample size was represented by point size. Model assumptions (eg, linearity, normality of residuals, and homoscedasticity) were assessed by visual inspection. Studies reporting nonfixed ranges for predictor variables were excluded from the relevant regression analyses to avoid arbitrary estimates.

Results

General Information of Included Articles

In total, 20 articles on the use of EMA to assess daily activities in populations with neurological disorders were included, representing 1128 participants (Figure 2). However, this number should be interpreted with caution, as several publications appeared to originate from overlapping datasets or closely related participant cohorts. Consequently, the reported participant total likely overestimates the number of unique individuals represented across studies. This overlap should also be considered when interpreting patterns in EMA protocol characteristics and adherence. The populations studied included individuals with stroke (n=11), acquired brain injury (n=3), traumatic brain injury (n=2), Parkinson disease (n=1), tinnitus (n=1), hereditary spastic paraplegia (n=1), and MS (n=1). Sample sizes varied considerably across studies, ranging from 7 to 212 participants. The majority of the included studies were observational, alongside 2 longitudinal studies and 2 randomized controlled trials. The studies were published between 2012 and 2024. Most studies (15/20) were conducted primarily in a home setting, often combined with brief laboratory visits. Three studies were conducted entirely in the home environment, 3 exclusively in community settings, 1 exclusively in a hospital, and 1 across both home and hospital settings. An overview of the included studies is presented in Table 1.

Figure 2. Study flowchart.

Table 1. General information about the included studies.

Study	Setting[a]	Study type	Population
Blome et al [35]	Home	Observational (qualitative and exploratory)	People with multiple sclerosis (n=17)
Broen et al [36]	Home	Observational (feasibility study)	Parkinson disease with motor fluctuations (n not stated)
Bui et al [37]	Home + laboratory visits	Observational	Mild-to-moderate stroke (n=202)
Bui et al [38]	Community + laboratory visits	Longitudinal observational	Mild-to-moderate stroke (n=212)
Ezekiel et al [39]	Community (not explicitly stated)	Observational (qualitative usability)	Acquired brain injury (n=7)
Forster et al [40]	Hospital	Observational (pilot study)	Acquired brain injury with cognitive or motor impairments (n=15)
Hart et al [41]	Community	Randomized controlled trial (protocol)	Moderate-to-severe traumatic brain injury (n=60)
Henry et al [42]	Home	Observational (pilot)	Tinnitus (n=24)
Jean et al [43]	Community	Observational (preliminary)	Stroke (first-ever ischemic/hemorrhagic, n=36)
Lau et al [44]	Home + laboratory visits	Observational/prospective cohort	Stroke survivors (n=40, aged 18-65)
Lau et al [45]	Home + laboratory visits	Observational	Stroke survivors (n=40, aged 18-65)
Lau et al [46]	Home + laboratory visits	Observational	Stroke survivors (n=40, aged 18-65)
Lau et al [47]	Home + laboratory visits	Observational	Stroke survivors (n=40, aged 18-65)
Lenaert et al [48]	Home + laboratory visits	Feasibility study/observational	Acquired brain injury (stroke or traumatic brain injury, n=17)
Lenaert et al [49]	Home + laboratory visits	Longitudinal observational	Stroke (n=30)
Sartori et al [50]	Home + laboratory visits	Cross-sectional observational	Hereditary spastic paraplegia (n=50)
Shi et al [51]	Home + laboratory visits	Prospective observational	Stroke (n=202)
Rabinowitz et al [52]	Home + laboratory visits	Randomized controlled trial (exploratory)	Traumatic brain injury (minimum 6 months after injury, n=23)
Villain et al [53]	Hospital (baseline) and home (follow-up)	Prospective observational	Mild ischemic stroke (baseline n=44; follow-up n=34)
Villain et al [54]	Home + laboratory visits	Observational	Minor ischemic stroke (n=34)

[a]Setting refers to the context in which ecological momentary assessments were conducted, as described in the included studies. “Home” indicates assessments primarily conducted in participants’ home environments; “community” refers to assessments conducted in everyday environments beyond the home (eg, during daily life in the community); “hospital” refers to inpatient or clinical settings; and “home + laboratory visits” indicates ecological momentary assessment conducted in daily life combined with scheduled research or clinical visits.

Content Related

Across the included studies, questions about daily activities differed in both temporal framing and linguistic phrasing (Table 2), yet all were designed to capture participants’ engagement in daily activities. Some studies used explicitly time-bound prompts with multiple-choice response options, such as “What are you doing right now?” [40,42], whereas others referred to a retrospective period, for example, “What have you been doing over the past hour?” [41,52]. The degree of temporal specificity ranged from minutes [39] to hours [41]. By contrast, Lau et al [45] used a general, non-time-specific question (What are you doing?). In terms of phrasing, the verb “doing” was consistently used to denote the performance of or engagement in daily activities. Six studies [39-42,45,52] addressed participants in the second person (you), whereas 3 studies [36,48,49] used first-person phrasing (eg, “What am I doing?”). Notably, in 11 [35,37,38,43,44,46,47,50,51,53,54] of the 20 included articles, the exact wording of the daily activity question was not reported, either in the main manuscript or in the available supplementary materials.

Table 2. Content-related daily activities questions and answer possibilities.

Study	Questions on daily activities	Answer possibilities	
		Multiple choice answers	Open box
Blome et al [35]	Usual activities (question not reported)	A lot of daily activity options (options not reported)	Not reported
Broen et al [36]	Currently I am:	Resting, working, housework, hygiene, eating, drinking, relaxing, conversating, or other	Not reported
Bui et al [37]	Daily activities (question not reported)	Physical, cognitive, social, activities of daily living, instrumental activities of daily living, vocational, or passive leisure activities. Further grouped into "total productive" versus "nonproductive, sedentary" activities.	Not reported
Bui et al [38]	Daily activities (question not reported)	Physical, cognitive, social, activities of daily living, instrumental activities of daily living, vocational, or passive leisure activities. Further grouped into "total productive" versus "nonproductive, sedentary" activities.	Not reported
Ezekiel et al [39]	What have you been doing for the last 10 minutes?	Looking after myself, sport exercise, working or studying, social activities, using a computer/tablet/phone, household or family tasks, hobby or quiet pastime, or traveling	Not reported
Forster et al [40]	What are you doing right now?	Exercising, therapy, drinking coffee, taking a break, watching TV, eating, listening to radio/music, reading, surfing the internet, talking to others, or being outside	Not reported
Hart et al [41]	What have you been doing over the past hour or so?	Learning/school activity, working, household chores/pet care, leisure activity, pray/worship/meditate, resting/sleeping, watching TV/video, walking, shopping/errands, talking or socializing, reading, listening to music/radio/podcast, playing videogames/e-games, active play/sports/exercise, intimate relations, social media/internet/email/texting, preparing food/cooking, care of children, or other	Not reported
Henry et al [42]	What are you doing right now?	Working at paid job, watching TV/computer, etc, eating a meal, physical activity, or other	Not reported
Jean et al [43]	Current activity (question not reported)	Doing nothing or resting, work, sports, watching television, listening to music, having an in-person conversation, having a phone conversation, nonphysical leisure, personal hygiene, eating, or other daily life activities	Not reported
Lau et al [44]	Current daily activity (question not reported)	Multiple choice options were not reported.	Not reported
Lau et al [45]	What are you doing?	List of 44 daily activities, developed based on validated ecological momentary assessment surveys and the Activity Card Sort. According to the Activity Card Sort, activities were categorized into 4 domains (instrumental activities of daily living [eg, shopping], high-physical-demand leisure activities [eg, gardening], low-physical-demand leisure activities [eg, watching TV], and social activities [eg, visiting family or friends]), or an additional domain of activities of daily living (eg, toileting).	Not reported
Lau et al [46]	Daily activities (question not reported)	Multiple choice options were not reported.	Not reported
Lau et al [47]	Current activity (question not reported)	List of 44 daily activities (eg, watching TV, eating out, gardening), developed based on validated ecological momentary assessment surveys and the Activity Card Sort.	Not reported
Lenaert et al [48]	What am I doing (just before the beep)? And also? And?	Doing nothing, resting, work, household, self-care, taking care of partner, relaxation, or something else	Not reported
Lenaert et al [49]	What am I doing?	Nothing, resting, working, household, self-care, relaxing, traveling, or other	Not reported
Sartori et al [50]	Ongoing activity (question not reported)	Not reported	Categorized into productive, leisure, interactions, personal care, and others (open-ended)

XSL•FO
RenderX

Study	Questions on daily activities	Answer possibilities	
		Multiple choice answers	Open box
Shi et al [51]	What activities they were engaging in (question not reported)	Productive (eg, eating, exercising, visiting health care providers) or nonproductive (eg, resting, smoking, and doing nothing). Options were not reported.	Not reported
Rabinowitz et al [52]	What have you been doing over the past hour or so?	Learning/school activity working, household chores/pet care, leisure activity, pray/worship/meditate, resting/sleeping, watching TV/video, walking, shopping/errands, talking or socializing, reading, listening to music/radio/podcast, playing videogames/e-games, active play/sports/exercise, intimate relations, social media/internet/email/texting, preparing food/cooking, care of children, or other (to be specified in textbox)	Not reported
Villain et al [53]	Activities of daily living (question not reported)	Leisure activities (sport, nonphysical leisure, watching television, or listening to music) and activities of daily living (working, shopping, cooking, or housework). Options were not reported.	Not reported
Villain et al [54]	Activities (question not reported)	Multiple choice options were not reported.	Not reported

As presented in Table 2, various response formats were used to assess daily activities. As many as 19 [35-49,51-54] of the 20 included studies relied on multiple-choice response options with predefined activities, whereas 1 study [50] allowed open-ended responses. Several studies offered highly detailed lists of daily activities, often based on validated instruments. For instance, Lau et al [45,47] presented a list of 44 discrete activities derived from validated EMA surveys and the Activity Card Sort, which were subsequently grouped into 4 functional domains—instrumental activities of daily living, high-physical-demand leisure, low-physical-demand leisure, and social activities—with an additional category for basic activities of daily living [45,47]. Bui et al [37,38] also used a multidimensional classification, grouping activities into physical, cognitive, social, activities of daily living, instrumental activities of daily living, vocational, and passive leisure activities, and further categorizing them as "total productive" versus "nonproductive/sedentary" [37,38]. Forster et al [40], Henry et al [42], Ezekiel et al [39], Rabinowitz et al [52], and Hart et al [41] provided varied lists encompassing both work-related and leisure activities, including digital media use (eg, listening to music, social media, and gaming) and household responsibilities (eg, cooking and caring for children). Additionally, 3 studies [43,48,49] explicitly included the option "doing nothing." The option "other" was included in 6 studies; however, it was not always clear whether participants could provide a written specification for this response or whether it simply indicated that none of the listed options applied [36,41-43,49,52]. In 5 studies, the specific multiple-choice response options were not reported in either the main manuscript or the supplementary material [44,46,50,53,54]. The complete set of detailed data is presented in Table 2.

Alongside items related to daily activities, the EMA protocols included measures of various additional constructs, as daily activities were not the primary focus of all included studies. To support synthesis and interpretation, these constructs were classified using the PEO model. Within this review, daily activities are conceptually understood as emerging from the dynamic interaction among the person, environment, and occupation, consistent with occupational science perspectives. However, for the purpose of this supplementary analysis, the PEO model was applied analytically by examining its components separately. This approach was used to categorize EMA items that addressed person-, environment-, or occupation-related aspects without constituting direct assessments of daily activities. Although the PEO domains are inherently interrelated, considering them as distinct analytical categories enabled the identification of common patterns and areas of emphasis across studies (Table 3).

XSL•FO

[a]PEO: Person-Environment-Occupation.

[b]PANAS: Positive and Negative Affect Schedule.

Within the person domain, the PEO model distinguishes among physical, affective, and cognitive dimensions. Physical aspects were frequently assessed across the included studies and included symptoms such as pain, fatigue, mobility limitations, stress, and somatic complaints [35,36,38,42,44-49,51]. One study [39] also incorporated objective performance indicators, such as reaction time, as a proxy for fatigue. Affective measures were particularly prevalent, capturing mood states ranging from positive (eg, cheerfulness) to negative (eg, anxiety, depression, and feelings of worthlessness). Emotional valence was assessed using either discrete affective descriptors (eg, Positive and Negative Affect Schedule [PANAS] items) or global mood ratings. Cognitive constructs included concentration, cognitive complaints, mental fatigue, self-reflection frequency, and perceived effort (eg, Lau et al [45-47], Forster et al [40]; Sartori et al [50]; Shi et al [51]), although these were assessed far less frequently than physical or affective dimensions [40,45-47,50,51].

Within the environment domain, additional EMA items were categorized into physical, institutional, cultural, and social environments according to the PEO model. Only the physical and social environments were represented in the included studies; no EMA items addressed institutional or cultural environments. The physical environment was typically assessed through questions about participants' immediate location [37,38,41-43,48-51] and environmental conditions such as noise or loudness [36,42]. Assessments of the social environment focused on the presence or absence of social company, perceived social support, and experiences of social isolation [36-38,40-43,48,50-52].

Within the occupation domain, considerably fewer EMA items addressed this aspect than the person and environment domains. In the PEO framework, occupation is typically divided into self-care, productivity, and leisure. Only 1 study [35] explicitly assessed self-care activities. The remaining studies addressed the occupation domain more broadly by focusing on constructs such as activity quality, perceived importance of the event, satisfaction with the activity, judgment of performance, sense of accomplishment, perceived control over the activity, and whether the activity was considered important or unexpected [36,37,40,41,48-50,52].

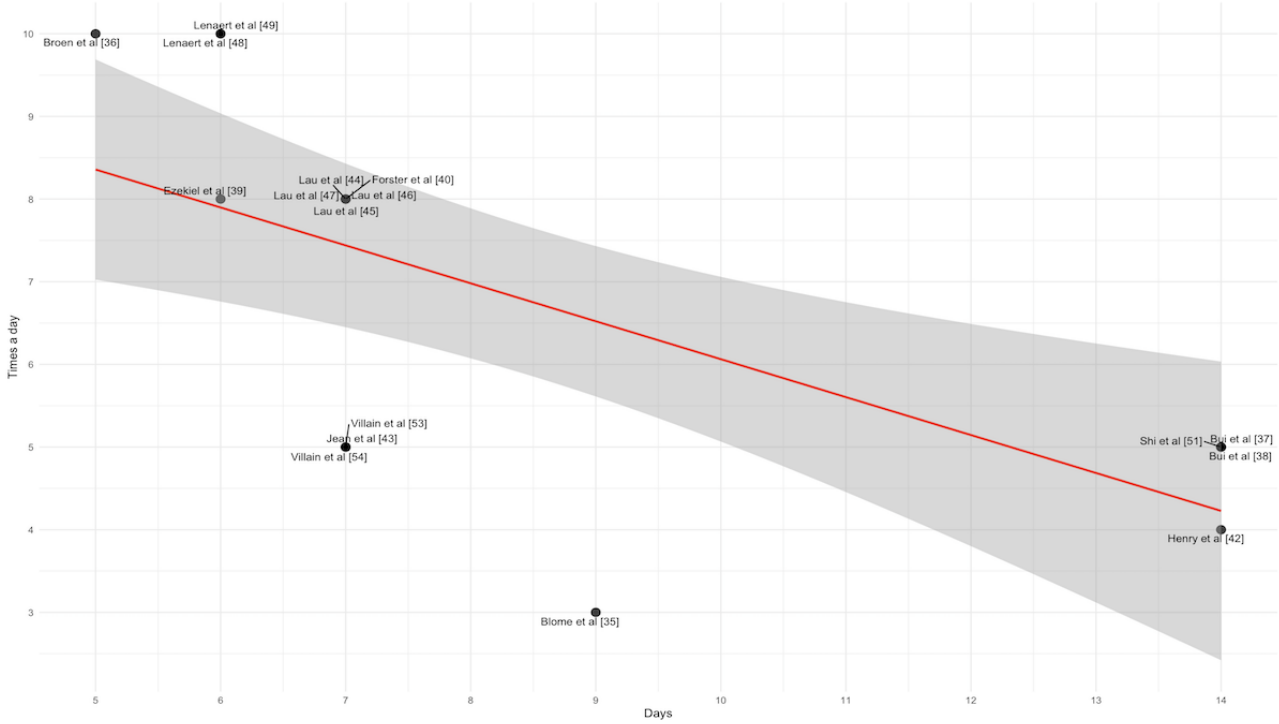
In addition to the constructs categorized according to the PEO model, some EMA measures could not be directly assigned to a single PEO component, including motivation and EMA disturbance. In 4 studies [44,46,47,50], motivation was assessed alongside PEO-related constructs, consistent with self-determination theory. One study [48] also assessed EMA disturbance, defined as the extent to which the EMA protocol itself was perceived as disruptive during daily life. The complete set of detailed data on these additional constructs is presented in Table 3.

Practical Application

Across the included studies, a variety of technological platforms were used, including the PsyMate app (n=3), the RealLife Exp app (n=2), the PIEL Survey App (n=4), EQ-5D-AA on a mobile phone, custom Android apps, movisensXS, Palm Pilot, and PMAT v2.1.2. EMA schedules also varied considerably across studies. The complete set of detailed data is presented in Table 4.

XSL•FO
RenderX

Table 4. Practical application.



Study	EMA[a] schedule	EMA tool	Time points	Adherence, %
Blome et al [35]	3 times/day for 9 days (morning, midday, and evening)	EQ-5D-AA on mobile phone	27	92.6
Broen et al [36]	10 times/day for 5 days, semirandom within 90-minute blocks (7:30 AM-10:30 PM)	PsyMate app (iPod Touch or own smartphone)	50	84.0
Bui et al [37]	5 times/day for 14 days between fixed time blocks (8 AM-10 PM)	Not specified	70	86.3
Bui et al [38]	5 times/day for 14 days, random start within fixed 2-hour blocks	Status/Post app (iPod Touch or iPhone)	70	84.0
Ezekiel et al [39]	8 times/day for 6 days; 2 fixed + 6 stratified random (10 AM-8 PM)	Custom Android app	48	Not reported
Forster et al [40]	8 times/day for 7 days, semirandom (8 AM-8 PM)	movisensXS (Android)	56	71.6
Hart et al [41]	5 times/day, pseudo-randomized over a 14-hour window. Duration in days not reported.	RealLife Exp app	Not reported	Not reported
Henry et al [42]	4 times/day for 14 days, fixed intervals with reminders	Palm Pilot (CERTAS software)	56	90
Jean et al [43]	5 times/day for 7 days, fixed time blocks per participant	PMAT version 2.1.2 (PDA)	35	74.1
Lau et al [44]	8 times/day, 7 days, 2-hour intervals (8 AM-10 PM)	PIEL Survey App	56	93.6
Lau et al [45]	8 times/day, 7 days, 2-hour intervals (8 AM-10 PM)	PIEL Survey App	56	93.6
Lau et al [46]	8 times/day, 7 days, 2-hour intervals (8 AM-10 PM)	PIEL Survey App	56	93.6
Lau et al [47]	8 times/day, 7 days, 2-hour intervals (8 AM-10 PM)	PIEL Survey App	56	93.6
Lenaert et al [48]	10 signals/day for 6 days, semirandom (7:30 AM-10:30 PM)	PsyMate	60	71.2
Lenaert et al [49]	10 signals/day for 6 days, semirandom (7:30 AM-10:30 PM)	PsyMate	60	65
Sartori et al [50]	6-8 times/day for 7 days, randomized (8 AM-10 PM)	Not specified	42-56	54.9
Shi et al [51]	5 times/day for 14 days, about 2.5-hour intervals (8 AM-10 PM)	iPod Touch or iPhone app	70	84.3
Rabinowitz et al [52]	5 times/day, pseudo-random within a 14-hour window, 7-18 days	RealLife Exp app	35-90	65
Villain et al [53]	5 times/day, 7 days (fixed blocks: 9 AM-10 PM)	Palm Tungsten E2	35	74
Villain et al [54]	5 times/day for 7 days	Palm Tungsten E2	35	74

[a]EMA: ecological momentary assessment.

Given the variability in EMA schedules, Figure 3 (also see [35-40,42-49,51,53,54]) provides a visual representation of the included protocols. Regarding prompt timing within the day, 3 main scheduling patterns were identified: fixed intervals (eg, Henry et al [42]), semirandom or pseudorandom prompts within predefined time blocks (eg, Broen et al [36] and Lenaert et al [48,49]), and mixed fixed and random approaches (eg, Ezekiel et al [39]). The number of daily prompts also varied substantially across studies, ranging from fixed schedules (eg, Lau et al [46]) to variable schedules reported as ranges (eg, 6-8 prompts/day in Sartori et al [50]; 7-14 prompts/day in Rabinowitz et al [52]). Studies reporting a range rather than a fixed number of daily prompts were excluded from the exploratory regression analyses to avoid arbitrary estimates. In addition, Hart et al [41] was excluded because of insufficient reporting on EMA duration. Consequently, the exploratory regression analyses included 17 studies. The number of daily prompts ranged from 3 to 10, whereas study duration ranged from 5 to 14 days. Some studies combined shorter study periods with high sampling intensity. For instance, Broen et al [36] and Lenaert et al [48,49] collected data over only 5 days but prompted participants up to 10 times per day, representing the highest daily sampling intensity. Conversely, Henry et al [42], Shi et al [51], and Bui et al [37,38] collected data over 14 days but limited daily prompts to 4 or 5. A significant inverse association was observed (β=–.46, P=.004): studies with shorter durations generally used higher daily sampling frequencies, whereas those with longer study periods used fewer daily assessments. A slightly different pattern was observed in Blome et al [35], which used a 9-day protocol with 3 daily prompts. Approximately half of the included studies used a 7-day protocol with 5-8 prompts per day [40,43-47,50,53,54].

Figure 3. Regression analysis of the ecological momentary assessment schema of the included studies.

Additionally, adherence rates were examined in relation to the number of daily prompts. As shown in Figure 4 (see also [35-38,40,42-49,51,53,54]), adherence rates varied widely across studies, ranging from approximately 55% to more than 90%. No clear association was observed (β=–.919, *P*=.42). A slight positive trend was observed in Figure 5 ([see also 35,36,40-49,51-54]) between adherence and study duration, with longer studies tending to show somewhat higher adherence. However, this relationship did not reach statistical significance (β=.851, *P*=.28). Adherence rates were also examined in relation to the total number of EMA assessments (Figure 6; see also [35-38,40,42-49,51,53,54]). Overall, adherence was relatively high, with most studies reporting completion rates above 70%. The highest adherence (93.6%) was reported in studies with 56 assessments (eg, Lau et al [45-47]), whereas 1 study [35] reported similarly high adherence (92.6%) with 27 assessments. No significant linear association was observed between the total number of assessments and adherence (β=.087, *P*=.66). However, studies with a high number of assessments (>65) generally maintained adherence above 80% (eg, Bui et al [37] and Shi et al [51]), whereas studies with 50-60 assessments showed greater variability, with completion rates ranging from 55% to more than 90%. For consistency across the exploratory regression analyses, only studies reporting the complete set of required variables were included. Four studies were excluded because of incomplete reporting of adherence, EMA duration, or the total number of assessments. Specifically, Hart et al [41] and Ezekiel et al [39] did not report adherence data, whereas Rabinowitz et al [52] and Sartori et al [50] reported variable EMA schedules without a fixed study duration. To ensure comparability across analyses, these studies were excluded from the regression models and are therefore not represented in Figures 4-6. These findings should be interpreted as exploratory because of the limited number of included studies.

Discussion

Principal Findings

This scoping review aimed to map the existing literature on the use of EMA to capture daily activities in individuals with neurological disorders, with a specific focus on content-related aspects and practical application. Twenty articles published between 2012 and 2024 were identified in which EMA was used to assess daily activities. Although EMA has been available for several decades since its introduction by Csikszentmihalyi and Larson in 1987 [21], only 20 studies [35-54] have focused on this population with the explicit aim of gaining insight into daily activities [55,56]. This relatively small body of literature is surprising because improving daily activities is a central goal of neurological rehabilitation and is essential for maximizing recovery, maintaining independence, and supporting long-term health, participation, and quality of life after formal rehabilitation has ended [2,9,57]. Given that EMA is specifically designed to capture experiences and behaviors in everyday life, its application to assessing daily activities in neurological rehabilitation remains surprisingly limited.

While EMA holds clear promise as a method for capturing daily activities, it is important to distinguish it from emerging passive sensing approaches. Although technologies such as wearable sensors and smartphone-based tracking can objectively capture aspects of behavior (eg, movement, location, or device use), they do not provide direct insight into the meaning, intention, or subjective experience of daily activities [22]. EMA uniquely captures these experiential and contextual dimensions, which are central to understanding engagement in daily activities from a PEO perspective.

The aim of this review was not only to consider the theoretical potential of EMA but also to examine how it is currently being applied to gather information about everyday life in individuals with neurological disorders, with the goal of identifying opportunities for broader and more effective use. EMA protocols appropriately vary according to the research aims and the daily-life phenomena being captured. Nevertheless, transparent reporting of the specific EMA items used is crucial. This review revealed that such transparency was often lacking, hindering interpretation and comparison across studies. As a result of the limited number of EMA studies focusing specifically on daily activities, we also included studies in which this construct was assessed as a secondary outcome to map its current operationalization. This may explain why daily activity items were often not described in detail, as they were not the primary focus of many included studies. In addition, a key principle of EMA is its ability to capture experiences and behaviors in the moment, thereby minimizing retrospective bias. Yet, several studies framed their questions retrospectively, for example, by asking participants, “What have you been doing in the past hour?” [52]. This approach undermines one of the central advantages of EMA, highlighting a gap between its theoretical potential and its practical implementation [20,21,24]. These findings also point to the need for more structured guidance on the design and reporting of EMA protocols. In particular, greater consistency in the timing, phrasing, and content of EMA items would improve comparability across studies and enhance interpretability. Developing a core set of reporting recommendations or a checklist for EMA studies assessing daily activities in neurological populations may therefore be a valuable next step.

This limitation in temporal framing also intersects with how daily activities are conceptualized in EMA studies. Questions frequently rely on the verb “doing” to capture engagement in daily activities. Although Wilcock [58] described doing as a core dimension of human occupation—alongside being, becoming, and, later, belonging—this perspective suggests that focusing primarily on “doing” may not fully capture the complexity of engagement in daily activities among individuals with neurological disorders. When physical performance is restricted, such a focus may overlook other meaningful forms

XSL•FO
RenderX

of engagement, such as planning, initiating, or contributing to daily activities. From a theoretical perspective, doing represents only 1 dimension of the broader concept of engagement. A narrow emphasis on doing may therefore overlook aspects such as occupational deprivation and occupational alienation. Although these concepts were not directly assessed in the included studies, the observed patterns in EMA item content can be interpreted in light of established occupational science frameworks. For example, occupational deprivation refers to a state in which individuals are prevented from participating in meaningful occupations because of external constraints, such as environmental barriers, social restrictions, or health-related limitations [10,59]. Similarly, occupational alienation occurs when engagement in daily activities lacks meaning, purpose, or personal satisfaction, even when the activity is physically possible [10]. By focusing primarily on "doing," EMA protocols may overlook the depth and richness of information that can be obtained. However, incorporating other PEO elements—personal factors, environmental contexts, and characteristics of the occupation itself—can help offset the limitations of focusing solely on "doing" and provide more meaningful insights into daily activities [4,10,60].

The way an EMA question is phrased directly shapes the type of responses it elicits. The multiple-choice response options used in the included studies resemble a classification system—such as self-care, leisure, or productivity—rather than providing insight into how a daily activity is performed or how the individual is engaged in that activity. While such categories may serve a useful descriptive purpose, they often remain at the level of occupational type rather than capturing the richer dimensions of daily activity. This limited framing can also obscure the so-called dark side of occupation—activities that may be harmful, socially undesirable, or associated with negative consequences [61]. However, some studies included an "other" response option, which could, in theory, capture such activities. Similarly, activities such as "doing nothing" are rarely explored in depth, even though they may represent diverse states such as rest, disengagement, or lack of opportunity. Recent developments in EMA methodology suggest that open-ended response formats can address some of these limitations. Open-ended questions are increasingly being used in other fields to capture richer data—for example, in autism research, where participants may respond not only through writing but also through drawing, providing insight into nuances that predefined categories may not capture [62,63]. Although open-ended EMA questions require more time and effort to complete, they can generate a broader range of responses and uncover insights that researchers may not have anticipated [63,64]. In this context, the value of open-ended questions lies in their ability to reveal the complexity, individuality, and sometimes unexpected aspects of daily activities that might otherwise remain hidden.

In addition to items targeting daily activities, many EMA protocols incorporated a range of supplementary questions. Classification of these questions using the PEO model revealed that a substantial proportion pertained to person- and environment-related factors. The strong representation of person-related factors is consistent with the findings of a recent bibliometric analysis examining the use of EMA to capture daily activities across health and disability populations [31]. With respect to environmental factors, a pronounced imbalance was observed. Most questions addressed the physical and social environment, whereas the cultural and institutional dimensions were largely absent. Institutional factors, such as organizational routines, policies, or the physical environment of institutions, received little attention despite evidence from neurological rehabilitation research demonstrating their relevance to participation and engagement [65]. Although the limited assessment of institutional factors may partly reflect the predominance of home-based EMA studies, in which these factors are less salient, this gap is more concerning in ambulatory and inpatient settings. Similarly, the cultural environment remains underrepresented in EMA research on daily activities among individuals with neurological disorders. For example, sociological research has highlighted the importance of incorporating cultural dimensions to achieve a more comprehensive understanding of human behavior and experience [66]. Expanding EMA methodologies to systematically address both cultural and institutional contexts could enhance the ecological validity of findings and provide a more comprehensive representation of the environments in which daily activities occur. However, one could argue that these contexts are relatively stable throughout the day and therefore may not require frequent assessment using EMA. At the same time, other environmental dimensions, such as the virtual environment, are becoming increasingly relevant in contemporary life, yet none of the included studies assessed this aspect [3].

Beyond the content-related aspects, this review also provides insight into the practical application of EMA for capturing daily activities. The results indicate consistently high adherence rates, supporting the feasibility of EMA in this context. Similar patterns have been reported in other populations. For example, a scoping review in perinatal mental health reported an average compliance rate of approximately 80%, ranging from 63% to 96%, indicating strong feasibility [67]. In populations with psychosis, a systematic review found a mean survey completion rate of 67%, with more than 86% of participants meeting minimum engagement criteria [68]. Likewise, a cross-diagnostic study reported median adherence rates above 80%, with early response behavior strongly predicting sustained participation over time [69]. Collectively, these findings suggest that well-designed EMA protocols—carefully balancing sampling frequency, participant burden, and interface usability—can achieve high adherence, supporting both comprehensive data collection and sustained participant engagement. However, the available data do not allow conclusions regarding the optimal number of assessments per day or the ideal duration of EMA protocols. Beyond adherence, this review also identified substantial variation in EMA design characteristics, including the number of daily prompts, study duration, sampling schedules, and response windows. Although these findings provide an overview of how EMA is currently implemented to assess daily activities in neurological populations and may inform the design of future studies, the available evidence remains insufficient to determine which protocol configurations are most effective for optimizing feasibility and data quality.

XSL•FO
RenderX

Limitations

The findings of this review should be interpreted in light of several methodological limitations. First, the search strategy may have been subject to selection bias. Although a broad search strategy was applied, including the use of the MeSH term "Nervous System Diseases," variability in indexing and the hierarchical structure of MeSH may have influenced the retrieval of specific conditions. As a result, some conditions were captured implicitly, whereas others were included explicitly, reflecting a balance between sensitivity and specificity. Searches were conducted using EMA-related terminology in the title and abstract, which may have resulted in the omission of relevant studies that used similar methodologies without explicitly using these terms. Although studies were screened for core EMA characteristics whenever possible, some eligible publications may not have been identified. Consequently, the size and scope of the available evidence base may have been underestimated. In addition, although this approach aligns with the exploratory nature of a scoping review, the absence of an extended manual search strategy (eg, reference checking or citation tracking), beyond the gray literature search, may have further limited the comprehensiveness of the evidence base. Incorporating such strategies in future reviews could yield additional insights. Second, this scoping review was conducted in accordance with the framework proposed by Arksey and O'Malley [33] and reported following the PRISMA-ScR guidelines, strengthening its methodological rigor and transparency. Nevertheless, the limitations related to the search strategy and the variability in reporting across the included studies should be considered when interpreting the findings. Third, the predefined inclusion criteria may have introduced conceptual ambiguity. The identification of EMA studies was based on the presence of terms such as ecological momentary assessment, experience sampling methodology, or ambulatory assessment in the title or abstract. However, the operationalization of EMA varies substantially across studies, particularly with respect to sampling frequency, duration, and intensity (eg, once daily vs multiple prompts per day). As a result, studies using markedly different methodological approaches were grouped under a single EMA label. Future research would benefit from a more explicit definition of EMA to improve conceptual clarity and comparability across studies. Furthermore, although 20 studies were included, several publications originated from the same research groups. This suggests that similar theoretical and methodological perspectives may have informed multiple articles. It also cannot be ruled out that overlapping datasets were used, as many studies relied on comparable samples and study parameters. Although definitive conclusions cannot be drawn, the body of evidence may therefore represent fewer than 20 fully independent perspectives. This observation highlights the importance of considering not only the number of studies but also the diversity of methodological approaches when interpreting the findings. Finally, substantial heterogeneity was observed across the included studies with respect to sample size, study duration, the number of EMA prompts, and adherence reporting. This variability complicates direct comparisons across studies and limits the extent to which the findings can be synthesized beyond a descriptive level, consistent with the aims of a scoping review. Furthermore, the regression analyses should be interpreted as exploratory because of the heterogeneity among studies, the limited number of included studies, and the incomplete reporting of adherence data.

Future Directions

Therefore, future studies should prioritize greater transparency in reporting EMA protocols and work toward developing more standardized guidelines or checklists to support consistency in EMA design and reporting. Researchers are encouraged to move beyond a narrow focus on "doing" and explore alternative question formats—including open-ended or mixed-format items—that can capture richer, more nuanced information about the context, meaning, and personal relevance of daily activities. In addition, when using predefined activity categories, it is important to include response options that allow participants to report less commonly addressed or potentially negative occupations, acknowledging that not all daily activities are inherently positive. Future research should also investigate the conditions under which adherence is highest to better understand the factors that support sustained engagement in EMA studies.

Methodologically, participatory approaches—such as co-designing EMA items with individuals who have lived experience of neurological disorders—may help ensure that questions reflect the diversity and complexity of real-world engagement. Combining EMA with complementary qualitative methods (eg, brief interviews or activity diaries) could further deepen insights and capture aspects of occupational engagement that might otherwise be overlooked. These strategies would enable EMA to more fully reflect the dynamic interplay among personal factors, environmental contexts, and occupations, ultimately broadening its value in both research and clinical practice.

Conclusions

This review systematically mapped both what EMA captures about daily activities in individuals with neurological disorders and how EMA is implemented in this context. Regarding the content of EMA protocols, the findings showed that daily activities were predominantly assessed using items focused on the verb "doing" and mainly closed-response formats. Additional EMA questions addressed several components of the PEO model, although physical and social environmental dimensions were represented more frequently than cultural and institutional dimensions. Together, these findings suggest that current EMA approaches may provide a relatively narrow representation of daily activity performance and engagement, potentially overlooking important nuances of individuals' lived experiences. Regarding practical application, considerable variability was observed in EMA protocol characteristics, including assessment frequency, study duration, prompting schedules, and adherence rates. Although adherence was generally high across studies, the heterogeneity of protocols and the exploratory nature of the available evidence make it difficult to draw firm conclusions about which design characteristics best support feasibility and data quality in neurological populations. Rather than identifying an optimal EMA approach, this review provides an overview of how EMA is currently being applied and highlights areas requiring further investigation. Future EMA research in

XSL•FO
RenderX

neurological populations would benefit from greater transparency in reporting EMA items, broader use of open-ended response formats, and more systematic consideration of underrepresented environmental dimensions. In addition, studies directly comparing EMA protocol characteristics are needed to better understand how protocol design influences feasibility, adherence, ecological validity, and the quality of data collected for individualized assessment of daily activities.

Acknowledgments

The authors acknowledge the use of ChatGPT (OpenAI) for language refinement and text editing. OpenAI did not contribute to the study design, data analysis, or interpretation, and all authors take full responsibility for the content of the manuscript. The authors also thank Ine Oosterbos and Ferre Maesen for their assistance with the data extraction process.

Data Availability

This scoping review does not include original data or materials, as it synthesizes and analyzes findings from previously published studies. Therefore, no datasets or study materials are available for sharing.

Funding

This study was supported by a doctoral research grant from Hasselt University awarded to the principal investigator (ED; grant BOF24DOC43). No other financial or material support was received for this study. The funder had no role in the study design, data collection and analysis, decision to publish, or preparation of the manuscript. AR was supported by the Research Council of Finland (grant 360087) as part of broader research activities; this support was not awarded specifically for this study. The other authors received no funding related to this study.

Conflicts of Interest

None declared.

Abstract

Background: While half of individuals with Rett syndrome (RTT) are older than 50 years, research shows that they have low levels of physical activity, especially for those of advanced age and poor ambulation. Despite this evidence, recent studies underscore the potential of leisure-time physical activity interventions to improve health outcomes and quality of life for individuals with RTT.

Objective: This scoping review aimed to summarize the state of the science regarding physical activity interventions for individuals with RTT and their families across the life span; map the extent, range, and nature of research activity in telehealth; and describe outcomes targeted by interventions with a focus on health-related fitness.

Methods: Systematic searches were performed in the MEDLINE, Scopus, Google Scholar, and CINAHL Plus databases. The data charted from eligible studies included specific details about the participants, study design, setting, intervention characteristics, outcomes, and relevant key findings. Inclusion criteria were (1) original, peer-reviewed research; (2) full-text articles in English; (3) studies reporting a leisure-time physical activity intervention; and (4) a sample of individuals with RTT and/or caregivers.

Results: A total of 23 studies enrolled 200 participants in total (mean age 13, SD 7, range 2-48 years). Participants were all female individuals, and studies included mostly those who were ambulatory. RTT severity was reported in less than half (9/23, 39%) of the studies; however, participants with mild to severe scores were represented. Most of the studies (20/23, 87%) used a case study design or single-group repeated measures, and only 13% (3/23) were randomized trials. The focus was primarily on gross motor function, walking ability, and physical activity outcomes. In total, 39% (9/23) of the interventions implemented telehealth into their design, primarily using remote video calls between a physical therapist and the participants' parents.

Conclusions: The findings of this review provide a foundation for designing evidence-based, scalable physical activity programs tailored to the unique needs of individuals with RTT. The integration of telehealth strategies offers a promising avenue for enhancing accessibility and caregiver engagement.

Introduction

Rett syndrome (RTT) is a rare progressive neurodevelopmental disorder that is prevalent among female individuals [1,2]. RTT is characterized by impairments in motor function, communication, and cognitive abilities [3-5]. Half of individuals with RTT are older than 50 years [6]. Considering that mortality in RTT has been linked with several preventable factors such as declines in physical function and cardiorespiratory issues [7], there is a need to identify interventions that can improve and manage physical health and wellness.

Over 40 years of research have found that leisure-time physical activity (LTPA) participation has been identified as a key behavior for improving and managing physical and mental health among people with mobility disabilities [8,9]. LTPA refers to physical activities performed outside of regular work, including exercise; sports; and physically active hobbies such as walking for exercise, running, and similar activities done during discretionary time [10]. While there is a growing volume of research related to LTPA in more prevalent disability groups (eg, stroke, Parkinson disease, cerebral palsy, and multiple sclerosis) [8,9,11,12], less is known about its potential impact in preserving or improving health in individuals with RTT.

Although there are systematic reviews that highlight the multifaceted benefits of specific rehabilitation interventions in people with RTT [13-18], there has not been a review of LTPA interventions for this population. Compiling a single resource of LTPA interventions for RTT can help health professionals and caregivers quickly identify programs that extend outside the rehabilitation context and promote physical health and wellness across the life span. To provide a foundation that can guide future research in LTPA and telehealth for individuals with RTT, the objectives of this scoping review were as follows:

1. To aggregate and summarize the state of the science regarding LTPA for people with RTT across the lifespan
2. To describe LTPA intervention characteristics and their potential outcomes on physical health, function, and fitness
3. To explore telehealth technologies and their use in LTPA interventions

Methods

Study Design

This scoping review was conducted using the methodological framework developed by Arksey and O'Malley [19], which consists of (1) identifying a research question; (2) identifying relevant studies; (3) selecting studies; (4) charting the data; (5) collating, summarizing, and reporting the results; and (6) an optional consultation exercise. Additionally, recommendations and considerations to improve scoping reviews in health research were implemented [20,21]. This research adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for reporting, and a completed PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) checklist can be found in Multimedia Appendix 1.

Review Questions

The population, intervention, comparison, and outcome framework [22] was used to develop the guiding questions for this scoping review: (1) What is the state of the science regarding LTPA interventions for individuals with RTT? (2) What are the intervention delivery strategies and their outcomes, with a specific focus on health-related fitness [23] (cardiorespiratory fitness, muscular strength, muscular endurance, body composition, and flexibility)? (3) What telehealth strategies have been implemented?

Inclusion Criteria

Studies were deemed eligible for inclusion if they met the following criteria: (1) publications that were primary sources of original, peer-reviewed research; (2) LTPA interventions that incorporated the deliberate use of repetitive large body movements to improve, maintain, or change a component of health (exercise, recreation, and conditioning); (3) interventions that targeted people with RTT and/or caregivers; and (4) LTPA interventions that could be delivered in the community outside a rehabilitation setting and did not require the supervision of a licensed therapist. This study included all types of research designs, from case studies to randomized controlled trials (RCTs). Gray literature articles were excluded from review.

Search Process

A preliminary search of the PubMed database, Cochrane Database of Systematic Reviews, and Scopus database was conducted (CM), and no current or underway systematic or scoping reviews on the topic were identified. The text words contained in the titles and abstracts of relevant articles and the index terms used to describe the articles were used to develop a full search strategy.

The article search was conducted (CM) for all years up to September 30, 2025, in the following databases: MEDLINE, Scopus, and CINAHL Plus. Hand searches also included research found through Google Scholar and from the reference lists of existing RTT reviews.

Search Strategy

Article searches were generally conducted by integrating RTT terms (eg, "Rett syndrome" and "neurodevelopmental disorder") and LTPA key terms (eg, "physical activity," "exercise," and "sedentary activity"). Boolean operators were used to connect RTT terms with physical activity terms depending on the database. The MEDLINE database search string was as follows: "Rett syndrome AND physical activity."

Study and Source of Evidence Selection

Following the search, all identified citations were collated and uploaded into EndNote 2025 (Clarivate Analytics), and duplicates were removed. Titles and abstracts were screened by 2 independent reviewers (CM and BL) for assessment against the inclusion criteria for the review. Potentially relevant sources were retrieved in full text and saved as a PDF to a shared digital folder. Rationales for the exclusion of articles were recorded. Any disagreements that arose between the reviewers at each stage of the selection process were resolved through discussion with an additional reviewer (JR) during weekly meetings. The

XSL•FO
RenderX

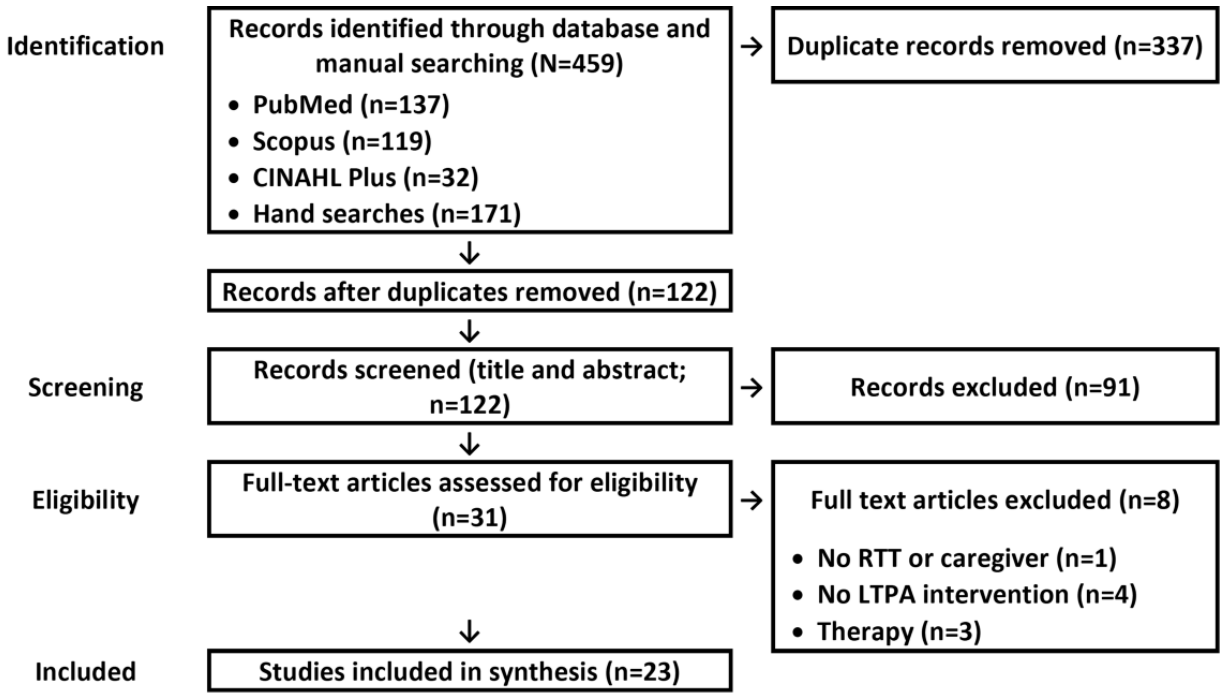
results of the search and the study inclusion process are reported in full and presented in a PRISMA flow diagram.

Data Charting

Data were extracted from the full texts of the articles by 3 reviewers. Extraction was guided by a data template in Microsoft Excel. One reviewer (CM) extracted data from all articles. Two reviewers (RY and AW) each reviewed half of the total articles as a way to ensure that all articles were reviewed by 2 reviewers. After reviewers charted data from the first 2 studies, the research team met to resolve any disputes and aggregate the data extraction results. Extracted data included specific details about the participants, concept, context, study methods, interventions, outcomes, and key findings relevant to the review questions. The final data extraction chart was cross-checked for accuracy by 2 analysts (CM and BL).

Data Analysis and Presentation

The data were organized graphically and in tabular form. These data included study parameters (design and country of origin), participant demographics and clinical characteristics (age, RTT severity, and ambulatory ability), intervention characteristics (duration, type, frequency, setting, and mode of delivery), outcomes and measures, and telehealth characteristics where applicable (mode of delivery and contact frequency). In instances in which there were multiple publications that were associated with a single trial, the extracted data were considered as a single article for the purposes of summation calculation or frequency counts.



A draft of the preliminary results and findings of this work was reviewed by the mother of an individual with RTT. Consistent with expert recommendations [20], she provided feedback to confirm whether the findings aligned with her experiences, identify any misinterpretations, suggest alternative conceptualizations, and add context to this work. Her feedback was documented in writing through email and integrated into this final work.

Results

Search Results

The search strategy yielded 459 records from 122 original research studies. After screening, of the 459 records, 31 (7%) were assessed for eligibility. Of these 31 publications, 8 (26%) were excluded due to not targeting individuals with RTT or caregivers (n=1) [24], not incorporating an LTPA intervention (n=4) [17,25-27], or administering an intervention that required a licensed therapist (n=3) [28-30]. After assessment, 23 articles were included in the final synthesis (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for the scoping review. LTPA: leisure-time physical activity; RTT: Rett syndrome.

Study Parameters

General study parameters are shown in Table 1. Most studies (21/23, 91%) were conducted in the last 20 years. The most common research designs were case studies (11/23, 48%) and within-group repeated measures (9/23, 39%). Among the 23 studies, 3 (13%) randomized designs were identified, with only 2 (9%) being RCTs. Almost every study reported at least one favorable result of their interventions, with the most common benefits being improved gross motor function (eg, sitting independently and standing transitions), improved walking ability, or an increase in physical activity or decrease in sedentary time.

XSL•FO

Table 1. General study parameters.

Study	Year	Design	Country	Notable results
Bumin et al [31]	2003	Case report	Turkey	Hand stereotypies reduced, feeding and hand skills improved, walking balance improved, environmental interaction increased, hyperactive behavior decreased, and anxiety decreased
Schaefer-Campion and Johnson [32]	2015	Case study	United States	Walked furthest using a toy shopping cart and anterior walker compared to other walking aids
Lerma-Castaño et al [33]	2024	Case study	Colombia	Improved gross motor function, balance, obstacle avoidance, and behavior
Downs et al [34]	2018	Randomized controlled trial	China	Improved gross motor function and BMI slightly decreased
Downs et al [35]	2023	Randomized controlled trial	Australia and Denmark	Sedentary time decreased
Imamura et al [36]	2020	Case study	Japan	Improved 10-m walk test performance
Kapel et al [18]	2022	Case study	Slovenia	Improved gross motor function
Lotan et al [37]	2004	Repeated measures	Israel	Improved gross motor function and cardiorespiratory fitness
Lotan and Barmatz [38]	2009	Case study	Israel	Improved communication and bodily control
Lotan et al [39]	2015	Case study	Israel	N/A[a]
Lotan et al [40]	2021	Repeated measures	Italy	Improved motor function, rehabilitation goal achievement, and good parental satisfaction
Lotan et al [41]	2021	Repeated measures	Ireland	Favorable telehealth rating by parents and positive rehabilitation goal attainment
Panzeri et al [42]	2024	Repeated measures	Italy	Improved endurance, participant preference for autonomous activities, and good parental satisfaction
Rocco et al [43]	2023	Case study	United States	Improved participation
Romano et al [44]	2022	Repeated measures	Italy	Most rehabilitation goals attained, improved gross motor function, increased physical activity, and higher motor functioning correlated with higher PA[b] level
Romano et al [45]	2022	Repeated measures	Italy	Scoliosis progression prevented and improved gross motor function
Romano et al [46]	2022	Repeated measures	Italy	Positive rehabilitation goal achievement; improved gross motor function; and high usefulness, adherence, and satisfaction
Romano et al [47]	2025	Repeated measures	Italy	Improved gross motor function
Stahlhut et al [48]	2020	Repeated measures	Denmark	Intervention rated as feasible; reduced sedentary time; and increased step count, walking capacity, quality of life, and rehabilitation goal attainment
Stasolla and Caffo [49]	2013	Case study	Italy	Increased ambulation and happiness and reduced stereotypies
Stasolla et al [50]	2018	Case study	Italy	Improved functional ability, mood, and social relationships
Escobar Torres et al [51]	2019	Case study	Spain	Improved functional ability, mood, social relationships, mobility, strength, and endurance
Zwilling et al [52]	2022	Randomized between-group intervention	Italy	COVID-19 lockdown did not negatively affect mothers' well-being

[a]N/A: not applicable.

[b]PA: physical activity.

Participants

Participant information is shown in Table 2. A total of 200 individuals with RTT were enrolled across the 23 included studies. In total, 13% (3/23) of the publications overlapped and reported separate results from the same sample of participants [40,44,52]. Sample sizes ranged from 1 to 42. Adults were underrepresented, with the mean participant age being 13 (SD 7) years and ages ranging from as young as 2 up to 48 years. A total of 65% (130/200) of the participants were ambulatory (independent or with assistance); 25% (50/200) were nonambulatory; and for 10% (20/200), ambulation was not reported or unknown. In total, 39% (9/23) of the studies reported a measure of RTT severity, which included at least one

XSL•FO
RenderX

participant with severe RTT. Only 22% (2/9) of these studies enrolled participants with mild RTT.

Table 2. Sample information (N=23).

Study	Year	Sample size, n	Mean age (y)	Age range (y)	Ambulatory	RTT[a] severity	Waitlist control

[c]Indicates staggered introduction of the intervention to establish experimental control.

[d]Indicates overlap in publications stemming from a single sample.

Intervention Characteristics

The intervention characteristics are shown in Table 3. The mean intervention duration was 30 (SD 35) weeks, ranging from a single week to 3 years. The most common setting was in the home and community, followed by physical therapy clinics. Most interventions were delivered by health professionals directly or indirectly as an activity program designed for a caregiver or parent to deliver. Interventions were delivered from twice per week to daily, with the typical frequency being 5 times per week. Mean session duration was 55 (SD 36) minutes per week, with some durations as short as 5 to 10 minutes. The types of interventions varied. Some studies (20/23, 87%) included therapy-driven programs, hydrotherapy, walking, exercise training, and motor activities. While most studies (19/23, 83%) integrated a single type of intervention, some (4/23, 17%) were multimodal. For example, one study included 5 different intervention types (motor activities, hippotherapy, hydrotherapy, exercise training, and walking) [18]. While intervention characteristics were typically reported in detail (duration, setting, and delivery), protocols were often superficially described and lacked sufficient details to allow for replication. For example, frequency was often reported as recommended times per week without providing actual adherence. Additionally, time per session was typically reported as a range that could vary based on progression or unknown factors. Finally, most interventions relied on tailored, individualized exercise programs that listed the prescribed activities but did not provide specific dose information or movement adaptations.

[d]ABA: Applied Behavior Analysis.

[e]MITAF: Integral Method of Functional Aquatic Work.

Measured Outcomes

The primary and secondary outcomes and measures reported in the included studies are shown in Table 4, and frequencies are shown in Table 5. The most frequent primary or secondary outcome was gross motor function (11/23, 48%), followed by LTPA (6/23, 26%) or walking ability (6/23, 26%). Several of the studies (7/23, 30%) assessed behavior, goal attainment, caregiver satisfaction and well-being, fine motor function, or communication as a primary or secondary outcome. Health-related fitness outcomes were not measured thoroughly. Some studies (9/23, 39%) reported body composition, balance, quality of life, flexibility, cardiorespiratory health, intervention feasibility, or mood; however, these variables were typically secondary or tertiary measures. Additionally, very few objective measures were used to support the primary or secondary objectives, with most of the studies (21/23, 91%) relying on clinical observational performance or self-report (parent or caregiver) measures. There were no studies that reported direct measures of strength or cardiorespiratory health.

Table 5. Frequency of outcome measures across included studies (n=23).

Outcome measure	Frequency, n (%)
Gross motor function	11 (47.8)
Physical activity	6 (26.1)
Walking ability	6 (26.1)
Behavior	5 (21.7)
Caregiver satisfaction and well-being	5 (21.7)
Fine motor function	4 (17.4)
Goal attainment	4 (17.4)
Communication	3 (13)
Mood	2 (8.7)
Feasibility	2 (8.7)
Cardiorespiratory health	2 (8.7)
Flexibility	2 (8.7)
Quality of life	2 (8.7)
Balance	1 (4.3)
Body composition	1 (4.3)

The studies that reported gross motor function were split between the use of RTT-specific motor assessment tools, including the Rett Syndrome Gross Motor Scale [53] and the Rett Syndrome Motor Evaluation Scale [54]. Physical activity was typically measured through step or activity counts using an accelerometer; however, 9% (2/23) of the studies estimated LTPA using a modified Bouchard activity record [55].

Telehealth Implementation

Among the 23 studies included in this review, 9 (39%) interventions were delivered through telehealth. These studies accounted for 77% (153/200) of the total participant population. Ambulatory participants made up approximately 59% of the total telehealth enrollment. Every telehealth study used a remote video call delivered by a health professional to a caregiver. Only one study augmented the video calls with an online monitoring platform (smartphone app) [47]. The most common frequency of video calls was once every other week (67%). Several studies only used video calls as needed or monthly. Very few telehealth procedural details (eg, communication, behavior change, or technical implementation strategies) were reported across these studies to support replication.

Discussion

State of Research

This scoping review summarized 23 studies involving LTPA for individuals with RTT, with a secondary aim of charting telehealth implementation. The findings reveal a growing body of evidence supporting the feasibility and potential benefits of LTPA interventions across diverse settings, delivery modes, and outcome domains. We discuss the current state of research on LTPA interventions, telehealth implementation, expected benefits, and recommendations for future research that could enhance LTPA interventions for individuals with RTT.

These study findings, similar to those of a recent scoping review of rehabilitation therapies, suggest a lack of studies that could be classified as high-quality evidence [56]. Regarding quality, there appeared to be 2 key limitations: sample size and study design. While many global regions were represented in our review (Table 1), study samples were predominantly small. Over half (12/23, 52%) of the studies included in this review did not incorporate a control or comparison group, and many studies (9/23, 39%) instead used a multiple-baseline design in which the intervention was introduced at different times across participants, settings, or behaviors to demonstrate experimental control (Table 2). Single-group within-subject designs may be appropriate for evaluating the effects of LTPA interventions in neuromuscular disorders, particularly in the context of small sample sizes (eg, 10-40 participants) [57]. On a positive note, our findings suggest that several research design decisions across these studies were consistent with recommendations from the International Rare Diseases Research Consortium for small-population clinical trials, including making use of longitudinal data to show how treatment effects evolve over time, using multiple end points, adjusting follow-up outcomes for baseline values rather than relying on a single change-from-baseline measure, and using registry data to aid in sample size estimates [58]. The only RCTs (2/23, 9%) were implemented by one researcher [34,35]. These studies were able to demonstrate an increase in gross motor skills with environmental enrichment and a small reduction in sedentary time through a telehealth-supported program.

Disappointingly, low rates of physical activity are common in RTT, particularly among people with RTT who have a mobility disability and a higher age [59,60]. A notable finding was that several types of home- and community-based LTPA interventions were successful in achieving their intended outcomes. An encouraging finding was that these interventions were adapted to the needs of individuals with RTT who were ambulatory and nonambulatory. Nonambulatory participants represented 65% of the sample, which was representative of the population [61]. Such adaptations and programs were particularly noteworthy for their inclusion of individuals with more severe levels of disability. However, the lack of depth in reporting intervention and implementation characteristics limits replication of current research efforts in this area. We encourage future LTPA research in RTT to provide more transparent details regarding intervention tailoring strategies, along with successful and unsuccessful lessons that have been learned from intervention delivery.

We found that caregivers were often the primary target for LTPA interventions. This approach likely reflects the severity of the children's disability, which limits the feasibility of direct participation or communication. Although caregivers play a vital role in fostering LTPA, particularly when communication difficulty in the child is a concern, caregivers experience substantial burden with LTPA interventions, which can manifest in various barriers, including limited time and resources, difficulty obtaining mobility aids, few trained professionals, and a lack of knowledge [62]. Caregivers of children or adult patients with RTT report barriers to LTPA that are consistent with those of other disability groups [62,63], including limited resources in the community, lack of transportation, lack of trained professionals, lack of suitable LTPA modalities and resources, and lack of knowledge [64,65]. Therefore, LTPA programs that are accessible and adaptable to the unique needs of individuals with RTT may promote LTPA and reduce caregiver burden [4].

Many of the targeted outcomes reported across the studies in this review were not objectively measured. There was a lack of health and fitness outcomes that are typical in LTPA interventions. For instance, there was not a single example of an objective muscle strength measure even though arm and leg muscle area measurements are significantly lower in female patients with RTT than in their male counterparts [3]. Gross motor function was a consistent positive finding [18,33,34]. There was little evidence to demonstrate an improvement in cardiopulmonary health, which is concerning because RTT is associated with cardiac arrhythmias that are a potential cause of sudden death [3]. Therefore, benefits as a result of LTPA for people with RTT should be interpreted with caution.

A notable gap identified in this study was the limited information on telehealth implementation. The use of telehealth as an intervention delivery platform may expand intervention reach and address enrollment barriers. Delivery of interventions through telehealth has been shown to be effective and important in neurodevelopmental rehabilitation and disability management [66,67]. Remote interventions in this review demonstrated positive goal achievement and caregiver satisfaction [35,40,41,47,48]. Consistent with findings across all included studies, we observed little to no direct communication with participants with RTT via remote telecommunication. While impaired communication is common in individuals with RTT [68], a major concern of their caregivers [69], and a barrier to LTPA participation [62], it is unclear whether direct participant communication through telehealth is feasible. For example, one study demonstrated significant potential in supplementing telehealth coaching using alternative augmentative communication [70]. While direct interaction with participants is typical in telehealth exercise interventions for individuals with disabilities [71], achieving meaningful communication with participants with RTT may require additional support from speech-language therapists or a family member. Although the intervention characteristics were often superficially reported across studies, the description of telehealth delivery and engagement of participants with RTT was even more limited.

XSL•FO
RenderX

A deeper understanding of the factors contributing to telehealth implementation success and failure could help guide future research in this area.

Consultation Exercise

The consultation exercise reinforced and contextualized several key gaps identified in the literature. The consulted caregiver emphasized that effective LTPA interventions for individuals with RTT must be tailored to age and ambulation status, echoing the heterogeneity observed across the included studies. Their insights highlighted the potential value of telehealth in supporting participation and accountability for families, particularly given the heavy caregiving demands that limit opportunities for structured physical activity. Importantly, the caregiver identified a critical service gap wherein adolescents and adults with RTT often lose access to outpatient therapy services, underscoring the need for accessible, home-based, or remotely delivered programs. The consultation also drew attention to the lack of standardized severity classifications in existing research and the absence of key outcome domains—such as muscle strength, cardiovascular health, balance, and quality of life—that families consider essential for daily functioning. These perspectives align with the broad variability in intervention characteristics and outcome measures found in our review and further support the need for consistent reporting and comprehensive assessment frameworks. Collectively, the consultation emphasized the urgency of developing adaptable, evidence-informed LTPA resources and best practice guidelines across the life span, particularly for nonambulatory individuals and those aging out of pediatric services.

Future Recommendations

The most promising outcomes observed in this scoping review were improvements in physical activity and walking ability. To advance the field and address existing gaps, future research should consider the following. First, studies should include more adults with RTT to better understand age-related changes in LTPA participation and intervention responsiveness across the life span. Second, while the feasibility of interventions was often reported as good, future research should add greater levels of detail in their protocols and modalities to increase the reproducibility of their design. For example, the walking trials administered by Schaefer-Campion and Johnson [32] illustrated nuanced differences in walking aids for a child with RTT that can inform decisions for future studies to foster walking ability. Conducting larger and more frequent multisite RCTs with appropriate control conditions may strengthen causal inferences. Adopting objective measures for aspects of health-related fitness such as strength across studies would facilitate cross-study comparisons and meta-analyses. Because low physical fitness, gait abnormalities, and comorbidities such as scoliosis and osteoporosis can be potential barriers to participation in LTPA [4,72,73], it is important to confirm the short-term efficacy of interventions that may mitigate barriers and increase LTPA in RTT.

Moreover, the addition of telehealth communications and remotely delivered interventions at home may be ideal for overcoming community barriers to LTPA among people with RTT. Telehealth LTPA clinical trials bypass the need for on-site visitation and have reached the largest sample sizes among people with physical disabilities, which would be ideal for rare diseases and conditions such as RTT [74,75].

Limitations

Several limitations should be acknowledged. Many of the included studies partially reported or did not report at all critical variables such as RTT severity, exercise protocols, or outcome frequency, thereby making it difficult to generalize the findings of this scoping review. Due to the lack of randomized trials, this review focused on non-RCTs, and the heterogeneity in study designs, sample sizes, and intervention protocols limits the generalizability of the findings. Classifying interventions as LTPA was challenging because the studies often involved a mixture of community-based exercise and physical therapy. This limitation reflects the field itself rather than being a limitation of this review specifically. Different operational definitions of LTPA could yield different conclusions. The heterogeneity of RTT (eg, variability in severity, age, and functional ability), combined with small sample sizes and diverse study designs, limits comparability across studies and complicates the synthesis of findings and interpretation of overall effects. Reliance on observational measures and caregiver-reported outcomes introduces potential bias. Finally, with a strong focus on pediatric populations, this review highlights the lack of evidence related to adults with RTT despite over half of individuals with RTT living beyond 50 years of age [6].

Conclusions

This review underscores the potential of LTPA interventions to enhance wellness and functional outcomes in individuals with RTT. Telehealth strategies show promise for improving accessibility and caregiver engagement. Nevertheless, further research is needed to establish best practices, optimize delivery models, and ensure inclusivity across the life span. Future studies should incorporate objectively measured health outcomes to verify both short- and long-term benefits while also providing detailed reporting on intervention tailoring and implementation strategies, including factors contributing to both successes and challenges.

Abstract

Background: Both ankle-foot orthoses (AFOs) and footwear adaptations are used to improve gait across a broad range of neuromuscular disorders. AFOs and footwear can each independently influence gait through the manipulation of certain design parameters, such as AFO footplate stiffness or the use of a forefoot rocker. While the effects of design parameters from AFOs and footwear on gait have been investigated independently, how these parameters interact to influence walking biomechanics remains poorly understood.

Objective: This systematic literature review aims to provide an overview of the interacting effects between AFOs and footwear on gait biomechanics from both a theoretical standpoint and through the synthesis of existing literature.

Methods: A search of existing literature was conducted across 4 major databases. Studies were eligible if they included adult participants from healthy or patient populations. Studies included should have investigated biomechanical gait outcomes recorded during walking with an AFO and at least two different footwear conditions. Quality assessment was performed using the Downs and Black checklist and AFO reporting guidelines.

Results: A total of 14 studies were included in this review. Across these 14 studies, a total of 204 participants (108 healthy, 84 patients after stroke, and 12 unilateral ankle weakness or pain) were included. The majority of these studies were within-subjects designs. Footwear adaptations were primarily changes to the heel-sole differential (HSD; 7/14), followed by forefoot rockers (5/14), with some studies on changes to heel shape and hardness (3/14), and a study on mediolateral wedging. These adaptations were used in combination with primarily rigid AFOs (10/14), with studies also using dorsiflexion-free and frontal plane restrictive AFOs.

Conclusions: Increasing the HSD can be used to increase knee flexion across the stance phase in rigid AFO users, including in the third rocker when HSD is manipulated between the shoe and AFO. Beyond changing the HSD, there is a lack of well-designed experimental studies exploring footwear adaptations. Detailed reporting of both AFO and footwear design choices is necessary for future work in order to make informed statements on biomechanics.

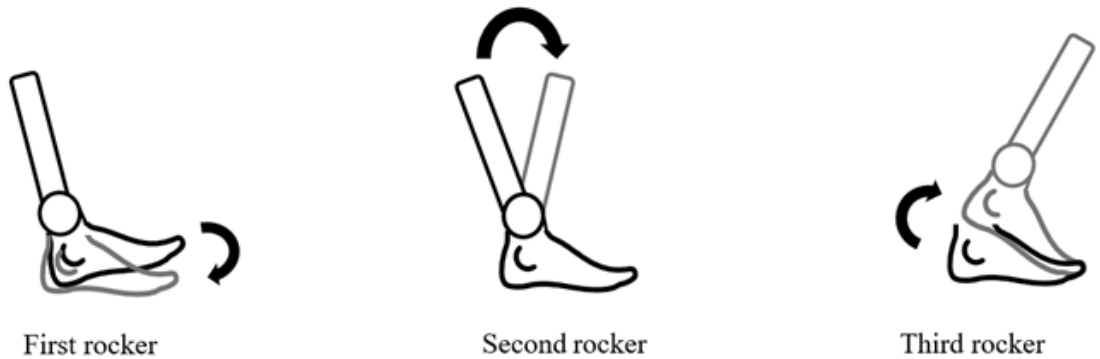
Introduction

Background

The ankle-foot complex plays a crucial role in human walking due to its contributions to both balance and forward propulsion [1]. Plantarflexor muscle weakness, due to neuromuscular disorders such as stroke, can disrupt the biomechanics of gait, leading to slower walking speeds and a less efficient gait pattern [2,3]. To facilitate mobility and an efficient walking pattern, ankle-foot orthoses (AFOs) may be prescribed.

There exists a wide range of AFOs in a variety of shapes, materials, and stiffnesses, with varying effects on patient gait biomechanics [4,5]. These design parameters are often used to optimize biomechanical outcomes for individual patients. For example, increasing the bending stiffness of an AFO can reduce knee flexion during the second rocker in patients with crouch gait [6]. Similarly, increasing footplate stiffness can maximize energy storage and return, reducing the energetic cost of walking [7].



Adapted footwear such as rocker shoes have been investigated independent of AFO use and shown to affect gait kinematics and kinetics [8,9]. As AFOs are typically worn with footwear, it is essential to consider how footwear design interacts with AFOs to influence gait. When combined, footwear and AFO form an integrated orthotic system where the shape and bending stiffness of both devices play a combined role in influencing how forces are transmitted through the lower limb during gait. Consequently, footwear adaptations can alter the biomechanical effects of AFOs on gait. Despite these interactions, the specific impact of different footwear parameters on AFO performance remains unclear [10]. The footwear design can either complement or counteract the intended mechanical function of the AFO. For instance, when the ankle is immobilized with a rigid AFO, increasing the heel-sole differential (HSD) can increase knee flexion during midstance [11]. Conversely, a rocker shoe with a proximal apex position may shorten stance phase duration [12] and reduce the energy storage and return of a carbon fiber AFO, potentially negating its benefits.

Although the importance of the interaction between AFOs and footwear is recognized, most existing research has focused on sagittal plane alignment, particularly the shank-to-vertical angle (SVA), and often within specific patient populations [4,10,11]. While systematic reviews have examined the biomechanical effects of footwear or AFOs independently [13,14], no systematic review to date has examined the biomechanical effects resulting from the interactions between ankle-foot orthosis and footwear combinations (AFO-FCs) in adults. The aim of this review is to provide a systematic overview of the current evidence on AFO-FCs. Specifically, it evaluates how footwear modifications, when paired with AFOs, influence gait biomechanics in both healthy adults, who provide insight into gait adaptations as controlled models, and patients with gait pathology. These findings are intended to inform clinical recommendations and identify directions for future research. A background on ankle-foot biomechanics and the theoretical effects of AFO-FCs in cases of dorsiflexor and plantarflexor weakness is first introduced to provide context for the findings of this review. Existing literature on AFO-footwear interactions in both patient populations and healthy adults is then synthesized to establish an evidence-based overview of the biomechanical outcomes resulting from AFO-footwear interactions.

Locomotion

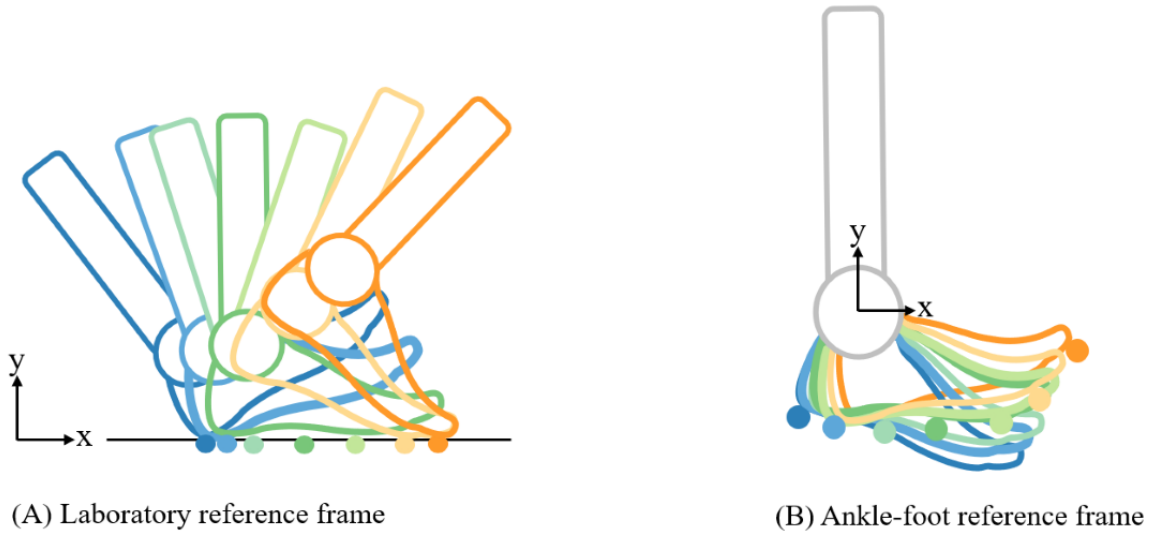
Human locomotion can be broken down into 2 main phases, stance and swing. The stance phase is typically defined as the moment the heel of the foot strikes the ground until the foot leaves the ground again [1]. During stance, the ankle-foot complex can be likened to the rolling of a wheel as the center of pressure (COP) moves from heel to toe [15]. Within stance, 3 subphases, known as rockers, can be distinguished as the COP progresses from heel to ankle to forefoot in a curved path relative to a fixed lower-leg coordinate system [16]. The period between initial contact and the forefoot touching the ground makes up the first rocker, also known as the heel rocker. Following this is the second, or ankle, rocker, where dorsiflexion takes place, and the foot remains flat on the ground. The third, forefoot rocker, begins as the heel leaves the ground and concludes with toe-off. The 3 rockers are illustrated in Figure 1.

Figure 1. The 3 rockers.

XSL•FO
RenderX

Together, these 3 rockers make up part of a phenomenon known as the "roll-over shape" (ROS). This term refers to the ellipsoidal trajectory of the COP relative to a fixed frame of reference at the ankle [17]. Figure 2 illustrates the transformation from the laboratory reference frame (A) to the ankle-foot reference frame (B). The ROS provides a useful framework for evaluating gait adaptations to AFOs, as it can demonstrate changes in timing and kinematics, providing insight into gait adaptations with a single measure. Figure 3 provides examples of the ROS for healthy individuals (A), two theoretical ROS for patients with calf muscle weakness (B), and visualizations of the ROS when walking with a rigid AFO, both without (C) and with an increased HSD (D). In healthy walking, the ROS is an arc that maintains a relatively constant radius even when walking speed or body weight is altered, due to physiological adaptations of the ankle-foot complex [17,18]. This consistent shape provides a predictable rollover, smoothing step-to-step transitions, allowing humans to walk with minimal energy expenditure [15,19]. Individuals with calf muscle weakness may have a shortened or flattened ROS of the ankle-foot complex compared to the typical arc [20]. Dorsiflexor weakness primarily affects the first rocker, while plantarflexor weakness impairs forward progression of the COP during the second rocker and reduces push-off power during the third rocker [1].

Figure 2. ROS across the 3 rockers. (A) The anteroposterior trajectory of the COP viewed from the global reference frame. (B) The circular trajectory of the COP when the origin is set at the ankle and aligned with the shank, creating the ankle-foot reference frame and forming the roll-over shape. COP: center of pressure; ROS: roll-over shape.



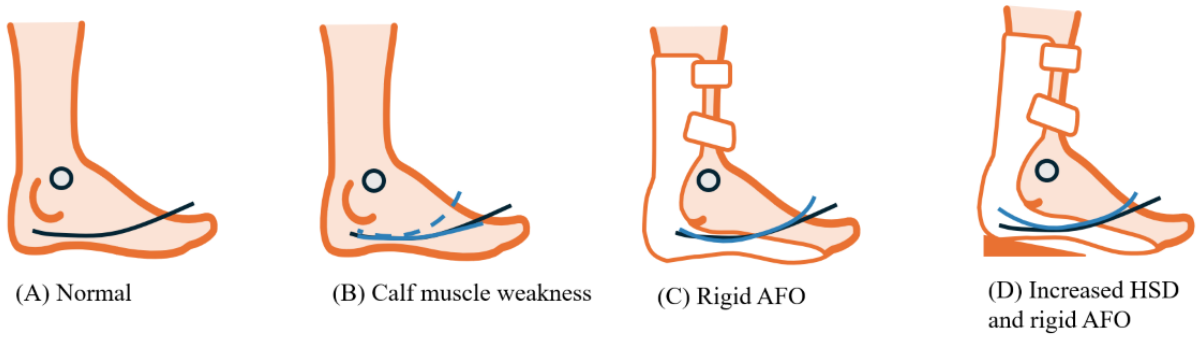


Figure 3. Schematic representation of ROS across clinical and AFO conditions. The gray circle indicates the origin of the ankle-foot reference frame. The black line indicates the normal ROS, and blue lines indicate the ROS under different conditions. (A) ROS for normal healthy walking, based on data from Hansen et al (2004) [18]. (B) Two theoretical ROS for patients with calf muscle weakness. The solid line represents patients with slow COP progression, while the dashed line represents patients with rapid tibial inclination and slow COP progression. (C) ROS when using a rigid AFO, based on data from Fatone et al (2007) [20] and Esposito et al (2021) [16]. (D) ROS when using a rigid AFO with increased HSD, based on data from Esposito et al (2021) [16]. AFO: ankle-foot orthosis; COP: center of pressure; ROS: roll-over shape.

AFOs are commonly prescribed to support patients with calf muscle weakness during gait [3,10,22]. While both passive and active AFOs (exoskeletons) exist, this review focuses on passive AFOs, which are more typically used by patients in daily life. Passive AFOs range from solid polypropylene designs to energy-returning carbon fiber leaf springs and can be tailored to control ankle joint motion to restore a more optimal gait pattern. However, while AFOs can improve stability and help re-establish a smooth ROS [20], their increased stiffness and

XSL•FO
RenderX

limited range of plantarflexion motion may reduce push-off power and limit gains in energy efficiency [23].

Footwear plays an important role in gait biomechanics, with design features such as the HSD, rocker soles, and heel hardness influencing how the COP progresses through each rocker relative to the ankle coordinate system [16,24,25]. When combined with AFOs, footwear characteristics can influence orthotic effects. Together, AFO-footwear adaptations offer a powerful means to restore the ROS and improve gait biomechanics in patients with plantar- or dorsiflexor- muscle weakness. However, their effects may differ across the 3 rockers, leading to complex interaction effects between AFO-FCs and gait biomechanics. The following sections summarize the biomechanical effects of the most commonly used AFO-footwear adaptations in the sagittal plane.

First Rocker

During the first rocker, the dorsiflexors generate a resistive moment that controls plantarflexion, gradually lowering the forefoot to the ground [1]. This negative work from the dorsiflexors leads to smooth knee and hip flexion and supports the controlled transition of the center of mass (COM) from one stance limb to the next [19].

When plantarflexion-restrictive AFOs are used to compensate for dorsiflexor weakness, this gradual transition of the COM is disrupted [26]. The reduced dorsiflexor contribution to the energy transfer between limbs and absence of controlled plantarflexion motion increases angular momentum at the knee and hip. This can result in rapid COP progression toward the midfoot, accompanied by increased knee and hip flexion during early stance [27]. Certain footwear adaptations may mitigate the adverse biomechanical effects of absent plantarflexion during the first rocker. For instance, a shoe with a rocker distal to the heel positions the COP more anteriorly at initial contact [28]. This reduces the ground reaction force (GRF) moment arm at the ankle and knee [28], reducing angular momentum and potentially promoting a smoother COM transition in patients using rigid AFOs. In contrast, a rocker proximal to the heel with a small radius combined with a rigid AFO could theoretically increase the GRF moment arm, thereby increasing angular momentum at the knee and hip.

Second Rocker

In healthy gait, once the foot is fully in contact with the ground, the gradually increasing plantarflexor activity generates a plantarflexor moment about the ankle joint, decelerating shank inclination and knee flexion [29]. During this phase, near-isometric activation of the plantarflexors combined with ankle dorsiflexion stretches the Achilles tendon, allowing elastic potential energy to be stored and later released as push-off power in terminal stance [29].

Throughout the second rocker, gradually increasing plantarflexor activity shifts the COP toward the forefoot. This progression lengthens the GRF moment arm relative to the ankle joint, contributing to knee and hip extension during terminal stance.

In the case of plantarflexor muscle weakness, insufficient force generation at the ankle may lead to rapid and excessive shank inclination, ankle dorsiflexion, and knee flexion, as well as increased knee and hip extensor moments [1,3]. Excessive knee flexion impairs elastic energy storage in the Achilles tendon and reduces the moment-producing capacities of the ankle plantarflexors, resulting in a flatter ROS and reduced push-off power [20]. A dorsiflexion-resistant AFO can help modulate the rate of forward shank inclination by providing an external plantarflexion moment. This reduces excessive knee and hip flexion, leading to a smoother ROS [3]. Positioning the forefoot apex more distally can prolong the second rocker and extend COP progression [30], potentially increasing external plantarflexion moments and hip and knee extension in AFO users. Conversely, a more proximal apex shortens the second rocker, leading to restricted COP progression and reduced knee extension and plantarflexor moments [12,31].

Third Rocker

During the third rocker, the heel lifts off the ground and COP progression and ankle plantarflexor moments approach their peak. At this stage, body weight rapidly transitions from single-limb to double-limb support and elastic energy stored in the Achilles tendon is rapidly released, generating positive ankle power and facilitating a smooth redirection of the COM into the subsequent stance phase, as well as rapid swing initiation of the trailing limb [1]. Adequate timing and sufficient magnitude of peak ankle power ensure rapid rotation of the shank-foot system over the forefoot [19].

The increase in plantarflexion moment during the second rocker contributes to forward progression of the COP and a gradual increase in ankle angular velocities [1]. As the COP progresses anteriorly toward the forefoot, it approaches the shoe's forefoot apex, which effectively acts as a rotational axis for the foot-shoe system. When the COP reaches this apex position, the external dorsiflexion moment generated by the GRF can no longer balance the internally generated plantarflexion moment, resulting in rotation of the foot about the forefoot apex and heel lift-off, marking the onset of the third rocker.

AFOs with energy-storing elements (such as springs or carbon fiber elements) can store mechanical energy during the second rocker and release it at push-off (third rocker) to aid propulsion. A more distal apex position could delay the onset of the third rocker, increasing COP progression, peak GRF moment arms, and ankle dorsiflexion, leading to greater energy storage in spring-like AFOs and enhanced push-off power when the energy is released in the third rocker. Additionally, changes in rocker radius can modulate timing and duration of foot-to-ground contact and shank kinematics during the third rocker, where a smaller radius accelerates shank inclination and energy release (smaller ROS arc), while a larger radius decelerates it, prolonging the third rocker phase (larger ROS arc). Table 1 summarizes the theoretical biomechanical effects across all 3 rockers for 3 types of footwear adaptations when used with an AFO that restricts both plantar- and dorsiflexion.

Table 1. Overview of theoretical kinematic and kinetic outcomes for different footwear adaptations with the use of an AFO[a] restricting plantarflexion and dorsiflexion.

	Heel-sole differential	Heel rocker apex position, radius/angle	Forefoot rocker apex position, radius/angle
Kinematics			
First rocker	Increasing HSD[b] increases SVA[c] and knee flexion	Larger radius/smaller rocker angle decreases rate of forefoot lowering	N/A[d]
Second rocker	Increasing HSD increases SVA and knee flexion	N/A	N/A
Third rocker	N/A	N/A	Smaller radius/larger rocker angle increases SVA and knee flexion and increases angular velocity of the foot-ankle-shank complex
Kinetics			
First rocker	N/A	• More distal heel AP[e,f] reduces ankle DF[g] moment • Smaller radius increases ankle DF moment	N/A
Second rocker	Increasing HSD increases knee extensor moment	N/A	N/A
Third rocker	N/A	N/A	• Smaller radius/larger rocker angle decreases peak knee extensor moment • More distal forefoot position increases PF[h] moment

[a]AFO: ankle-foot orthosis.

[b]HSD: heel-sole differential.

[c]SVA: shank-to-vertical angle.

[d]N/A: not applicable.

[e]AP: apex position

[f]For the purpose of this review, a more proximal heel radius refers to an apex position proximal to the heel.

[g]DF: dorsiflexion.

[h]PF: plantarflexion.

Methods

Study Design

This systematic review was registered with PROSPERO (International Prospective Register of Systematic Reviews; CRD42024625819) and is reported in line with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guideline [32].

Search Strategy

A systematic database search was performed by the primary reviewer using PubMed, Embase, Scopus, and Web of Knowledge. The search was performed using the following phrases: ankle foot ortho*, AFO, AFO-FC, orthotic*, orthosis, orthoses, splint, combined with biomech*, gait, locomotion, walk*, kinemat*, and adaptation, shoe, footwear, rocker, roll-over, insert, wedge, and tuning. Papers were retrieved from the beginning of the respective database history until December 2024. A follow-up search was conducted in May 2026. The complete search string for Scopus is:

TITLE-ABS-KEY((“ankle foot ortho*” OR “orthotic device” OR AFO OR “AFO-FC” OR (ankle AND (orthotic* OR orthosis OR orthoses OR splint))) AND (biomech* OR gait OR “gait analys*” OR locomotion OR walk* OR kinemat* OR tuning OR manipulation) AND (shoe* OR footwear OR rocker* OR “roll-over” OR insert* OR wedge* OR tuning))

The remaining search strings, including database-specific keywords, can be found in Multimedia Appendix 1.

Eligibility Criteria

Titles were excluded if they mentioned nonadult participants, animal participants, or cadavers. Review papers, protocols, or papers that investigated only movements other than walking, surgical techniques or surgery-related outcomes, or devices that were not AFOs, lower leg casts, or footwear were also excluded in the title exclusion process. Rigid lower leg (plaster) casts were considered to behave in a similar manner to rigid AFOs and were eligible for inclusion.

Abstracts were excluded if the abstract did not mention both footwear and AFOs and did not describe effects of footwear adaptation on gait while using an AFO. The abstract must have described walking with an AFO in at least two footwear conditions. Abstracts were excluded when footwear was manipulated in only the leg contralateral to the AFO.

XSL•FO
RenderX

Papers written in English, French, German, or Dutch were eligible for full-text selection. Inclusion criteria required that the study described or visualized the AFOs, footwear, and footwear modifications. To qualify, the footwear adaptation must have been applied externally to the AFO, either between the AFO and the shoe, the shoe itself, or between the shoe and the ground. Additionally, at least one of the following outcome measures must have been examined: sagittal plane lower-limb joint kinetics and kinematics, sagittal plane whole-body COM kinetics and kinematics, spatiotemporal walking parameters, muscle-tendon dynamics, lower-limb EMG (electromyography), COP, GRF, plantar pressure, or metabolic cost.

Selection Process

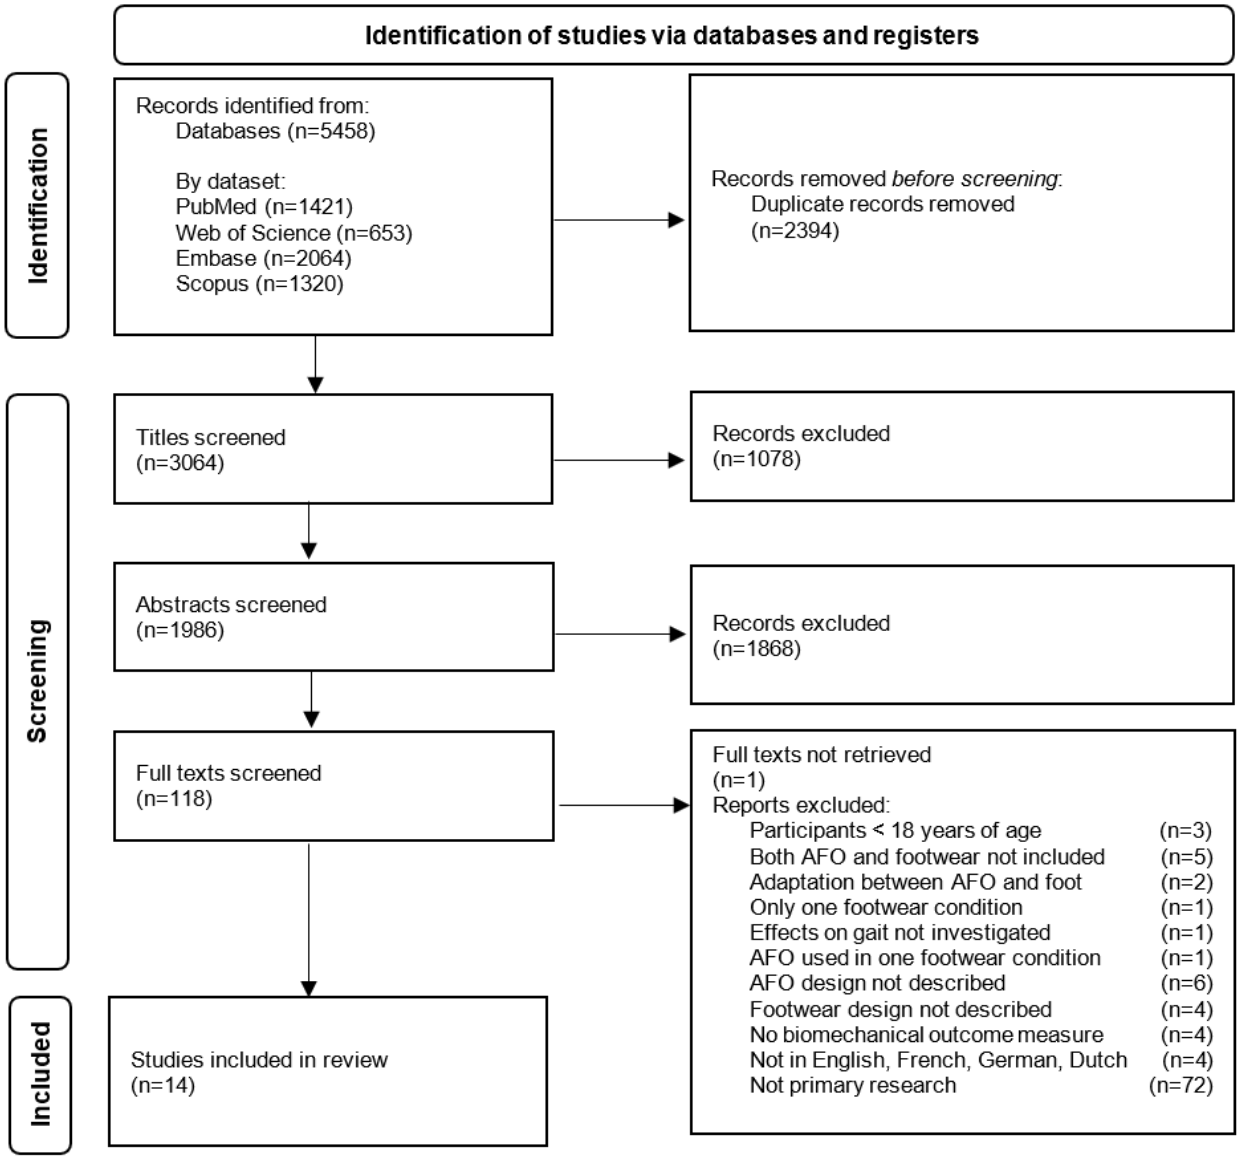
Screening was performed with the use of Catchii, a systematic review management tool [33]. Two reviewers independently screened papers at each stage of the inclusion process. Reviewers AM and CG performed the title and full-text screening, and the abstract inclusion process was performed by AM and JMH. Disagreements were resolved through discussion between each pair of reviewers. For each stage of the selection process, papers were excluded based on the first exclusion criterion that was met, and only that criterion was recorded.

Quality Assessment and Data Extraction

The quality of the included research was assessed using a modified Downs and Black Checklist [34]. This version of the checklist scored question 27 binarily, rather than out of the original 5 points, and is more suited to observational studies. Questions regarding follow-up were omitted from the checklist as gait studies are typically within-participant designs without follow-up. The final checklist was scored out of a potential 25 points. Adjusting for the omitted questions, a study could be considered “excellent” quality if it scored 23-25 points, “good” between 17 and 22 points, “fair” between 12 and 16 points, and “poor” if marked less than 12 points [35]. Only studies scoring “fair” or higher would be considered to have sufficient quality for data extraction.

A modified version of the AFO reporting checklist developed by Ridgewell et al [36] was used to evaluate the quality of AFO reporting. The checklist evaluates 3 categories: participant details, AFO details, and the experimental protocol. This checklist was developed for studies on children with cerebral palsy, and as such the section on participant details was excluded for the purpose of this review. Scoring followed the guideline provided by Ridgewell et al [36]. Reviewers AM and CG independently scored both checklists. Any disagreements were resolved through discussion.

Data were extracted by AM. A custom checklist was used to extract footwear design parameters. This checklist includes design descriptors such as outsole hardness and apex position but does not include manufacturing items such as last type or sole material. Only outcome measures listed in the inclusion criteria were included in this review. Data were systematically synthesized using a structured biomechanically informed framework. Data were synthesized first by footwear adaptation (eg, HSD), then by the phase of gait in which outcomes were measured, and finally by the specific outcome measure. For clarity purposes, all moments are reported as internal moments, with any values reported as external moments transformed by AM.



Results

Search Results

The systematic database search, including the updated search, resulted in 3064 papers after duplicates were removed. A total of 118 full texts were evaluated for inclusion in the review. Of these, 9 papers were written in German, and 1 paper in French, all of which were excluded due to not being primary research. A total of 14 studies were included in the review, following the inclusion procedure outlined in Figure 4.

XSL•FO
RenderX

Figure 4. Study selection flowchart including updated search. Exclusion criteria shown here were those used to exclude full texts. AFO: ankle-foot orthosis.

Study Characteristics

An overview of the participants, interventions, and study designs can be found in Table 2. The majority (10/14) of studies were within-subjects designs evaluating hemiparetic patients after stroke using solid dorsal AFOs.

[d]Denotes the gait speed was controlled across conditions.

[e]PF: plantarflexion.

Participant Characteristics

A total of 204 participants (108 healthy, 84 patients after stroke, and 12 with unilateral ankle weakness or pain) were included across all 14 studies. Seven papers examined AFO-footwear combinations in patients with hemiparesis secondary to stroke [37,38,40,43,44,47,48]. Hemiparetic participants ranged across studies from 11 months to over 10 years post stroke onset. Six studies recruited only healthy participants [28,39,41,42,45,49], and one study enrolled both healthy controls and participants with unilateral foot or ankle weakness or pain [46]. Of the 8 studies that included patients, 5 studies recruited participants who used AFOs in their daily lives [37,38,43,46,47], 1 study included only participants who had not used AFOs in their daily lives [48], and 2 studies did not specify whether AFOs were used in daily life [40,44]. Nine studies included gait speed as an outcome measure [28,37,38,40,42-44,47,48]. Three studies let participants walk at a self-selected walking speed and did not report it as an outcome. Of these 3 studies, one study controlled the speed between the trials [45], and 2 studies did not specify whether speed was controlled between conditions [41,49]. One study set a target gait speed based on the participants' leg length and a Froude number of 0.16 and used this for all conditions [46]. One study did not report gait speed as an outcome or specify if gait speed was controlled [39].

AFO Properties

A summary of the AFOs included in this review and their properties can be found in Table 3. A total of 19 different AFOs were used across the 14 included studies. Eight of the AFOs used a solid dorsal shell design constructed out of polypropylene [37,38,40,42-44,47]. One study used 2 AFOs with a "plastic shell," which are assumed to be polypropylene dorsal shell AFOs, one with plantarflexor resistance and one with a plantarflexion stop [48]. Four AFOs were carbon-fiber, of which 2 AFOs had ventral shells [41], 1 AFO a proximal cuff [46], and 1 AFO a dorsal shell [45]. While a walking boot was also investigated by Kearney et al [41], results from the cast were not included, as it did not meet the inclusion criteria of having the footwear adaptation be between the AFO and the shoe or ground. One AFO had a hinged ankle joint with adjustable medial and lateral struts which attached directly to an experimental shoe [28]. One study used 2 AFOs with the same design with either a medial or lateral strut [49]. These 2 AFOs were counted as 1 AFO in Table 3 as they were otherwise identical. The AFO had free dorsiflexion and plantarflexion but did not permit frontal plane motion. No information about any parameters other than strut position was given or possible to infer for this AFO. This study also examined a stirrup brace which restricted frontal plane movement and was considered an AFO. A plaster cast [39] was reported and categorized as an AFO for the purpose of this review. Including the cast, 11 AFOs had full-length footplates [37,39-42,44,46,47]. The length of the footplate was not stated or possible to infer from images for 7 AFOs [38,43,45,47-49]. Eight of the footplates were rigid [37-39,42,44,45,47], one was flexible throughout the footplate [45], and one was flexible at the metatarsophalangeal joint [43]. Two AFOs had indeterminable footplate stiffnesses, with the only description given as one AFO being "more flexible," and the other AFO being "less flexible" [41]. The footplate stiffness was not given or impossible to infer for 7 AFOs [28,40,47-49].

Footwear Adaptations

The footwear adaptations used for each study can be found in Table 4. Footwear adaptations are reported in the same manner as the respective study. Seven papers investigated adaptations at the heel of the shoe. The majority of these focused on increasing the HSD, either with insole wedges [41,45,46] or through altering the heel height of the shoe itself [47]. An overview of these adaptations can be examined in Table 5. One study used insoles to manipulate the SVA, but did not specify the shape, height, or location of these insoles [38]. One paper examined the effects of changing the shape and hardness of the heel of an experimental shoe [28]. One paper examined the effects of increasing the HSD using wedges, which were then translated to the design of a custom shoe and combined with a stiff rocker outsole [43]. Design parameters for that rocker outsole were not given; however, from the image provided, it can be inferred that an apex position proximal to the metatarsophalangeal joint was likely used.

Three studies compared standard shoes to rocker shoes [40,44,48]. All 3 studies used the same forefoot rocker design of an apex position at approximately 65% of the length of the shoe from the heel, and a rocker angle of 15° with a curved forefoot and stiff outsole. Farmani et al (2016) [37] studied the effects of adding a rocker sole directly to the footplate of a rigid polypropylene AFO compared to the same AFO with only a layer of nonslip rubber added to the footplate [37]. This rocker sole also had an apex position at approximately 65% of the shoe length with a beveled forefoot with a rocker angle of 15°, and as such is considered functionally a rocker shoe for the purpose of this review.

Dhalla et al [39] examined the effects of different types of cast shoes when used with a rigid walking cast. Schmalz et al [49] examined the effects of mediolateral wedging, in this instance

XSL•FO
RenderX

applying the wedges externally to the shoe. It is unclear whether the footplate of the AFO and wedge were the same length. A study from Arvin et al [42] compared a conventional solid dorsal AFO with a shoe to an AFO of the same manufacturer but with a shank inclined in dorsiflexion without a shoe. Both the traditional AFO with a shoe and the modified AFO worn without a shoe had the same SVA of 5°-7° inclination [42].

Quality Assessment

Study Quality

The scores for each included paper can be found in Table 2. The score each paper received per question can be examined in Multimedia Appendix 2 [28,37-49]. The majority of papers (10/14) were considered "good" quality, with the remaining papers (4/14) considered "fair." The lowest score given was 14. No paper received a "yes" for stating whether an attempt was made to blind either the participants or those measuring the outcomes.

AFO Reporting

Multimedia Appendix 2 provides an overview of the results of the AFO Reporting Checklist. A total of 19 different AFOs were used across the 14 included studies, with 2 studies using 2 different AFO designs, and 1 study comparing a walking boot to 2 different AFOs. The majority (10/14) of studies applied their modifications in a randomized order, 2 studies did not state whether randomization occurred, and 2 studies were case studies where randomization was not applicable. Over half (12/19) of the AFOs were custom manufactured, with only 1 AFO's manufacturing status being unclear. A clear motivation for why a specific AFO design was used was given for all AFOs. No consistent method of reporting AFO details was present across the included studies. AFO design details often had to be inferred from photos, with 8 of the AFOs having completely clear trimlines. The stiffness and ankle position were described in detail for 1 AFO. A clear description of the movements assisted or prevented was given for 13 of the AFOs.

Biomechanical Effects

Table 6 provides an overview of the outcome measures extracted for this review. Only outcome measures fitting the inclusion criteria outlined above were included for the purpose of this review. These outcome measures can be divided into 5 main categories: kinematics, kinetics, plantar pressure, spatiotemporal parameters, and GRF. Table 7 provides the effects of each type of footwear adaptation per outcome measure across the 3 rockers. All results are given for rigid AFOs unless otherwise specified.

Table 6. Outcome measures of interest.

Outcome measure	Included from reference number	Total patients (n)	Total healthy (n)
Kinematics			
Ankle	[44[a],46-48]	1 S[b], 12 U[c]	20
Knee	[27,36[a],42,44,46-48]	40 S	29

HSD

Increasing the HSD showed effects on gait across all 3 rocker phases, with insole wedges being used to influence biomechanics in the third rocker [43]. Increasing the HSD from 1 to 3 cm increases the peak dorsiflexor moment at the beginning of the second rocker, shifting the second rocker later in stance [46]. This change in HSD also increases the time required for the COP to reach peak anteroposterior velocity. Peak COP velocity occurred approximately 10% later in the stance phase when using a soft 3 cm wedge compared to a soft 1 cm wedge, and just over 30% of the stance phase later for a firm 3 cm wedge compared to a firm 1 cm wedge [46]. The peak knee extensor

XSL•FO
RenderX

moment during loading response increases and occurs later in the gait cycle as the HSD increases [46].

An increase in HSD increases the SVA in both healthy individuals and patients after stroke, resulting in greater knee flexion [38,43,45]. Similarly, a larger HSD increases the ankle dorsiflexion angle, plantarflexor moment, and hip flexion angle at midstance [45].

In the third rocker, the use of an increased HSD and rigid AFO elicited increases in knee flexion at toe-off when compared to a posterior leaf spring–AFO and standard shoes in a patient who had a stroke [47]. Larger plantarflexor and knee extensor moments in a patient who had a stroke were also observed at toe-off when compared to walking in only unmodified shoes [47].

Increasing the HSD linearly increased the radius of curvature of the ROS normalized to participant body height, with 3 cm wedges producing a radius of curvature in 4% of body height greater than 1 cm wedges [46].

A linear increase in forefoot pressure and simultaneous decrease in hindfoot pressure was found with increasing HSD [41]. There was no difference found between AFO stiffnesses when the same changes in HSD were applied [41].

Increasing the HSD did not affect walking speed but did decrease cadence in patients after stroke when compared to walking with shoes only, with a significant decrease in cadence when the shank was inclined by 10° [38]. There was also no difference in the duration of terminal stance regardless of AFO stiffness or HSD [41]. Similarly, there were no significant differences for speed, step length, or step width in healthy participants when the SVA is held constant between an AFO with an inclined shank and no shoe, and an AFO with a neutral SVA and a shoe with a 1 cm HSD [42].

Heel Rocker

Three different heel rockers were investigated across 2 studies. A heel with a 20-degree bevel reduced the knee extensor moment during loading response by 24% compared to a conventional men's dress shoe hard rubber heel when both were used with a rigid AFO [28]. The addition of a heel rocker to a walking cast allowed for a reduction in peak hindfoot pressure [39]. Conversely, a rigid whole-foot rocker applied to the same cast did not decrease hindfoot pressure; however, it did decrease peak forefoot plantar pressure [39].

Heel Hardness

Increasing the hardness of the heel external to the shoe increased the knee extensor moment during the loading response, with a hard rubber heel having a moment 31% higher than a SACH (solid ankle cushion heel), and 12% higher than a compressible crepe heel [28]. Harder heel wedges increased the peak ankle dorsiflexor and knee extensor moments during second rocker [46]. Increasing both the height and hardness of a heel wedge significantly delayed the timing during the stance phase of peak COP velocity, with the peak occurring approximately 15% later in stance for a firm 3 cm wedge compared to a compressible 1 cm wedge [46].

Forefoot Rocker

The use of a proximal forefoot rocker increased knee flexion at toe-off when used with a rigid AFO [37,43]. This increase in knee flexion also resulted in the GRF being more posterior to the knee joint during third rocker compared to a shoe with a standard forefoot [43]. In both plantarflexion stop and plantarflexion resistant AFOs, the addition of a proximal forefoot rocker significantly reduced the peak ankle plantarflexor moment when compared to the same AFOs and standard shoes [48].

In rigid AFOs, the addition of a proximal forefoot rocker increased walking speed when compared to the same AFO with a standard shoe [40,44]. Conversely, the use of a proximal forefoot rocker with dorsiflexion-free AFOs resulted in slower walking speeds when compared to those same AFOs and a standard shoe [48]. The stride length was also reduced in patients walking with dorsiflexion-free AFOs when paired with a proximal forefoot rocker compared to when paired with a standard shoe.

Mediolateral Wedging

Mediolateral wedging had limited effects on sagittal plane biomechanics. The peak knee extensor moment during third rocker was reduced with the use of either a medial or lateral wedge, although only significantly with the medial wedge, when paired with an AFO that restricted frontal plane motion at the ankle joint [49]. Medial or lateral wedging with either an ankle support or rigid AFO decreased the vertical component of the GRF when compared to a shoe without any wedging or AFO [49].

Discussion

Principal Findings

This review used a biomechanical framework to synthesize evidence on the interacting effects of footwear parameters and AFOs on gait outcomes in patients and healthy young adults. While it is evident that footwear adaptations can optimize gait biomechanics beyond what can be achieved by an AFO and standard shoe alone, large knowledge gaps remain, preventing empirical validation of many theoretical and biomechanical assumptions and adoption in clinical practice. The effects of plantar pressure [39,41] will be omitted from the discussion to focus on kinetics and kinematics.

Participants both with and without pathologies were included in this review, as healthy walkers can provide a valuable model for the biomechanical effects of AFO-FCs. Indeed, in the few studies that examined the same AFO type, footwear adaptation, and outcome measure, it was found that both patients after stroke and healthy walkers have increased knee flexion during the second rocker when the HSD is increased [38,43,45]. However, this heterogeneity in participants does require discretion when interpreting the results, as adaptations may not be transferable to all patient populations.

A wide range of AFO designs were included in this study; however, the majority (11/19) could be generalized as rigid AFOs which restrict both plantarflexion and dorsiflexion and

XSL•FO
RenderX

can be assumed to have negligible differences in their mechanical properties when interpreting sagittal plane gait variables.

Biomechanical Effects

Heel-Sole Differential

Adaptations increasing the HSD were comparatively well represented in this review, likely due to the SVA being considered a core component of the AFO tuning process [11,50]. Indeed, increasing the SVA, such as with a larger HSD, causes a cascade effect on lower limb kinematics and kinetics when the ankle joint is fixed. Notably, a larger HSD increased knee and hip flexion during the second rocker [45]. This increase in knee flexion was seen across all 3 papers that evaluated knee angle as a result of changing HSD in both healthy participants and patients after stroke [38,43,45]. Although a larger HSD was reported to increase ankle dorsiflexion despite the use of a rigid AFO, it should be noted that this increase may be due to marker placement on the shoe while using insoles to increase the HSD, causing an increase in SVA without a change in the participants' ankle angle [45].

With a constrained ankle joint, changes in HSD affect both the knee and hip joints, indicating that shank kinematics are also influenced. This is supported by the study of Kerkum et al (2021) [7], which examined the dynamic SVA at midstance during walking with an AFO and found that, with a rigid AFO, the SVA increases as HSD increases [45]. Intuitively, the HSD can be used to influence lower limb joint kinematics in the first and second rockers; however, when the HSD is altered within the shoe, kinematics and kinetics at the ankle, knee, and hip joints are also influenced in the third rocker for rigid AFO users [47]. This is likely due to the fixation of the ankle joint, causing the shank to become more inclined as the foot-to-floor angle increases with a larger HSD, even as the heel leaves the ground in the third rocker. When the ankle joint is not constrained, it is able to adapt to changes in the HSD, leaving shank kinematics unaffected [21,51]. These findings suggest that patients who wear rigid AFOs and experience excessive knee extension may benefit from an increased HSD.

Ikeda et al (2018) [46] demonstrated that the ROS radius of curvature could be linearly increased with a constrained ankle and increasing HSD. Conversely, past research has shown that ROS are not affected by an increased HSD for unconstrained ankles [21]. As ROS radii between 20% and 30% leg length have been shown to optimize metabolic rate [15], the use of HSD to tune the ROS radius in rigid AFO users may be something to consider when optimizing energy consumption. Walking speed and cadence remained unaffected across different HSD settings, suggesting that while HSD can be used to manipulate joint kinetics and kinematics, it may have a limited impact on spatio-temporal parameters.

Heel Rocker

It was shown that a heel with a 20-degree bevel could reduce the knee extensor moment in the first rocker [28]. This follows biomechanical theory, which suggests that a heel rocker will reduce the moment arm of the GRF, thereby reducing the peak moments and angular velocities at the knee and ankle joints, facilitating smooth COM transfer. In other words, the use of a heel rocker could elicit a steeper ROS arc during first rocker, increasing the rate of forward progression of the COP. This suggests that such a heel rocker could be used to improve the walking efficiency of patients using rigid AFOs who struggle with step-to-step transitions or walk with excessive knee flexion at the start of the second rocker.

Changes in walking speed were not observed when a heel rocker was used with a rigid AFO [28]. As the other study that examined heel rockers did not look at temporal effects, no conclusion can be drawn based on the evidence presented in this review.

Heel Hardness

A more compliant heel was associated with reduced ankle dorsiflexor and knee extensor moments at initial contact, likely due to a shortened moment arm of the GRF [28]. Following biomechanical theory, it was seen that a more compliant heel had a similar effect to a rocker heel in terms of decreasing the knee extensor moment during the loading response [28,46]. The study by Wiest et al (1979) [28] demonstrated that a SACH could reduce the knee extensor moment during initial contact more than both a crepe heel and 20-degree beveled heel. As the SACH was constructed out of medium-density polyurethane, it may be more compressible and have greater force distribution properties than the crepe heel and incompressible heel, resulting in a smaller GRF moment arm at the knee and ankle joints at initial contact. The use of a compressible heel may therefore help reduce joint loading and smooth step-to-step transitions at initial contact for individuals with a heavy heel strike.

Increasing heel hardness was associated with increased peak dorsiflexor and knee extensor moments during the first rocker, as well as delayed peak moment timing [46]. These effects were most pronounced with wedges thicker than 1 cm, suggesting a threshold beyond which mechanical influence plays a greater role due to the increased vertical component of the GRF.

Ikeda et al [46] found that a more compliant heel placed the ROS center of curvature more posteriorly when compared to a stiffer heel. This is in line with the work of Hansen et al [52], which demonstrated that more compliant feet have a more curved ROS compared to less compressible prosthetic feet. This suggests that the use of a compressible heel wedge could be used to decrease the rate of COP forward progression during first rocker when using a rigid AFO, thereby increasing the steepness of the ROS arc. Using a more compliant heel may be a method of increasing the steepness of the ROS arc without introducing greater moments at the joint, such as with a harder heel. While harder heels were associated with greater gait speeds, they may also increase joint loading, which could be detrimental in populations with joint degeneration or pain [28]. When joint loading is not a concern, harder heels may be used to slightly increase gait speed due to the increased moments and angular momentum at the knee and ankle, leading to a faster COM transition between steps.

Forefoot Rocker

In patients after stroke, the use of a proximal forefoot rocker demonstrated differing effects depending on the type of AFO

XSL•FO
RenderX

used. When paired with rigid AFOs, it increased knee flexion at toe-off as well as walking speed when compared to the same AFO with a standard shoe. This increase in walking speed may be due to improved rollover through the restoration of a more typical ROS radius caused by an increase in the COP velocity during third rocker. In line with this finding, it has been shown that a proximal forefoot rocker used without an AFO can facilitate improved weight transfer and a steeper ROS arc in healthy participants [25]. Increasing knee flexion at toe-off may also be beneficial in patients with limited foot clearance using rigid AFOs.

When combined with dorsiflexion-free AFOs, the peak ankle plantarflexor moment decreased when compared to the same AFO used with a standard shoe. This is likely due to the moment arm of the GRF being shortened by the proximal position of the rocker apex. These dorsiflexion-free AFOs were also shown to decrease stride length and walking speed when used with a proximal forefoot rocker instead of a standard shoe, possibly due to the reduced plantarflexor moment during third rocker.

Future Steps

A key finding of this review is the lack of research into varying rocker parameters such as both heel and forefoot apex positions and rocker radii when AFOs are used. The evidence from the limited studies included in this review suggests that rocker outsole parameters can have a significant impact on both healthy and pathological gait, indicating that further research into these areas could benefit AFO users. Of the 5 studies that used forefoot rockers, 4 studies used the same design [37,40,44,48], with limited reasoning behind their choice, and the fifth did not provide any descriptor of the rocker design [43]. It would be beneficial when using different AFOs with the same footwear adaptations to compare the same outcome measures, as this furthers the understanding of the complex interactions between AFOs and footwear combinations.

Future studies would benefit from studying the effects of differing forefoot rocker design choices, as these have been shown to have a significant impact on gait biomechanics [8,9,25]. In particular, understanding the biomechanical effects of differing apex positions and radii across a variety of AFO designs beyond rigid polypropylene AFOs would be beneficial. These parameters directly affect the GRF lever arms and shank kinematics, in addition to the timing of key gait events, and as such may have significant contributions to improving gait efficiency. A core understanding of the mechanisms driving biomechanical adaptations could lead to improvements in tuning AFOs to improve step-to-step transitions and minimize energy expenditure for patients with a range of pathologies.

An aim of this review was to consolidate evidence across diverse pathologies; however, the majority of included studies focused on patients after stroke and healthy participants. Broader representation would improve the generalizability of findings, as gait impairments in stroke differ from those in conditions such as cerebral palsy, multiple sclerosis, or peripheral neuropathy. Furthermore, focusing on a single pathology overlooks the considerable variability that exists within that group, potentially masking important individual differences. This narrow scope may hinder clinical decision-making, as practitioners often treat diverse patient populations and require evidence that supports personalized, condition-appropriate prescriptions. Future work should consider broadening the scope to include a wider range of pathologies in order to improve the clinical relevance and applicability of findings.

Limitations

A very specific set of exclusion criteria was used for this review. While the number of included studies reflects similar reviews and the existing knowledge gap, a broader inclusion protocol could have been beneficial. For instance, the inclusion of papers that did not use an AFO for all conditions but had multiple footwear adaptations could still have provided insight into the effects different footwear adaptations may have on biomechanics. Furthermore, data were extracted by a single author, and while the included results were examined by the other 2 authors of this review, it is possible that some data were overlooked or inconsistently collected during the inclusion process, introducing a risk of subjective bias and potentially reducing the reproducibility of this review's findings. As all studies included at least one significant finding, there may be a risk of publication bias. However, due to the design of the included studies, a formal assessment of publication bias was not performed.

While the papers included in this study were mostly of "good" quality, none could be considered "excellent." This is largely due to no studies being blinded; however, due to the physical nature of the interventions, it would be difficult to truly blind participants and researchers. It is important to note that 4 of the 5 studies using forefoot rockers belong to the same institution. While each paper from that group reported different outcome measures, the same rocker parameters were used for all 4 papers.

A major limitation of this review is the lack of empirical descriptors given for interventions. Without empirical descriptors, it is difficult to draw scientifically sound conclusions from the presented outcomes. Many AFO details were inferred, or the details provided were too vague to derive conclusions from. For instance, 2 AFO designs were described as "more stiff" or "less stiff" than the other [41]. As AFO stiffness has a significant impact on knee and ankle kinematics, whether that difference in stiffness is 1 or 5 Nm/deg can have a substantial influence on gait outcomes [53]. Compounding this issue, very few studies gave sufficient detail about their adaptations, and there was often minimal description of the footwear being used. This lack of transparency makes it difficult to replicate findings or understand the specific mechanical contributions of the footwear-AFO combinations being tested.

Conclusions

The results demonstrate that footwear adaptations can be used to optimize AFO effects for individual patients. However, while the biomechanical effects of increasing the HSD with a rigid AFO are well explored, there exists limited information regarding the effects of other outsole design parameters and compliant AFOs. Further understanding of the interactions between AFOs and rocker outsole parameters is required to maximize AFO effectiveness across different patient populations. Future research should investigate the effects of

XSL•FO
RenderX

varying forefoot parameters, including rocker radius, apex position, and footplate stiffness, in combination with a wider range of AFO designs including energy-storing AFOs. Explicit and consistent reporting of AFO and footwear design properties is necessary to make meaningful conclusions on biomechanical outcomes.

Abstract

Technology-based interventions in the field of disability and rehabilitation, which serve assistive, therapeutic, and/or service delivery functions, are considered complex due to the skills required of providers and recipients, degree of individual tailoring, and diversity of use settings. Feasibility studies are an important step in the evolution of complex interventions that can help refine the intervention, inform implementation, and prevent wasted resources. However, guidance is lacking regarding specific considerations for feasibility studies of technology-based interventions in disability and rehabilitation, which leaves researchers and developers reliant on resources from other fields that do not address important technology properties. To advance the field, context-specific definitions, considerations, and evaluation dimensions must be explicitly outlined to ensure that feasibility studies are constructively designed to meet the unique needs of these interventions. In this viewpoint article, we (1) propose a definition and framework for feasibility studies within the specific context of technology-based disability and rehabilitation interventions, (2) highlight important and unique imperatives for feasibility studies of these interventions, and (3) articulate relevant feasibility dimensions and associated evaluation criteria for these interventions. Building on previous work, we distinguish between feasibility studies, wherein we focus on iterative intervention refinement by addressing key development questions (eg, usability), and pilot studies, which are small-scale versions of a larger study that will evaluate intervention outcomes. Integrating previous typologies, we present 13 feasibility dimensions relevant to technology-based interventions and provide sample evaluation criteria, focusing on the intervention itself rather than study design considerations (eg, trial management). This information may be useful for research and development communities (academic, clinical, or industry) to inform comprehensive feasibility studies that examine unique aspects of technology-based interventions to promote real-world impact. This contribution encourages greater harmonization of terminology and evaluation methods to streamline interpretation and comparison across studies.

Introduction

Technology-Based Interventions in Disability and Rehabilitation

Innovative technology-based solutions are increasingly sought to meet the evolving needs of health and social service systems, particularly since the onset of the COVID-19 pandemic [1-3]. In the field of disability and rehabilitation, technology-based interventions involve structured use of technological devices or systems to achieve targeted goals related to health, function, or participation. Technology-based interventions can be broadly classified as serving assistive, therapeutic, and/or service delivery purposes [4]. Assistive products, such as wheelchairs, hearing aids, and communication devices, help optimize a person's functioning to reduce disability [5]. Therapeutic interventions restore or improve function through the use of technologies including robotics, alternative reality systems, and exercise-based video games. Technology-mediated service delivery models replace or augment existing services to improve care access or maximize efficiency through approaches like telerehabilitation, web or mobile apps, and smart home monitoring systems. Technology-based interventions encompass the core technology products, such as the devices, software, or platform, as well as services (eg, training) and systems (eg, smart home system) that enable use of the intervention. Target users of such interventions may include rehabilitation patients, people with disabilities, clinicians, or care partners.

XSL•FO
RenderX

Regardless of intended function and target population, technology-based interventions are considered complex for several reasons. They often require providers and recipients to learn specific skills and necessitate customization or tailoring to individuals and/or specific contexts or settings of use [6]. Varying these factors may also engender technical complexity (eg, privacy, data security, reliability, usability, and scalability) that needs to be managed. Rapid testing may help uncover design requirements that are not identified during initial design activities and guide iterative intervention refinement.

Feasibility and Pilot Studies

Feasibility is a vital facet in the Medical Research Council (MRC) framework for complex intervention development and evaluation [7]. Dictionaries define feasibility as the possibility, capability, likelihood, or reasonableness that something can be made, done, or achieved [8,9]. In the context of health research, feasibility studies refer to preliminary research before a main study to determine whether future work can and should be done, and to inform the design of such work [10]. According to the MRC framework, feasibility studies should address both the intervention itself (ie, content and delivery), as well as study design and process considerations for future evaluation (eg, recruitment, data collection, outcome measurement) [7]. Common aspects of feasibility studies include a focus on process rather than outcomes, exploration of key areas of uncertainty, and evaluation of multiple dimensions based on predetermined success or progression criteria [11,12]. Thorough feasibility studies prior to larger-scale evaluation contribute to better interventions, stronger evaluation designs, greater likelihood of successful implementation, and fewer wasted resources [7,11].

Historically, the terms feasibility and pilot have been used interchangeably and inconsistently in the literature, causing confusion about their scope and objectives [13,14]. In response to this lack of terminological clarity and growing interest in the field, Eldridge et al [10] developed an international consensus–based conceptual framework for feasibility and pilot studies that has been widely cited. According to their framework, feasibility studies ask whether something can be done, if it should be done, and *how* it should be done. Pilot studies are considered a subset of feasibility studies that ask similar questions but do so by conducting a small-scale version of a future study (or parts of it) [10]. It is now generally accepted that feasibility studies represent an overarching type of research concerning whether something will work, with pilot studies as a subset that specifically aim to test the operation of a future larger study [10,14,15].

Rooted in phased clinical trial practices, the Eldridge et al [10] framework focuses on studies conducted in preparation for a randomized controlled trial (RCT). However, RCTs are often inappropriate for technology-based interventions in disability and rehabilitation due to practical challenges (eg, need for prolonged intervention use across diverse settings, difficulty matching the speed of technology advances), scientific limitations (eg, lack of masking, and limited generalizability to real-world contexts), and ethical concerns of withholding interventions with observable benefits (see Wang et al [4] for detailed description of these issues). Given the challenges associated with reliance on phased clinical trial practices, new approaches have been proposed to generate evidence for technology-based interventions in disability and rehabilitation [4,16]. An alternate field-specific conceptualization of feasibility studies is thus warranted.

Feasibility Evaluation of Technology-Based Interventions

To address the challenges above, Wang et al [4] proposed the Framework for Accelerated and Systematic Technology-Based Intervention Development and Evaluation Research (FASTER), a three-phased approach to evidence generation informed by the MRC guidance: (1) development, (2) progressive usability and feasibility evaluation, and (3) scaled evaluation and implementation [4]. The aim of the feasibility phase is to progressively refine the intervention prototype through small-scale iterative usability testing and assessment of other process concerns (eg, acceptability, adherence, and intervention safety) [4]. By uncovering insights on how to improve intervention features, the feasibility phase is essential to promote future uptake and sustained use [4]. Within the feasibility phase, FASTER promotes a variety of research designs and methodologies to gain a comprehensive understanding of the intervention, its users, and their contexts of use. Teams are encouraged to progressively address issues identified in previous work and tailor the feasibility evaluation to key research questions, uncertainties, and intervention maturity [4]. However, no guidance is offered on what aspects of feasibility may be relevant.

To our knowledge, no existing frameworks delineate aspects of feasibility relevant for technology-based interventions. While previous work has provided guidance on the design, key features, and areas of evaluation for feasibility studies across various health-related fields (eg, pharmaceuticals [17], public health [12], psychology [11], and rehabilitation [18,19]), these resources do not account for aspects of feasibility related to interactions between users, technology, and the environment (eg, usability and technical performance), or unique considerations for disability and rehabilitation populations (eg, duration and diversity of intervention use). Specification is important since feasibility studies are applied differently across fields. Technical feasibility studies within engineering or computer science disciplines generally assess whether a system can be developed to perform its intended functions within defined constraints and are therefore typically undertaken in highly controlled settings. Within business settings, feasibility studies assess the likelihood of success for a proposed commercial product or service considering factors like market demand and financial viability. A comprehensive harmonizing framework is needed to provide field-specific guidance for feasibility studies of technology-based interventions, insofar as their potential to perform as expected and deliver intended outcomes.

A harmonized framework could promote more efficient and theoretically driven intervention design, development, and evaluation. Currently, researchers and developers resort to borrowing and “translating” concepts from sources in other

XSL•FO
RenderX

fields—a time-consuming undertaking that requires deep familiarization with new literature. This translation leads to differences in interpretation and application of concepts, making it difficult to compare and consolidate across studies. Without unified and cohesive resources, research in this area remains conceptually and empirically fragmented, delaying the pace and quality of innovation. To advance the field amidst rapid digitization of tools, services, and programs, a comprehensive framework is needed that outlines feasibility considerations, dimensions, and evaluation criteria pertinent to technology-based interventions. Such a framework will help researchers and developers achieve consistency and comparability, providing a foundation to develop best practices for studying the feasibility of technology-based interventions for disability and rehabilitation.

Aims

This viewpoint article aims to (1) propose a definition and framework for feasibility studies within the context of technology-based disability and rehabilitation interventions, (2) highlight important and unique imperatives for feasibility studies of these interventions, and (3) articulate feasibility dimensions and evaluation criteria relevant to these interventions. We focus on the feasibility of the intervention itself rather than study design and process considerations (eg, trial management) for which suitable field-specific guidance is available [18-21]. It is hoped that this discussion encourages comprehensive feasibility studies that examine unique aspects of technology-based interventions to promote real-world research impact.

Authorship Identity Statement

For transparency, we highlight key identities of the authorship team informing this viewpoint. The authors have varied disciplinary backgrounds (kinesiology, occupational therapy, cognitive sciences, rehabilitation science, biomedical engineering, and computer science) and degrees of clinical, research, and lived experiences related to rehabilitation and assistive technologies. Our experiences span diverse populations (eg, traumatic brain injury, respiratory conditions, stroke, and dementia), technologies (eg, telerehabilitation, smart homes, mobility devices, artificial intelligence, robotic rehabilitation, and assistive devices), and user groups (eg, care recipients, partners, providers, industry, and policymakers), across the lifespan (children to older adults). These experiences shape our assumptions about the iterative multifaceted nature of technology-based intervention research and inform our interpretation of the literature.

Defining Feasibility Studies of Technology-Based Interventions

Building on conceptual definitions from Eldridge et al [10] and FASTER [4], we propose the following adapted definitions of feasibility and pilot studies for application to the context of technology-based intervention research in the field of disability and rehabilitation (Textbox 1).

Together, feasibility and pilot studies aim to gather insights about intervention features and their delivery [4,11,19]. This involves a focus on issues related to the intervention (eg, practicality, usability, and safety) and its implementation, as well as gaining a comprehensive understanding of user experience with the intervention across use contexts [4,19,22]. Once an intervention is sufficiently developed and data support its feasibility, pilot studies may be undertaken as part of the scaled evaluation and implementation phase [4,11]. Pilot studies have a greater focus on outcomes and may be more likely to consider additional scientific, logistical, or study process factors relevant to the design of future larger definitive studies, such as recruitment and retention rates, data completion and quality, and effect size estimates for efficacy measures [11,19]. At this stage, technology-based interventions should be evaluated with target users in real-world settings to enable realistic measurement of use and abandonment, effects on health or social outcomes, and economic considerations [4,7]. Pilot studies can be particularly valuable to inform such research and scale evaluation across time periods, user groups, care contexts, or geographic locations.

The next section highlights imperatives for evaluating the feasibility of technology-based interventions in disability and rehabilitation, followed by a summary of potential feasibility dimensions and associated evaluation criteria. To reiterate, we focus on the feasibility of the technology-based intervention itself, rather than study design and process considerations for future larger evaluation studies. Hence, factors related to study procedures (eg, recruitment, data collection, research infrastructure) are not included. Readers are directed to other works that discuss these aspects of study feasibility for intervention research, which are readily applicable to technology-based interventions [17-20]. We recognize there is overlap between intervention and study feasibility, and as such, information presented below may be useful for either purpose.

Textbox 1. Proposed definitions for technology-based interventions in disability and rehabilitation.

Feasibility study: preliminary investigation of a concept of, a part of, or a whole new technology-based intervention to assess its viability and inform its iterative refinement by addressing uncertainty about key development and design questions, such as how well an intervention prototype can be used (ie, usability), whether it should be used, and how it should be used.

Pilot study: specific type of feasibility study that is a small-scale version of a part of or whole, larger future study that evaluates outcomes, such as the use, effectiveness, or impacts of a new technology-based intervention. Pilot studies may be conducted in either controlled or naturalistic real-world contexts and require the intervention to be administered. Pilot studies involve target end-users, or participants who have some of the characteristics or experiences of the target end-users or knowledge of the experiences and contexts of target end-users. Decisions about the study context and participants depend on factors such as technology readiness or ethical concerns (eg, anticipated risk to target end users).

RenderX

Imperatives for Evaluating the Feasibility of Technology-Based Interventions

Developing a new technology-based intervention is an iterative nonlinear process that often involves cycles of prototyping, evaluation, and refinement [4]. Several rounds of feasibility testing and design modification may be warranted before an intervention is considered for larger-scale evaluation. While most interventions require some form of feasibility study, the inclusion of technology and unique needs of disability and rehabilitation populations introduces additional complexities that merit consideration. Based on our collective research and clinical experiences, literature review, and application of the FASTER framework [4], we synthesize 10 imperatives that feasibility studies for technology-based disability and rehabilitation interventions should address. These imperatives relate to target user populations; technology and intervention design; and regulatory, policy, and funding constraints (Textbox 2). While some are not entirely unique to technology-based interventions, the inclusion of technology complicates how these imperatives are addressed.

XSL•FO
RenderX

Textbox 2. Imperatives for feasibility studies of technology-based interventions in disability and rehabilitation.

Target user population needs

1. Accounting for diversity in user groups and target aims.
   - Technology-based interventions in disability and rehabilitation may have several different user groups and various target health or functional outcomes. [7] The profile of individuals receiving these interventions may also be complicated by heterogeneity, comorbidities or concurrent needs, and involvement in multiple interventions[23].
   - Triangulation of multiple research methods and/or data sources provides a more complete understanding of feasibility and maximizes knowledge gained about the intervention from smaller sample sizes [24].
2. Identifying meaningful user outcomes for health and social function.
   - Technology-based interventions for disability and rehabilitation populations serve functions beyond the medical model (curing symptoms or impairments), addressing issues related to health and social outcomes, such as management of chronic conditions, participation, and social inclusion.
   - While the focus of feasibility studies is not to evaluate intervention efficacy, exploring mechanisms of action and identifying the potential impacts and meaningful outcomes for users can help refine intervention features and inform future studies [4].
3. Creating conditions for meaningful feedback from different user groups.
   - Multiple user groups may interact with or be impacted by rehabilitation and assistive technology interventions, such as persons with a disability or clinical condition, clinicians, caregivers, and family members.
   - Given that different user groups may have distinct needs, values, capacities, and perspectives, creative testing approaches may be needed to simulate the experiences of various groups using the intervention in real-world conditions for them to provide meaningful contextualized feedback.
   - There may be stigma associated with the intervention that requires care to ensure that users feel comfortable testing it and providing feedback.

Technology and intervention considerations

1. Navigating technological complexities.
   - Technology-based interventions in disability and rehabilitation may be complex due to the number of technology components encompassed and their flexibility (ie, customizability) [7], skills required by service providers and recipients,[7] degree of individual tailoring required [7], and diversity of use settings [7]. These factors are complicated by variable levels of digital literacy and technical expertise among service providers and recipients who must learn and adapt to the technology.
   - Diverse study designs and methods from technical and clinical disciplines are thus needed to generate evidence for the feasibility and benefits of technology-based interventions [4].
2. Evaluating technology properties in real-world settings.
   - Evaluating technical performance (eg, system performance and reliability) and usability is critical to the development of new technology-based interventions [25]. These factors should be considered in early feasibility testing and require unique approaches to evaluation.
   - At the feasibility stage, intervention performance and usability should ideally be explored beyond a controlled lab environment [4,25]. Real-world testing considers how technology properties (eg, components and functions) may be affected by environmental conditions such as lighting, flooring, or background noise.
3. Monitoring adaptations needed to accommodate user needs.
   - Modifications to a rehabilitation or assistive intervention and its application may be needed to accommodate individual user needs or specific use settings. Adaptability to enable such modifications is a key feature of implementation success that should be addressed in feasibility testing.
   - Monitoring the frequency, extent, and impact of intervention modifications at the feasibility stage can provide important information regarding adaptability and help identify overly rigid features as well as opportunities for increased flexibility.
4. Incorporating relevant support services.
   - Support services are often required to facilitate technology-based interventions, including eligibility and fit assessment, device customization, user training, product servicing or maintenance, and technical support [4].
   - Incorporating aspects of these support services during feasibility testing can provide a more realistic evaluation of how the intervention may function in real-world environments.
5. Capturing appropriate duration and diversity of use.
   -

XSL•FO
RenderX

Technology-based rehabilitation and assistive intervention use is often not discrete but rather may be used for prolonged or lifelong periods in various settings (eg, hospital or care center, home, workplace, community) that may each be associated with unique privacy, ethical, social, or security concerns.

- Evaluating feasibility at appropriate intervals in diverse real-world contexts is important to identify changes in user experience that may occur during activities with differing demands, in unique environments, or due to changing individual circumstances over time (eg, decline in health status or new social environment).

Regulatory, policy, and funding constraints

1. Navigating and obtaining regulatory approvals.
   - Some rehabilitation and assistive technologies may be classified as medical devices requiring regulatory approval (eg, Health Canada, Federal Drug Administration, and European Medicines Agency).
   - Depending on jurisdictional requirements, specific outcomes or data may be needed to obtain relevant approvals, documentation of which may be initiated at the feasibility stage (eg, history of risk management and safety plans).
   - Development teams should be aware of applicable device classifications and associated requirements so they can be addressed in subsequent studies.
2. Examining variability in funding and reimbursement structures.
   - Funding sources (eg, publicly funded health care, third-party insurance, and self-pay) and reimbursement policies for technology-based interventions vary across jurisdictions, meaning there may be uncertainty about optimal approaches to providing access and establishing commercial feasibility.
   - Data related to the cost of the intervention and/or potential cost savings may support market research and commercial feasibility studies to establish a clear pathway for providing access.

Evaluating the Feasibility of Technology-Based Interventions in Disability and Rehabilitation

Here we outline our approach to consolidate potential areas of focus for feasibility studies of technology-based interventions in disability and rehabilitation. Broadly, we "translated" existing concepts from other fields to better fit technology-based interventions by addressing important considerations in this field (see Imperatives for Evaluating the Feasibility of Technology-Based Interventions) and identified additional areas where needed. The first author identified sources by searching Google Scholar and PubMed using keywords including "technology," "intervention," and "feasibility" and reviewing forward and backward references. Commonalities across sources were clustered, synthesized, and organized into dimensions that were reviewed by other authors and refined through discussion. Based on our knowledge and experiences in the field, we developed guiding questions for each dimension by adapting existing descriptions from the literature where possible and selected sample evaluation criteria. Throughout this process, conflicting ideas were iteratively resolved through deliberation until consensus was reached.

Most feasibility aspects included here are not new, but rather a collection of those described in other fields [11,12,17-20], which we curated and adapted to this unique context. In particular, we drew upon guidance from Bowen et al [12] who proposed 8 areas of focus for feasibility studies in public health research that are relevant to technology-based interventions: (1) acceptability, (2) demand, (3) implementation, (4) practicality, (5) adaptation, (6) integration, (7) expansion, and (8) limited efficacy testing [12]. These areas were a foundation upon which we supplemented additional properties relevant to technology-based interventions.

Dimensions Overview

Table 1 summarizes feasibility dimensions for technology-based interventions with associated guiding questions and sample evaluation criteria. We use the term "dimension" to describe aspects of feasibility, while evaluation criteria refer to different types of information to address the guiding questions. These criteria include relevant constructs or properties for qualitative inquiry, specific measured parameters and outcomes, and potential analysis tools or frameworks. Each dimension is discussed within the subsections below, including literature examples to illustrate specific points. These dimensions encompass clinical, technical, and commercial properties, but are not exhaustive or prescriptive. Rather, it is a starting point for determining pertinent issues and research questions on an individual basis, which may be addressed in a single study or through the course of multiple studies. As some dimensions are highly interrelated and evaluation criteria may be relevant across multiple dimensions, readers are encouraged to select dimensions and criteria based on the unique context and maturity of their intervention, providing appropriate justification.

XSL•FO
RenderX

Table . Proposed feasibility dimensions for technology-based interventions with associated guiding questions and sample evaluation criteria.

Dimension	Guiding question	Sample evaluation criteria
Technical performance[a]	To what extent does the performance of a technology-based intervention satisfy its requirements and meet its intended goals over a specified period of time in a given context?	• Accuracy • Responsivity and responsiveness • Reliability • Sensitivity • Error resolution • Maintenance and repair
Safety	To what extent is a technology-based intervention associated with risk of harm?	• Frequency and severity of adverse events • Perceived safety • Risk management framework
Tolerability	To what extent can a technology-based intervention be used without experiencing unacceptable discomfort?	• Device comfort and fit • Serial symptom assessment • Ecological momentary assessment • Use sessions terminated due to discomfort
Acceptability[b]	To what extent is a technology-based intervention judged by users and other interest holders as suitable, appropriate, or satisfactory towards addressing its intended aim(s)?	• Satisfaction • Perceived appropriateness • Interest or intention to use • Recommendations to others
Demand[b]	To what extent is a technology-based intervention likely to be used by its intended users for its intended purpose?	• Engagement • Sustained use and abandonment • Perceived value • Interest or intention to use • Accessibility • Availability of alternatives
Usability[c]	To what extent does a technology-based intervention enable users to accomplish its stated goal(s) effectively, efficiently, and to their satisfaction?	• Usability attributes • Performance measures (eg, tasks completed, errors) • Behaviors or affective responses (eg, observed or verbalized) • Perceived usability • Degree of exertion, demand, or workload
Adaptability[b]	To what extent can a technology-based intervention be modified to meet the needs of diverse users and use contexts?	• Frequency, extent, and impact of device modifications • Changes in user experience or impact resulting from modifications • Protocol deviations • Device fit assessments • User settings and configuration • Accessibility features
Practicality[b]	To what extent can a technology-based intervention be used in its intended setting(s) given resource constraints such as space, equipment, personnel, and time?	• Space required for use and storage • Duration and ease of equipment set-up and take-down • Compatibility with existing equipment • Personnel and training requirements
Implementation[b]	To what extent can a technology-based intervention be deployed and used as intended in environments with varying levels of control?	• Adherence • Fidelity • Contexts of use • Implementation barriers and facilitators

XSL•FO
RenderX

Dimension	Guiding question	Sample evaluation criteria
Integration[b]	To what extent can a technology-based intervention be incorporated into existing systems?	• Perceived fit within organizational capacities and workflow • Fit within organizational culture • Perceived fit within daily routine • Sustainability
Impact[b]	To what extent does a technology-based intervention show promise in eliciting positive changes for its target population?	• Changes in clinical measures • Appropriateness of measures • Maintenance of changes • Perceived benefits • Caregiver burden • System efficiency
Ethicality	To what extent is a technology-based intervention aligned with ethical values?	• Bioethics (eg, Principlism) • Technology ethics • Prognosis Research Strategy framework • Model for the Ethical Evaluation of Socio-Technical Arrangements framework • Reflective questioning • Socratic approach
Commercial viability	To what extent does a technology-based intervention show promise towards being economically viable for commercialization?	• Production and operation costs • Cost-effectiveness • Economic modeling • Product-market fit

Technical Performance

Users of technology-based interventions rely on systems that perform consistently to achieve their goals. Technical flaws and system errors are frequently cited as barriers to technology adoption [27,28]. Technical performance examines how well a technology-based intervention satisfies its functional requirements and meets its intended goals over a specified time period in a given context. This reflects aspects of technology performance evaluation from systems and design engineering [29]. Whereas usability focuses on interaction between the user and the technology, technical performance is more concerned with the function of the technology itself.

In systems engineering, technical performance measures refer to measurable qualities that determine whether a system satisfies key technical requirements [26]. Relevant technical performance measures for a project depend on the type of technology and its intended functions. Table 2 summarizes select technical performance measures with examples from interventions in disability and rehabilitation. While these properties may be initially addressed during intervention development, the feasibility stage extends performance evaluation to real-world contexts to identify features requiring refinement [4].

XSL•FO
RenderX

Table . Select technical performance measures relevant to technology-based interventions in disability and rehabilitation.

Measure	Definition[a]	Example
Accuracy	The closeness of agreement between an observed value and an accepted reference value (ground truth).	In a feasibility study of a sensor motion detection system for fall prevention in hospitalized older adults, Ferrari et al [30] assessed the accuracy of sensor output data by establishing its correlation with observer ratings of participant movement from video recordings.
Responsivity and Responsiveness	How well a system adjusts to commands or cues promptly.	Fang et al [31] evaluated the responsiveness of a Rotational Orthosis for Walking with Arm Swing system by assessing whether a measurable movement was produced that was close to the user's target joint trajectory.
Reliability	Likelihood of a system performing its intended function without error for a given period of time under a specified set of conditions.	Awad et al [32] assessed the reliability of the ReWalk ReStore soft robotic exosuit by measuring device malfunctions during usage.
Availability	Likelihood that a system is operational at a given point in time under a given set of environmental conditions.	Marschollek et al [33] assessed the technical feasibility of a smart home monitoring system by measuring the downtime of installed systems in relation to their up-times.

[a]According to American Society for Quality [34].

Safety

Several authors identify safety as a critical component of intervention feasibility, and it is among the most common measures reported by feasibility studies in rehabilitation research [20]. Safety refers to the risk of harm imposed on intervention recipients or others affected by the intervention [35]. In some cases, safety is closely related to technical performance. "Design for safety" is an approach whereby products and systems are purposefully engineered to prioritize the safety of people who interact with them, with specific features designed to proactively address safety risks [36]. For example, a robotic exoskeleton could be made "fail-safe" by defaulting into a safe system state upon detecting an operational error to prevent injury caused by excessive force applied to a limb [37]. Thus, intervention safety may depend on appropriate technical performance.

Safety is typically operationalized as the extent to which an intervention is associated with adverse events, such as injuries or disease exacerbations. Measuring the frequency and severity of adverse events provides information about the risks and potential harm of an intervention in a given setting. Defining adverse events prior to commencing evaluation helps ensure relevant incidents are captured and properly managed. For technology-based interventions, researchers may wish to evaluate users' ability to complete tasks safely while using the device. This can be accomplished through behavioral observation and coding safety incidents and near misses. Perceived safety from the perspective of users and members of their support system may also provide valuable insight, particularly for devices that involve loss of control (eg, robotic exoskeletons), or those that target vulnerable populations like people with dementia.

Wang et al [38] provide an example of multidimensional safety evaluation in a study evaluating contact sensors for powered wheelchairs among older adults with dementia [38]. A multiple single-subject mixed methods design was used, involving quantification of safety-related incidents observed by the investigator during testing with older adults in nursing homes, and qualitative exploration of perceived safety via debrief interviews with participants and focus groups with staff. Investigator observations showed that while the sensors successfully detected most obstacles, minor design faults (eg, gaps between panels) led to some performance errors, and more sensors were needed for complete environmental coverage to minimize injury risk. The qualitative analysis revealed that resident and staff perceptions of safety were mixed, leading the authors to identify a need for further safety improvements by increasing sensor reliability and coverage [38]. This study demonstrates the close relationship between safety and technical performance and underscores the importance of assessing and redesigning for safety when developing technology-based interventions for people with cognitive impairment.

Tolerability

Related to safety is the concept of tolerability. The US Food and Drug Administration defines tolerability as the degree to which adverse effects can be tolerated by participants [35]. For technology-based interventions, we conceptualize tolerability as the degree to which users can engage with the intervention without experiencing unacceptable discomfort. Tolerability is particularly important for interventions that are associated with discomfort, such as neuromodulation [39], brain-computer interfaces [40], and prosthetic devices [41], although it may also be relevant for other types of interventions that serve populations with sensitivities (eg, chronic pain, headaches, and autism spectrum disorder). It has important implications for other dimensions such as acceptability, usability, demand, implementation, and ultimately adoption. For example, device fit and comfort are critical factors in long-term use and abandonment of upper limb prosthetics [41]. Assessing tolerability can also help determine appropriate treatment dosage.

XSL•FO
RenderX

Self-report measures are useful to capture side effects or changes in participants' condition while interacting with the intervention. For example, symptoms or discomfort can be rated before, during, and after intervention use with condition-specific instruments, or generic subjective rating scales (eg, Visual Analog Scale, Visual Rating Scale, Numeric Rating Scale, and Borg Scale) [42]. Validated device-specific comfort questionnaires are also available for some interventions, such as wheelchairs [43] and wearable computers [44]. When testing interventions in real-world settings, ecological momentary assessment (EMA) can be a useful approach. EMA involves repeatedly sampling participants' current condition in real-time within their natural environment [45]. Technology-based interventions offer unique opportunities to embed EMA (eg, mobile app prompts), allowing teams to gather detailed and context-rich data on participant discomfort, stress, fatigue, and frustration. By assessing users' condition at various time points in everyday environments, EMA can provide valuable insight into factors that influence tolerability and help monitor cumulative stress from long-term use.

Some objective methods of assessing comfort have been described. Physiological measures (eg, heart rate, skin conductance, and muscle activity) can identify adverse stress responses associated with the intervention. Pressure sensors and movement analysis techniques have been used to capture compensatory movements that indicate discomfort [42]. Finally, observational analysis of participants' behavior during the intervention can help identify signs of discomfort, fatigue, or frustration [42].

Intervention usage (eg, frequency, duration, or maintenance) is sometimes reported as a measure of tolerability by indicating whether demands are appropriate, or if participants avoid the intervention due to discomfort. In such cases, it should be clear why usage metrics are framed as measures of tolerability rather than engagement or adherence, and how information about tolerability is inferred. For example, a study on a smart glasses social communication aid for people with autism assessed tolerability based on participants' ability to wear the device during coaching sessions [46]. The authors were interested in how well participants tolerated the smart glasses due to their sensory and cognitive challenges, rather than whether they chose to use the smart glasses (ie, engagement) or comply with a prescribed treatment plan (adherence).

A good example of tolerability evaluation can be found in a case study from Ryan et al [47] on the integration of transcranial direct current stimulation (tDCS) into a pediatric inpatient brain injury rehabilitation program [47]. Individual session tolerance was monitored using pre- and postratings of common tDCS side effects (eg, headache, fatigue, itching, and tingling). A postintervention Tolerability Questionnaire [48] was also used to assess tolerance across the study period, which involved the participant ordering a list of common activities from most to least enjoyable (eg, playing games, watching TV, going to the dentist, and getting a needle), and rating their tDCS experience relative to those activities. With minimal symptom exacerbation within sessions and a favorable rating of tDCS relative to other activities, the authors concluded that tDCS was tolerated well by the participant and could be incorporated into inpatient rehabilitation [47].

Acceptability

Acceptability is a foundational aspect of feasibility that describes how individuals involved in an intervention react to it [12]. While empathizing with users to understand their needs and preferences is a vital step in designing an intervention, perspectives may change once users actually experience it, underscoring the need for user involvement throughout development and evaluation [4]. According to Nielsen [49], technology is accepted when it satisfies the needs and requirements of its users and other interest holders. Thus, acceptability can be defined as the extent to which users of a technology-based intervention and other interest holders judge it to be suitable, appropriate, or satisfactory for addressing its intended aim. Acceptability is an important predictor of use behavior that precedes technology adoption [25]. Ultimately, successful implementation relies on procedures that are acceptable and meet the needs of individuals who deliver, receive, or otherwise engage with an intervention [11,50].

Efforts have been made to better understand and operationalize acceptability. Several theories have been proposed to explain technology acceptance, the most prominent of which include Technology Acceptance Model (TAM and TAM2), Combined Technology Acceptance and Theory of Planned Behavior Model, Motivational Model, and Innovation Diffusion Theory [51]. Combining principles from many models, the Unified Theory of Acceptance and Use of Technology (UTAUT and UTAUT2) posits that acceptance and intention to use technology are dependent on one's beliefs about performance expectancy (utility toward one's goals), effort expectancy (ease of use), and facilitating conditions (organizational and technical support), as well as subjective norms regarding their use of the technology, all of which are moderated by gender, age, experience, and voluntariness of use [52]. For health care interventions, Sekhon et al [50] developed the Theoretical Framework of Acceptability, which conceptualizes acceptability through 7 constructs: (1) affective attitude, (2) burden, (3) perceived effectiveness, (4) ethicality, (5) intervention coherence, (6) opportunity costs, and (7) self-efficacy [50]. It is clear that the acceptability of technology-based interventions in health care is complex and multidimensional, with several interacting factors related to beliefs and attitudes that overlap with other feasibility dimensions.

Satisfaction is considered an indicator of acceptability that can be measured quantitatively using questionnaires [50]. Sekhon et al [50] developed the Theoretical Framework of Acceptability Questionnaire, a general measure reflecting the Theoretical Framework of Acceptability constructs that can be adapted for various health care interventions [53]. Other generic satisfaction scales include the Client Satisfaction Questionnaire [54], Acceptability of Intervention Measure [55], and Intervention Appropriateness Measure [55]. For technology-based interventions, the TAM questionnaire evaluates acceptance based on perceived usefulness and ease of use [56]. Textbox 3 highlights acceptability and satisfaction questionnaires relevant to technology-based interventions [4]. Comprehensive reviews

XSL•FO
RenderX

of satisfaction and acceptability tools for assistive technologies [57] and mobile health programs [58] are also available.

Textbox 3. Sample acceptability and satisfaction questionnaires relevant to technology-based interventions in disability and rehabilitation.

Generic health care intervention measures

- Theoretical Framework of Acceptability Questionnaire [53]
- Client Satisfaction Questionnaire [54]
- Acceptability of Intervention Measure [55]
- Intervention Appropriateness Measure [55]

Generic technology measures

- Technology Acceptance Model Questionnaire [56]
- Unified Theory of Acceptance and Use of Technology Questionnaire [59]

Assistive technologies

- Quebec User Evaluation of Satisfaction with Assistive Technology 2.0 [60]
- Almere Technology Acceptance Questionnaire [61]
- Remote Monitoring Satisfaction Survey [62]
- Satisfaction with Prosthesis Questionnaire [63]
- Satisfaction with Amplification in Daily Life Questionnaire [64]

Therapeutic technologies

- Physiotherapy Mobile Acceptance Questionnaire [65]
- Exergame Enjoyment Questionnaire [66]
- Virtual Rehabilitation User Satisfaction Evaluation Questionnaire [67]
- Immersive Experience Questionnaire [68]
- Questionnaire for User Interaction Satisfaction [69]

Telehealth and mobile service delivery

- Telemedicine Satisfaction Questionnaire [70]
- Telemedicine Satisfaction and Usefulness Questionnaire [71]
- Telehealth Satisfaction Scale [1-3]
- Service User Technology Acceptability Questionnaire [72]
- Website Satisfaction Scale [73]
- Digital Health Acceptability Questionnaire [74]

Although satisfaction questionnaires are simple quantifiable measures, qualitative methods often elicit a deeper understanding of user experiences and acceptability at the feasibility stage [11,75]. Interviews and focus groups can be conducted after users have tested an intervention to gather perspectives regarding appropriateness of the intervention and delivery approach to inform iterative refinement. Qualitative inquiry is particularly valuable to probe the unique and nuanced aspects of technology acceptability in the field of disability and rehabilitation, such as social implications of observable assistive technologies across use contexts.

Importantly, intervention maturity and stage of development influence acceptability. For instance, early stages may involve low-fidelity intervention prototypes that users trial on a single occasion and must imagine the experience of living with in real-life circumstances. Conversely, high-fidelity prototypes in later stages allow users to trial the intervention in real-world environments, over longer periods, and in more diverse contexts. Acceptability should thus be viewed as a dynamic attribute that warrants consideration throughout evaluation.

Demand

Technology innovations in disability and rehabilitation are designed to address unmet needs by providing a new solution or service not available through conventional means. However, the likelihood that an intervention will be used to serve this function cannot be fully understood until in the hands of its target population. Based on interaction and experience with a prototype, demand evaluates the likelihood that a technology-based intervention will be used by intended users [12]. Demand is closely tied to acceptability, as users are more likely to engage with an intervention that is deemed suitable or

XSL•FO
RenderX

satisfactory. By estimating future use, demand also has implications for the commercial viability of technology-based interventions.

A relatively straightforward indicator of demand is user engagement. Cavanaugh [76] describes engagement as efforts by users to start and continue with an intervention. Engagement differs from adherence in that it implies an active and volitional choice to interact with an intervention in a meaningful way, rather than passive compliance with a prescribed plan. Therefore, it reflects the extent to which a technology-based intervention is likely to be used, particularly for those that involve free use in uncontrolled contexts, such as home-based exergames, virtual reality programs, and assistive devices. Evidence across various types of technology-based interventions shows that user engagement is an important predictor of future use and intervention success [77]. In digital health research, engagement has been conceptualized as a multidimensional construct involving observable behavior (ie, usage parameters) and subjective experience characterized by attention, interest, and affect [78]. Behavioral usage parameters relevant to gauging demand include the frequency, duration, and depth (ie, variety or intensity) of usage [78]. For interventions that use websites, mobile apps, gaming systems, or other digital devices, these metrics may be captured automatically through system logs. The User Engagement Scale measures engagement experience based on aesthetic appeal, focused attention, novelty, perceived usability, felt involvement, and endurability [79].

Engagement should ideally be monitored longitudinally, as diminished use and abandonment are common in digital health and assistive technology interventions [80,81]. While engagement may be high initially, it often tapers over time as novelty fades. Considering this "law of attrition," Eysenbach [81] recommends analyzing determinants of engagement with eHealth programs and characteristics of subgroups that maintain and discontinue engagement [81]. Feedback from participants regarding perceived value of the intervention and interest in continuing its use in their routine practice or daily activities can help understand demand. Qualitative inquiry is valuable to obtain a nuanced understanding of engagement by addressing questions such as *how*, *why*, and *when* users choose to engage with the intervention, and to appreciate psychological or social experiences of interacting with the intervention. This can help drive intervention refinement to promote more meaningful and sustained use, ultimately increasing demand.

Usability

Rehabilitation and assistive technology interventions aim to provide a useful and *usable* tool to accomplish the goal of optimizing function and reducing disability. According to the International Organization for Standardization (ISO) 9241-11:2018, usability refers to how well a system, product, or service can be used by its target users in a specific context to achieve their goals with effectiveness, efficiency, and satisfaction [82]. Usability is a common area of evaluation for rehabilitation and assistive technologies with important implications for their acceptance, adoption, and effectiveness [83,84]. It is a key component of feasibility studies that is particularly important for iteratively refining intervention features [4].

The ISO emphasizes the multidimensional nature of usability, highlighting effectiveness, efficiency, and satisfaction as key elements [82]. Similarly, Nielsen [85] identifies 5 usability heuristics in his textbook Usability Engineering: (1) learnability, (2) efficiency, (3) memorability, (4) errors, and (5) satisfaction. Building on these conceptualizations, Quesenbery [86] coined the 5E's of usability for user experience design: effectiveness, efficiency, engagement, error tolerance, and ease of learning. Table 3 summarizes these usability attributes. While not exhaustive, these attributes are a useful starting point for evaluating usability.

XSL•FO
RenderX

Table . Usability attributes and definitions.

	Usability attributes	Definitions
ISO Standard 9241-11:2018 [82]	Effectiveness	Accuracy and completeness with which users achieve intended goals or outcomes
	Efficiency	Resources used (eg, time, human effort, cost, and materials) relative to results achieved
	Satisfaction	Extent to which the user's physical, cognitive, and emotional responses that result from the use of a system meet the user's needs and expectations
Nielsen's Usability Engineering [85]	Learnability	How easily a technology can be learned such that the user can rapidly begin to use the technology to perform the necessary tasks
	Efficiency	How well the user can achieve a high level of productivity with minimum resource requirements (eg, time, money, effort)
	Memorability	How easily the user can remember how to use the technology such that they can return to the product easily with minimal relearning after a period of disuse
	Errors	The extent to which errors are minimized and catastrophic errors are avoided
	Satisfaction	How pleased the user is with their experience of the technology
Quesenbery's 5E's of Usability [86]	Efficiency	The speed with which the user can complete work accurately using the technology
	Engaging	How pleasant, satisfying, or interesting it is for the user to interact with technology
	Error tolerance	How well the technology prevents errors and helps the user recover from errors that occur
	Easy to learn	How well the product supports the user in initial orientation and deeper learning

Design engineering practices provide various approaches for evaluating usability. According to Nielsen [85], usability can be tested directly through behavioral measures (what people do) or indirectly assessed based on attitudinal beliefs of the user (what people think). Direct methods of usability testing consider how technology is actually used by measuring behavior or performance [25,85]. This can involve quantifiable performance metrics or qualitative methods such as participant observation and/or review of materials produced by the user [25]. Relevant performance measures depend on goals of the intervention and may include accuracy, task completion time, and errors (recoverable and unrecoverable) [85]. Think-aloud protocols, which involve users verbalizing their thoughts while interacting with technology, are a valuable strategy to identify usability problems with small samples. Finally, observational analysis techniques involve coding participant behavior while using the technology [85].

Indirect or attitudinal methods of usability evaluation explore user perspectives regarding their experience interacting with technology, which can be done through questionnaires, interviews, focus groups, or other methods [25,85]. Some argue these measures of user attitudes reflect technology acceptability rather than usability per se [25]. Nevertheless, subjective experience questionnaires are the most common method of usability evaluation across assistive and rehabilitation technology intervention studies [87,88]. Textbox 4 lists usability questionnaires for technology-based interventions. Qualitative feedback through posttesting interviews or focus groups is recommended to gain a deeper understanding of why usability problems exist and how they should be addressed [25,89].

The most appropriate usability evaluation methods depend on project context and intervention maturity. Available options also depend on the context in which the intervention is studied, for example, under natural settings in real-world target environments, scripted use within a controlled laboratory environment, or only perceptions and expectations about hypothetical use [89]. Combining direct and indirect measurement often provides a more comprehensive understanding of usability by not only identifying apparent usability issues but also exploring why they exist and how they can be resolved [25]. Early usability studies might benefit most from think-aloud, observation, and focus group methods within scripted use contexts to gather rich data targeting specific issues with small sample sizes [25]. At the feasibility stage, real-world use is important, and usability evaluation might involve a combination of performance measures, observation, questionnaires, and interviews [4]. For larger and longer-term outcome studies, performance measures are likely most

XSL•FO
RenderX

informative [25]. Readers are directed to Liu et al [25] for a thorough discussion of usability measurement, including examples from rehabilitation and assistive technology interventions.

Textbox 4. Example usability questionnaires for technology-based interventions.

- System Usability Scale [90]
- Usefulness, Satisfaction, and Ease of Use Questionnaire [91]
- NASA Task Load Index [92]
- Telehealth Usability Questionnaire [92]
- mHealth Application Usability Questionnaire [93]
- Usability Scale for Assistive Technology-Wheeled Mobility [94]
- Usability Scale for Assistive Technology-Computer Access [95]
- Accessible Usability Scale [96]

Adaptability

Technology-based interventions for disability and rehabilitation are characterized by diversity in user populations and use settings [4]. Device modifications or personalized intervention features may therefore be needed to accommodate individual users. Adaptability is the degree to which a technology-based intervention can be modified to meet the needs of diverse users and use contexts [12]. Evaluating adaptability can help define the scope of the target population, identify overly rigid features, and determine opportunities for increased flexibility to enable personalization.

Adaptability encompasses the frequency, extent, and reasons for intervention modifications, as well as any unique user needs that could not be accommodated through modifications. Adaptable interventions are expected to achieve similar outcomes despite changes in features or delivery format to accommodate individual needs [12]. Thus, it is important to assess the impact of modifications, including whether implementation processes, user experiences, and outcomes are consistent across modified versions [11]. Addressing adaptability also provides an opportunity to test the processes that enable personalized modifications, such as fit assessments, trial periods, technical support, and professional follow-up.

The importance of considering the adaptability of early prototypes is evident in a study from Pellichero et al [97], which evaluated the usability and usefulness of a blind spot sensor system for powered wheelchairs [97]. Although customization of sensor mounting, feedback configuration (ie, sounds, lights, or vibration), and sensor parameters (detection distances) were available through an associated smartphone app, the study was conducted with a standardized set-up preventing customization. The authors subsequently postulated that insufficient customization may have limited participants' use of the system during the 2-month home trial period and influenced perceived usability and usefulness. Customization of the sensor system according to individuals' abilities, preferences, and environment was thus recommended for future research and implementation [97]. This example illustrates the interrelatedness of feasibility dimensions, highlighting how adaptability has important implications for evaluating other aspects of intervention feasibility (eg, usability and demand). It also demonstrates how allowing opportunities for customization and assessing subsequent modifications during early-stage evaluations can help optimize interventions to accommodate diverse user needs.

Practicality

The best of interventions will not be successful unless they are practical within user and organizational capacities. Practicality refers to how well an intervention can be used in its intended setting given resource constraints like space, equipment, personnel, and time [11,12]. Literature across an array of technology-based interventions consistently highlights practical factors as important barriers to clinical implementation [98-100]. Disability and rehabilitation interventions may be deployed in hospitals or care centers, clinics, homes, or other community settings that have variable resource capacities, making practicality an important consideration.

Physical factors related to practicality include space and equipment needs for intervention use and storage [98,100]. System interoperability and compatibility with existing equipment and infrastructure is also important. For example, whether an exergame deployed for home use is suitable for conventional recreational gaming systems and whether it successfully integrates with commercial wearable heart rate monitors. Personnel required to facilitate intervention use should be assessed, including the level of training and expertise needed [98,101]. Time limitations are a well-documented barrier to implementation of rehabilitation technologies, which can encompass the duration of training, set-up, use, and take-down [98,101].

Implementation

To understand whether an intervention will work, it is important to explore the process of how it is delivered and received [102]. The implementation dimension evaluates how well a technology-based intervention can be deployed and used as intended in target settings with varying levels of control. This is important given the diversity of contexts in which technology-based disability and rehabilitation interventions are used [4]. Examining implementation helps understand how well the intervention can be delivered and what supports are needed to enable successful delivery [11]. It can also inform the training and support required for users to learn and apply the technology appropriately. The context of use, within a controlled lab

XSL•FO
RenderX

environment, home, or community setting, is an important consideration to determine the conditions under which the intervention is likely to succeed and identify features requiring adaptability [4,11,102].

Process evaluations assessing implementation describe the quality or integrity with which an intervention is delivered by monitoring adherence and fidelity [102]. Adherence is traditionally defined as the extent to which the behavior of an intervention recipient corresponds with the prescribed program [103]. Whereas we describe *engagement* above as an active choice to interact with the intervention in a meaningful way, we use the term *adherence* in reference to whether participants use the intervention as prescribed in its delivery [76]. Adherence is a common measure among feasibility studies of rehabilitation interventions that can be quantified via self-report or observation as the proportion of intervention components (eg, appointments, training sessions, modules, and tasks) completed by participants relative to those prescribed [20]. These measures, which translate well to technology-based interventions serving therapeutic or service delivery functions and may be captured through automated system logs, can help infer the burden of intervention demands and appropriateness of procedures [19]. For assistive technologies, adherence is poorly defined [104] and infrequently reported [105]. In reporting guidelines for assistive technology outcomes, Tuazon and Jutai [105] identify frequency, duration, and continuance (or discontinuance) of use as measures of adherence. We argue that these usage metrics reflect adherence when the intervention is used *as* recommended, but may be more appropriately viewed as measures of engagement in conditions of free voluntary use. Given the apparent similarity and overlap between adherence and engagement, we encourage authors to thoughtfully consider and rationalize their application.

Fidelity refers to whether the intervention is delivered as intended [102]. Self-report checklists and/or observational methods may be used to assess the degree to which intervention delivery and use align with key features of the intended design. This includes components or ingredients of the intervention and the level of competence demonstrated by intervention providers [11], which can help determine the training required to achieve proficiency and fidelity. A benefit of technology-based interventions is the possible integration of screen, audio, or video recordings that capture user behavior, enabling assessment of fidelity or adherence. For interventions that require complex technology operation, user perceptions regarding the ease of achieving fidelity may be informative and can be assessed using the Agency for Healthcare Research and Quality Feasibility Assessment for Wide-Scale Implementation (Criterion 2) [106]. These approaches to fidelity assessment work well for technology-based interventions with therapeutic or service delivery functions, for which treatment theory can be readily defined and interventions can be manualized, allowing active ingredients to be monitored [107]. In a provocative discussion, Lenker et al [108] highlight historical inadequacy of fidelity reporting in assistive technology research, which they attribute to poorly defined treatment protocols, temporal delays between device use and evaluation, and lack of available measurement tools to capture intervention attributes. To strengthen the quality of assistive technology research, they recommend greater inclusion of treatment theory, better specificity in intervention characterization, and routine fidelity monitoring [108].

The distinction between intervention and study feasibility is particularly blurred within the implementation dimension. For example, the fidelity by which clinicians deliver a tele-rehabilitation intervention and the extent to which recipients adhere to the program will likely have implications for both the success of the intervention itself (ie, whether benefits are achieved by recipients), as well as the scientific integrity and outcome of research studies evaluating the intervention. A clear rationale for evaluating implementation should be specified based on development stage (eg, refining intervention or study procedures).

Integration

Organizational support and alignment with system-level priorities are frequently cited as facilitators to technology implementation in disability and rehabilitation practices [98-101]. The integration dimension considers the “fit” of a technology-based intervention in terms of how well it can be integrated into existing systems within its target settings [12]. A focus on system-level integration is important as it likely affects implementation quality and eventual technology adoption. Importantly, there may be multiple systems into which a technology-based intervention must integrate. For example, therapeutic exergames may be initially introduced by therapists within a clinical setting and subsequently integrated into individual or family routines at home for continued practice. Assessing integration across all relevant systems can help resolve incongruencies and proactively enact strategies that support technology transfer.

Several system-level factors have been reported in the literature that influence integration of technology-based interventions in disability or rehabilitation practice. Reviews identify a lack of intervention fit within organizational capacities and workflows as important barriers to technology adoption, which may include referral processes [100], scheduling [98,100], service delivery models [100], and length of therapy sessions [98,100]. Organizational culture and policy, particularly regarding technology in practice, is another important factor that can facilitate or hinder integration [99,100].

The Agency for Healthcare Research and Quality Implementation Feasibility Assessment evaluates integration factors by having service providers rate intervention fit with organizational capabilities (Criterion 1) and alignment with policies and incentives (Criterion 2) [106]. The Program Sustainability Assessment Tool can be used to assess organizational structures and processes that promote sustained integration [109]. From the perspective of clients and families, the ease of integrating a technology-based intervention in their home environment and daily routine is a priority [110].

Impact

Performance expectancy, or perceived usefulness, is a leading determinant of acceptance and use of technology-based interventions among therapists, caregivers, and people with disabilities [101,111,112]. The impact dimension evaluates the

XSL•FO
RenderX

promise or potential that a technology-based intervention shows in eliciting positive change for its target population. This dimension has been renamed from *limited efficacy* described by Bowen et al [12] to recognize the diverse aims of technology-based interventions and methods through which their benefits may be evaluated. Although the focus of feasibility research is process rather than outcomes, this stage is an opportunity to gather preliminary evidence on participant responses to the intervention [11,12,18,19].

Various research designs involving quantitative, qualitative, or mixed methods approaches may be used at the feasibility stage to explore potential impacts of technology-based interventions. Preliminary effects can be measured using descriptive observational studies, case reports or series, single-subject designs, interrupted time series designs, or one-group pretest-posttest designs [4]. Outcomes of interest for care recipients include symptoms, functional performance, participation, mobility, quality of life, and other psychosocial constructs [57]. The purpose of evaluating impact during the feasibility stage is not to definitively establish effectiveness but rather to test assessment procedures that accompany the intervention, evaluate appropriateness and sensitivity of outcome measures, and inform features of intervention design including duration and dosage [11]. Qualitative feedback is essential to accomplish these goals by exploring user perceptions regarding perceived benefits and the meaningfulness of outcome measures [75].

For care providers, the usefulness of technology in supporting care is an important driver of adoption [101], indicating that perceived job performance or quality of care are relevant measures of impact. For technologies designed to reduce therapist workload, such as autonomous robots and exoskeletons, impact may also be measured in subjective task effort or stress and burnout, which are common among care providers [113]. Alleviating caregiver burden is a target of some interventions for which impact may be investigated using the Caregiver Assistive Technology Outcome Measure [114]. System-level impacts are also relevant to technology-based interventions, which may include measures of resource use, service efficiency, and access to care [115-117].

Ethicality

Ethical concerns are barriers to adoption and commercialization across a variety of technology-based approaches in disability and rehabilitation [118-120]. Common ethical concerns include challenges related to privacy, security, equity, stigma, autonomy, and power [118-120]. There are calls for more proactive consideration of ethics during development, evaluation, implementation, and policymaking processes for technology-based interventions [120]. The ethicality dimension considers the degree to which a technology-based intervention aligns with values of biomedical and social ethics. Ethical evaluation during feasibility studies can help anticipate and address concerns that may affect eventual adoption or policy [4].

Ethical concerns occur in the field of disability and rehabilitation when there is conflict between two or more biomedical or societal values. For example, protecting the safety of older adults using smart home monitoring technologies while maintaining personal privacy [121]. Applied ethics frameworks outline considerations for identifying and navigating these conflicts. Principles of bioethics and technology ethics may be useful for identifying value conflicts among technology-based interventions. Bioethics, concerned with ethical issues related to biomedicine and health care, includes 4 primary principles: (1) autonomy (personal choice), (2) beneficence (provision of benefit), (3) nonmaleficence (avoidance of harm), and (4) justice (fairness and equity) [122]. Technology ethics address issues related to technological advancements; relevant concepts overlap with bioethics and include human welfare, ownership and property, privacy, freedom from bias, universal usability, trust, autonomy, informed consent, accountability, identity, calmness, and environmental sustainability [123].

Based on these concepts, ethical domains relevant to the intervention can be compiled in consultation with users and other interest holders [121]. As the intervention is trialed during feasibility testing, conflicts across these domains can be monitored through discussion with users and reflective questioning about how the technology is used and any unexpected secondary effects [121]. A Socratic approach to questioning can be used, which poses morally relevant questions to highlight value issues related to health technologies [124]. The Model for Ethical Evaluation of Sociotechnical Arrangements (MEESTAR) is another tool to guide dialog on ethical analysis, designed specifically for assistive technologies [125]. It comprises seven ethical dimensions (care, autonomy, safety, justice, privacy, participation, and self-conception) across four levels (harmless, ethically sensitive with possibility of compensation, extreme ethical sensitivity requiring monitoring, opposition of use) and three perspectives (individual, organizational, society). Key questions are provided to support ethical discussion across the seven dimensions.

An example of ethical evaluation during feasibility testing can be found in a study from Kernebeck et al of an app- and sensor-based assistive technology intervention for caregivers of people with dementia [126]. In addition to exploratory outcome measures, the study involved a process evaluation of implementation, mechanisms of impact, and intervention context, including ethical implications. The ethical evaluation was a workshop based on MEESTAR conducted after the intervention with the study team, interest holders, and advisory board members. The authors highlight how this process supports the design of their intervention to reflect appropriate ethical orientation considering the values of independence, privacy, and safety from multiple perspectives [126].

Commercial Viability

Cost and affordability are priorities in decisions regarding rehabilitation and assistive technology interventions from the perspective of clinicians, care recipients, families, health care organizations, and policymakers [98,99,127,128]. Yet, economic factors are infrequently and inadequately captured in research on these interventions [129]. The commercial dimension evaluates the degree to which a technology-based intervention shows promise toward being economically viable for commercialization. While often reserved for later

XSL•FO
RenderX

implementation stages, gathering data on economic considerations at the feasibility stage can help refine intervention features to better fit the market, be more cost-efficient, and support commercialization.

Various economic evaluation methods are described in the complex intervention and health technology assessment literature. Cost-utility and cost-effectiveness analyses compare the costs and health outcomes of a new intervention against a comparator (eg, current standard of care), but use different measures of health outcome [130]. Cost-effectiveness analyses employ natural units of clinical effect, such as life-years or cases of disability, while cost-utility analyses, a subtype of cost-effectiveness analysis, use generic measures of health status reflecting both morbidity and mortality (eg, disability-adjusted life-years) [130]. Cost-benefit analyses express costs and benefits in financial terms and aim to capture a broader range of economic costs, including those not directly related to health outcomes (eg, cost of travel to care) [130]. Cost-utility analyses are favored in policy decision-making regarding health technologies because they allow comparison across conditions and intervention approaches [128].

The comprehensive economic evaluations described above may not be appropriate at the feasibility stage. During early development and testing of health technologies, Sculpher et al [131] recommend that economic evaluation should focus on defining and understanding the costs of existing practice that the new technology may help alleviate, and exploratory economic modeling of potential cost-effectiveness using data from existing studies or limited prospective data collection [131]. Relevant costs to consider for assistive and rehabilitation interventions include device production, assessment and training services, staffing, and servicing or maintenance. In terms of economic value, cost savings can be characterized through factors such as improved health outcomes, reduced costs of care, increased productivity, and decreased caregiver burden [129]. These exploratory economic feasibility approaches can inform intervention refinement by helping to redesign device features using more cost-efficient methods and improve efficiency of delivery services.

Discussion

Overview

Feasibility studies are of growing importance in intervention research and frameworks are available to guide this work across health disciplines, yet none specifically address technology-based interventions, which are inherently complex and necessitate iterative development and evaluation approaches [4]. This viewpoint helps define the scope of feasibility studies for technology-based interventions and highlights considerations for this work in the field of disability and rehabilitation. Key contributions and practical uses are discussed below.

Contributions and Recommendations

Chiefly, this article is intended to support researchers and developers (in academic, clinical, or industry settings) by providing clarity on terminology in feasibility studies of technology-based interventions. Reviews of feasibility research across health disciplines have identified inconsistent use of terminology and variability in methods of evaluation [13,20]. Synthesizing concepts from feasibility literature and research on rehabilitation and assistive technology interventions, we outline various dimensions of feasibility specifically relevant to technology-based interventions and highlight potential criteria for their evaluation (Table 1). This can inform the design of comprehensive feasibility studies that reflect unique technological considerations and the complex factors that influence rehabilitation intervention outcomes. Integrating engineering practices and digital health concepts, we collated conceptual definitions and practical examples (Tables 2 and 3) to facilitate dialog between technical developers and clinical research teams. The compiled measurement instruments (Textboxes 3 and 4) can help tailor data collection approaches and tools for specific types of technology-based interventions. Ultimately, our contributions serve to harmonize terminology and evaluation methods, enable critical selection of feasibility dimensions and criteria, and facilitate interpretation and comparison across studies.

To our knowledge, this is the first attempt to consolidate information on feasibility studies specifically for technology-based interventions. While further refinement may occur in time, this work provides essential background material to support study design decisions. Those seeking to apply information in this article should be aware of general best practices for feasibility studies [10,12,17]. We recommend that teams carefully select and justify the most appropriate dimensions and evaluation criteria according to their project needs, relevant uncertainties, and field-specific considerations (Textbox 2). These decisions are influenced by various contextual factors like intervention maturity, risk profile, and setting; Multimedia Appendix 1 provides sample reflection questions to support critical decision-making. Setting *a priori* success criteria for each feasibility dimension promotes rigor within and between studies for evidence building. Importantly, failure to achieve criteria may signal the need for intervention refinement (eg, software improvements to enhance usability). The process of feasibility evaluation is thus highly iterative, whereby multiple rounds of testing may be warranted to progressively refine intervention prototypes until comprehensive success criteria are met [4]. For instance, it may be appropriate to first establish user acceptability and demand with early-stage prototypes for interventions involving technology that is expensive or difficult to produce, while high-risk interventions with potential harms or discomforts necessitate early focus on safety and technical performance.

This work is also relevant for improving alignment between research and policy on technology-based interventions. The feasibility dimensions we delineate align with and extend current practices in health technology assessment—the comprehensive review process that informs policy recommendations on adoption of new technologies in health systems [127]. While health technology assessment approaches differ between jurisdictions, there is a common shared focus on considering factors beyond only clinical evidence on safety and effectiveness [127,132]. Health technology assessment processes around the world recognize the importance of organizational integration,

XSL•FO
RenderX

economic and resource efficiency, social implications, equity, ethical ramifications, and user and public perspectives in decision-making [127,132]. These multidimensional factors and their application to technological interventions are not specifically articulated in existing feasibility literature and thus may not be considered until their implementation, after significant resources have already been invested in development and outcome evaluation. By considering these factors in the early stages of evaluation, potential issues can be proactively identified and addressed through refinement of intervention features and delivery approach, which we emphasize as a key aim of feasibility studies for technology-based intervention. In doing so, innovations can be advanced with the greatest likelihood of attaining policy support for widespread adoption to the benefit of people with disabilities or rehabilitation needs and the communities that support them.

Future Directions

The ideas in this viewpoint represent the experiences and opinions of a small authorship team. While a useful guide for research and development, it is a starting point for future work. There is a need for broader discussion and engagement among interest holders in this space to establish consensus on feasibility considerations and dimensions in this field. It is our hope that this article serves as a catalyst for such dialog. Future directions building on this work may include the development of decision aids (eg, checklists, workflows, and case examples) and reporting guidelines to ensure adequate consideration, justification, and operationalization of relevant feasibility issues during the intervention development process. Decision tools may also help guide the process of iteratively refining and advancing intervention prototypes. Methods of weighting or prioritizing feasibility dimensions could also be useful in the context of limited resources or competing priorities.

Acknowledgments

This article was written in partial fulfillment of academic requirements for a graduate-level individual reading and research course (Foundations in Rehabilitation and Assistive Technology) within the Rehabilitation Sciences Institute, Temerty Faculty of Medicine, University of Toronto. The authors wish to thank the other students from this course, Erica Dove and Chaitali Desai, for their support and feedback related to this work. The authors also thank the anonymous reviewers for their feedback, which has helped to improve this article.

Funding

No direct funding was obtained to support this work. JS received graduate scholarship funding support from the Temerty Faculty of Medicine (University of Toronto), Ontario Graduate Scholarship, and Canadian Institutes of Health Research.

Authors' Contributions

JS researched and drafted the manuscript, which was subsequently reviewed and edited in collaboration with ASH and RHW. All authors approved the final version of the manuscript prior to submission for publication.

Conflicts of Interest

None declared.

Abstract

Background: Physical inactivity significantly contributes to the rapid decline in clinical and health-related outcomes among patients undergoing hemodialysis. Exergaming may offer a safe, effective, and sustainable solution for maintaining adequate physical activity levels in these patients.

Objective: This study aims to support its clinical applicability; our aim was to examine the attitudes and expectations of health care providers regarding intradialytic exergaming (IEG) in hemodialysis care in Slovakia.

Methods: We conducted 21 individual, in-person, semistructured interviews with health care providers. Using purposive sampling, we included training assistants, nurses, nephrologists, and managers from 2 dialysis centers in Slovakia. The verbatim transcripts of interviews were qualitatively analyzed using an inductive thematic analysis approach. The identified codes and themes were further deductively categorized into the strengths, weaknesses, opportunities, and/or threats quadrants of the Strengths, Weaknesses, Opportunities, and Threats (SWOT) framework.

Results: We identified 2 strengths, 2 weaknesses, 3 opportunities, and 3 threats of IEG. Strengths included health care providers' enthusiasm and belief in the safety of IEG. Weaknesses involved concerns about the complexity of IEG and low digital literacy among patients and providers. Opportunities were seen in improving information availability and specificity, adjusting clinical culture, and tailoring exercises. Threats included skepticism about the availability of financial resources for IEG, resistance to changes in clinical practice, and issues related to patient behavior and privacy.

Conclusions: Health care providers perceived IEG as a safe and appropriate intervention for clinical practice. To improve implementation strategies, it is important to consider specific expectations regarding resource availability, as well as the technological and organizational aspects of IEG.

KEYWORDS

hemodialysis; exergaming; qualitative research; intradialytic exergaming; health care providers; physical activity

Introduction

Maintaining adequate physical activity is one of the key challenges in the self-management of patients with chronic conditions. Kidney Disease Improving Global Outcomes Clinical Practice Guideline for the evaluation and management of chronic kidney disease recommends that all patients with chronic kidney disease be advised to undertake moderate-intensity physical activity for a cumulative duration of at least 150 minutes per week, or to a level compatible with their cardiovascular and physical tolerance [1]. Insufficient physical activity in patients with chronic diseases is associated with higher rates of

XSL•FO
RenderX

hospitalization, disability, and mortality, as well as increased financial and clinical burdens on both individuals and the health care system [2-5]. Health-related complications and behavioral limitations associated with primary chronic diseases, coexisting comorbidities, and the side effects of therapeutic procedures negatively affect patients' physical activity levels [6-11]. To address these complications and limitations, various exergaming strategies have been introduced as innovative behavioral interventions aimed at reducing sedentary lifestyles and promoting physical activity among individuals with chronic diseases [12-18].

Current evidence on the clinical application of exergaming, defined as the interactive experience of playing video games that require physical exertion or movement [19], indicates beneficial effects on physical activity behaviors and overall physical functioning in patients with chronic diseases. Benefits include greater adherence to recommended daily physical activity levels, enhanced muscle strength, endurance, physical capacity, and improved postural control, balance, and motor functions [20-27]. Maintaining regular physical activity, muscle function, and overall physical conditioning is a fundamental aspect in clinical management of chronic kidney disease, particularly for patients undergoing hemodialysis [28-30]. Low levels of physical activity and their progressive decline over time in patients undergoing hemodialysis are associated with increased morbidity, higher risks of all-cause and cardiovascular mortality, and poorer disease prognosis [31-36]. Given that many of these patients experience limitations and insufficiency in performance of daily physical activity and face a high risk of protein-energy wasting, malnutrition, and dynapenia or sarcopenia [37-41], intradialytic exergaming (IEG) may serve as a well-suited and effective component of clinical behavioral interventions [42-45].

The development and implementation of clinical behavioral interventions that primarily target physical activity and exercise through exergaming technologies present a highly challenging task [46-48]. Planning, execution, and continuation of such interventions for patients undergoing hemodialysis demand a comprehensive understanding of the disease's clinical and therapeutic background, the physiological effects of exercise, and current clinical guidelines for exercise prescription [28,49]. Additionally, effective integration of technological solutions into clinical practice requires consideration of logistical, financial, legislative, and organizational factors [50,51]. From an organizational perspective, it is necessary to understand and consider the qualitative dimensions of patients' and health care providers' awareness, knowledge, expectations, skills, competencies, cognition, and attitudes toward IEG [52-57].

Therefore, the aim of our study was to explore attitudes and expectations of health care providers regarding IEG in hemodialysis care in Slovakia. As participating health care providers had no prior experience with IEG, our study did not seek to evaluate actual experiences with the intervention. Rather, it focused on health care providers' hypothetical perceptions, attitudes, and expectations concerning the potential implementation of IEG in hemodialysis care. To achieve this objective, we used the Strengths, Weaknesses, Opportunities, and Threats (SWOT) framework to analyze collected data and guide the formulation of results. The SWOT framework provides a practical approach for evaluating the factors that may influence the success or failure of a procedure by examining both internal capabilities (Strengths and Weaknesses) and external challenges (Opportunities and Threats). It organizes these factors into 4 categories: Strengths are internal assets that enhance performance indicators and support the achievement of objectives. Weaknesses refer to internal limitations that may reduce the acceptability or effectiveness of the procedure. Opportunities are external conditions or emerging trends that can be leveraged to improve outcomes or broaden impact. Threats encompass external risks or challenges that may undermine the procedure's success or sustainability. As a strategic management tool, SWOT analysis supports informed decision-making by identifying key internal and external factors, thereby facilitating the effective introduction and integration of innovative procedures into clinical practice [58-62].

Methods

Study Design

This study was part of a project investigating the acceptability and effectiveness of a 12-week progressive, individualized, supervised intradialytic resistance training intervention on muscle function among patients undergoing hemodialysis. The study was an ancillary qualitative substudy conducted within the overarching framework of project NCT03511924 (ClinicalTrials.gov) [63]. Although the intervention resulted in moderate to large improvements in muscle function, the acceptability of intradialytic exercise and the sustainability of its benefits remained low [64,65]. In the current study, we used a 2-step qualitative design to explore and categorize health care providers' attitudes and expectations regarding IEG among patients undergoing hemodialysis. In the first step, we explored health care providers' perspectives using inductive thematic analysis (guided by [66] of data collected from participants' interviews. In the second step, we deductively classified the identified codes and themes using a SWOT analysis approach (as outlined [59].

Participants

We recruited participants from 2 dialysis centers located in Slovakia. Training assistants, nurses, nephrologists, and managers were eligible to participate if they had been employed or actively involved at the dialysis center for the entire duration of the 3-month intradialytic exercise intervention and were at least 18 years of age. This criterion ensured that participants had direct experience with the implementation of intradialytic exercise in routine clinical practice and were able to provide hypothetical insights into factors influencing the initiation and implementation of IEG. Furthermore, nurses, nephrologists, and managers were required to have a minimum of 2 years of professional experience in their respective roles. All available health care providers from 2 dialysis centers were prescreened based on their age, sex, and professional experience, including the total number of years worked in both current and previous health care positions and roles. While all participants had experience with the previously implemented intradialytic exercise intervention, none had prior experience with IEG. To

XSL•FO
RenderX

ensure diversity within the sample, individuals of different ages and professional backgrounds were purposefully selected and invited to participate in the study via an email sent by 2 members of the research team (AZ and IMS). Health care providers who accepted the invitation received oral and written information about the study, provided written informed consent, and had their interview date and time scheduled. We continued to include participants until we reached sufficiency of information for all studied topics. This occurred when responses to questions from successive participants became repetitive and no longer provided new, unique insights to the outcome of the study [67].

Data Collection and Procedures

Individual, in-person, semistructured interviews with health care providers were conducted using an interview guide (Multimedia Appendix 1). The interviews began in June 2019, approximately 1 month after the completion of the intradialytic exercise intervention study. Members of the research team (AZ, IMS, and DK) developed the interview guide using the Patient-Centered Access to Health Care framework [68] and the Biopsychosocial Model of Responsiveness to Physical Activity [69] as conceptual frameworks. Three senior members of the research team (JR, ZDV, and AMG) evaluated the initial interview guide and proposed adjustments to enhance its clarity. Further minor adjustments were made following a pilot interview with one dialysis center health care provider. During the interview process, the researchers continually adjusted the guide to delve into areas of specific interest, aligning with best practices for qualitative data collection [70].

The final interview guide covered 4 scope areas (detailed in Multimedia Appendix 1). The first 3 areas explored (1) the perceived benefits of physical activity for dialysis patients in general, (2) the perceived benefits and risks of intradialytic exercise, and (3) experiences with implementing exercise interventions in clinical settings. Findings from these 3 areas were presented in a separate article [65]. The fourth area focused on participants' perspectives on variations in intradialytic exercise interventions, with particular emphasis on IEG. Participants were asked about their opinions and suggestions on alternatives to intradialytic exercise interventions, as well as their attitudes and expectations regarding IEG. Data from this area served as the basis for the current article. The open-ended questions in the interview guide allowed participants to share their attitudes and expectations regarding IEG, enabling interviewers to probe deeper into individual perspectives. Participants were encouraged to elaborate and highlight issues they deemed important. The research team facilitated verbal expression and logical thought development, taking field notes when necessary.

Three members of the research team (AZ, IMS, and DK) conducted interviews from June 2019 through November 2019. Prior to the interviews, written informed consent was obtained from participants, along with a brief personal questionnaire summarizing their sociodemographic characteristics (age and sex) and professional experiences (years in previous and current job positions). The interviews were held in Slovak language, either in private meeting rooms at dialysis centers (for nurses and nephrologists) or in an office at the authors' workplace (for assistants and management staff). All interviews were conducted individually, involving only the participant and 1 or 2 members of the research team (AZ, IMS, and DK). The researchers conducting the interviews had no prior personal or professional relationships with the participants. Before the interviews began, ZDV instructed the researchers on optimal design and conduct of qualitative research interviews and assessed their professional backgrounds, potential biases, and personal interests related to the interview topics. To enhance confirmability, the research team comprised members with diverse theoretical and professional backgrounds, including Sports Sciences, Occupational Therapy, Health Psychology, Nursing, Digital Health, and Clinical Nephrology. Furthermore, team members were actively involved in all stages and levels of the data analysis process. This facilitated critical reflection on emerging interpretations, ensured consideration of multiple perspectives, and helped maintain a close connection between the findings and the participants' accounts while minimizing the influence of individual researcher biases. All interviews were audio-recorded with the participants' consent. The interview transcripts were not returned to participants for comments or corrections, and no follow-up interviews were conducted.

Data Handling and Analysis

During data handling, AZ and IMS transcribed all interview audio recordings verbatim and anonymized them, ensuring the removal of all personal participant data. AZ and IMS manually reviewed all transcriptions, comparing them to the audio recordings to verify the accuracy and authenticity of the transcripts. The authenticated transcripts and audio recordings were subsequently uploaded to the MAXQDA® standard platform (VERBI Software).

We analyzed the collected evidence of health care providers' perspectives regarding IEG in 2 steps. In the first step, we used Braun and Clarke [66] thematic analysis to inductively explore and identify codes, themes, and their patterns, specifically related to participants' attitudes and expectations. Two members of the research team (AZ and IMS) repeatedly read the original Slovak transcripts to familiarize themselves with the data (Phase 1) and then independently generated codes for the entire dataset (Phase 2). Quotations included in the paper were translated from Slovak into English by 2 members of the research team (AZ and IMS), and translation accuracy was reviewed by a senior member of the research team (ZDV). Outputs of initial coding were exchanged between 2 members (AZ and IMS) for coding quality cross-check. Four coding meetings (2 online, 2 in-person) were initiated to discuss problematic codes, disagreements in coding, and appeals to recode until consensus in the coding output was achieved. Through iterative discussion and reexamination of the transcripts, codes were refined and, where necessary, recoded until consensus was reached. Both researchers then associated thematically similar codes into groups and subgroups regarding attitudes and expectations on IEG (Phase 3). These themes were subsequently cross-referenced with the raw data to ensure they accurately represented the participants' experiences (Phase 4). The final output of the coding process and thematic code grouping was reviewed, discussed, validated, and approved by 3 senior members of the research team (JR, ZDV, AMG; Phase 5). At

XSL•FO
RenderX

the end of the first step of data analysis, the entire research team documented their findings and collectively summarized health care providers' attitudes and expectations regarding IEG (Phase 6). Using this procedure, we identified 139 codes and categorized them into 54 subthemes and 5 overarching themes.

In the second step, we used a SWOT analysis approach to organize emerging themes into strengths and weaknesses [potential internal factors], and opportunities and threats [potential external factors]. We conducted a deductive analysis using a revised SWOT model specifically adapted for health care research. The model is built on 3 foundational pillars: addressing stakeholder expectations, evaluating resource management, and considering contextual developments [59]. One member of the research team (AZ) extracted relevant parts from the results of the inductive thematic analysis and categorized them into the 4 quadrants of the SWOT framework. During this process, all codes and subthemes derived from the inductive thematic analysis were systematically examined and categorized as either internal or external factors. Internal factors were defined as those originating within the dialysis centers and directly related to their organizational structures, personnel, operational routines, and implementation processes. External factors were defined as those arising outside the dialysis centers and beyond their direct control, including health care policies, reimbursement frameworks, technological advancements, and broader societal and patient-related influences. They were then evaluated in terms of their hypothetical positive or negative effects on the initiation and implementation processes. Strengths were identified as internal benefits positively related to the IEG at dialysis centers. Weaknesses were identified as internal limitations that might negatively affect or impede the exergaming during dialysis. Opportunities were considered external factors that could positively enhance the applicability and sustainability of IEG. Lastly, threats were identified as external factors that could pose barriers to or adversely affect the implementation of IEG [71]. Afterward, members of the research team (JR, ZDV, AMG; and MA, LK, TJ serving as independent experts not involved in data collection) reviewed and validated whether the content extracted through inductive thematic analysis was appropriate and whether its deductive categorization aligned with the quadrants of the SWOT framework. Using this approach, 43 categories were generated, resulting in 2 strengths, 2 weaknesses, 3 opportunities, and 3 threats regarding IEG. The process of mapping the results of the inductive thematic analysis onto the SWOT framework is presented in the analytical flow table (Multimedia Appendix 2).

Ethical Considerations

The study protocol was reviewed and approved by the Ethics Committee of the Pavol Jozef Šafárik University in Košice, Slovakia [approval no. 14N/2017]. Written informed consent was obtained from all study participants. We report this qualitative study according to the Standards for Reporting Qualitative Research and the Consolidated Criteria for Reporting Qualitative Research guidelines (Checklist 1) [72,73]. The research team comprised experts from various fields, including Sports Sciences (AZ, PhD), Occupational Therapy (MA, MSc), Health Psychology (IMS, PhD; DK, MSc; ZVD, prof; AMG, prof), Nursing and Digital Health (LK, PhD; TJ, prof), and Clinical Nephrology (JR, PhD and MD). All team members had prior experience in researching older people with chronic diseases, as well as expertise in designing, analyzing, and writing qualitative studies.

Results

Characteristics of the Sample (Demographic Data)

We invited 24 health care providers from 2 cooperating dialysis centers to participate in our study. Three care providers (1 nurse and 2 nephrologists) declined to participate due to high workloads and privacy concerns. We conducted semistructured, individual interviews with 3 training assistants, 11 dialysis nurses, 5 nephrologists, and 2 members of dialysis center management. Of the 21 participating health care providers, 11 were recruited from the first dialysis center (6 dialysis nurses, 2 nephrologists, 2 training assistants, and 1 dialysis center manager) and 10 from the second dialysis center (5 dialysis nurses, 3 nephrologists, 1 training assistant, and 1 dialysis center manager). Interviews lasted between 20 and 60 minutes, with an average duration of 39 minutes. One-fourth of the participants were over 50 years old, one-third were male, and half had over 15 years of professional experience. Table 1 provides the demographic and working experience characteristics for each participant's professional position.

Table . Participants' demographic and working experience characteristics by professional position.

Professional position (n)	Sex (male/female), n	Age (years), mean (SD)	Working experience (years), mean (SD)
Dialysis nurse (n=11)	0/11	45.2 (8.1)	18.2 (10.0)
Nephrologist (n=5)	4/1	46.8 (12.6)	20.6 (11.8)
Training assistant (n=3)	2/1	21.7 (0.6)	1.0 (0.0)
Dialysis center manager (n=2)	2/0	55.5 (2.1)	16.0 (1.4)
Total (n=21)	8/13	43.2 (12.5)	16.1 (11.0)

Overview of Findings From Inductive Thematic Analysis and SWOT Analysis

Using inductive thematic analysis, we identified 139 codes, which we then grouped into 54 subthemes and further organized into 5 overarching themes. These themes reflect a range of perspectives, including (1) mixed attitudes toward IEG: balancing optimism and skepticism, (2) attitudes on the acceptability and long-term sustainability of IEG interventions for patients, (3) expectations for addressing patients' individual needs in IEG interventions, (4) expected benefits of IEG, and (5) expectations of the potential risks and barriers associated with IEG.

The SWOT analysis led to the identification and formulation of 2 strengths, 2 weaknesses, 3 opportunities, and 3 threats concerning IEG (Figure 1). (1) Strengths included (a) health care providers' beliefs that exergaming is a safe activity to perform during dialysis, along with their (b) enthusiastic attitudes toward its integration into clinical practice. (2) Weaknesses reflected concerns about (a) the technological complexity of exergaming devices and platforms, and (b) inadequacies in patients' access to and experiences with digital technologies. (3) Opportunities reported by health care providers included (a) uncertainty regarding alternative forms of exercise that could be implemented during dialysis, (b) calls for changes in dialysis culture, particularly to ensure better availability and greater specificity of information and support for IEG, and (c) suggestions and tips regarding the settings and modifications of exergaming interventions to facilitate their implementation during hemodialysis therapy. (4) Threats included (a) health care providers' skepticism about the availability of financial resources, (b) factors related to patients' behavior, personal space, and privacy, and (c) the resistance to IEG interventions among some health care providers. The overall categorization of the outputs derived from the inductive thematic analysis into the SWOT framework is presented in the analytical flow table (Multimedia Appendix 2).

Figure 1. Strengths, Weaknesses, Opportunities and Threats framework (SWOT) analysis template of identified and formulated themes regarding health care providers' attitudes and expectations on Intradialytic Exergaming (IEG). HP: health care provider.

RenderX

Strengths of IEG

Safety

Health care providers regarded exergaming as a safe activity to be undertaken during dialysis. They expressed that, when properly introduced, clinically monitored, and technologically supervised, exergaming does not pose any additional health-related risks for patients undergoing hemodialysis. Other participants stated that they were either unaware of or not qualified to comment on any potential health risks that might be affected by IEG.

Health care providers mentioned that they had no prior experience with IEG and limited knowledge and familiarity with technology-based exercise interventions. They anticipated that, prior to the commencement of IEG, both patients and the hemodialysis care team would be adequately introduced to, and familiarized with, the exergaming environment, its functions and controls. Care providers stated that a comprehensive introduction to IEG could help minimize the risks of misuse, underuse, or overuse of the system.

> *No, I'm not sufficiently educated and experienced in this area [of exergaming]. So, I can't say exactly what types of exercises are suitable. Because not all stretching or resistance exercise can be done during dialysis… they should definitely be designed by someone who is a muscle [kinesiology] specialist. So, not just like, 'Here's a spring or band, exercise with it up and down, and it will go better.* [Nephrologist, male, 44 years old, 20 years of professional experience]

Health care providers emphasized the importance of clinical monitoring in managing potential health-related risks associated with IEG. During hemodialysis, patients must maintain a stable body position to ensure effective extracorporeal blood circulation. Sudden or uncontrolled movements of the torso or limbs could compromise vascular access and impair the efficiency of the dialysis process. Care providers emphasized the necessity of monitoring patients' activity during IEG to safeguard the adequacy and efficacy of the therapy. They also noted that end-stage kidney disease and the hemodialysis procedure itself may contribute to clinical risk conditions, such as dialysis-induced hypotension, hypertension, dysrhythmias, infections, or bleeding, which could potentially be influenced by exergaming during treatment. As such, these conditions must be closely monitored and evaluated. Once appropriate clinical monitoring is in place, health care providers did not anticipate an increased risk of injury or complications related to the patient's clinical profile.

> *We have quite an aged dialysis population. So, they generally have quite osteoporotic bones. It really needs to be individualized based on who the patient is, right? Because we have elderly women who have recently fallen. So, it's really necessary to approach each patient individually, considering their diagnoses, their age, and essentially what can be done with them, just like you were assessing at the beginning, I believe.* [Nephrologist, male, 40 years old, 10 years of professional experience]

> *The safety risk could be that the patient becomes so immersed in the game that they forget they are connected to the dialysis machine. They might get agitated during gameplay, causing their blood pressure to rise, or they could accidentally pull out the needle with a sudden movement or if they get startled. Such consequences would need to be addressed.* [Nephrologist, male, 40 years old, 10 years of professional experience]

> *No [risks for IEG], I don't think so. Only if it could be that his [patient's] blood pressure increases [during exergaming], right? And then the consequences would have to be dealt with.* [Nurse, female, 38 years old, 16 years of professional experience]

Regular inspections of exergaming technology used in dialysis health care settings are essential to ensure patient safety. Health care providers noted that undetected defects, faults, or failures in exergaming systems could increase the risk of injury and health-related complications. However, they stated that these risks could be mitigated through regular, properly conducted technical inspections, including evaluations of both the physical integrity and functional safety of the exergaming technology.

> *I would say the technical aspect of such things [exergaming]. It is related to some devices or controllers, and it is electronics, you know, which is not that simple. Technical side of dialysis is my area and everything technical here requires certain maintenance and also inspection when used. Within a certain time frame during use. All of this must be well controlled.* [Manager, male, 54 years old, 9 years of professional experience]

> *The question is, who is supposed to technologically secure all of this, the technology. We were distributing headphones to patients for listening to the television program… they got damaged.* [Nephrologist, 68 years old, 40 years of professional experience]

Health Care Providers' Enthusiasm

Patients undergoing hemodialysis often spend treatment sessions engaging in passive activities such as watching television, browsing the internet, reading, or listening to music. However, health care providers have noted that these activities often become monotonous and repetitive, leaving patients feeling bored, as they are disconnected from their real-life interests and hobbies. Care providers anticipated that IEG could serve as a more stimulating and varied alternative, an unconventional activity that captures attention, is personalized, and offers greater enjoyment through content that is engaging, distracting, and fun.

> *It might be fun and maybe the dialysis would pass more quickly for them... That would be perfect because they would have visuals, maybe play something, and just exercise along with it. Would that be one way to motivate the patient? Even someone*

XSL•FO
RenderX

who is shy might get into it. [Nephrologist, male, 43 years old, 19 years of professional experience]

Yes, because many of them watch things that are completely pointless or repetitive. There are people, yes, I can say, there are people here who watch educational programs, which is great. They are constantly learning. But there are also younger ones, for example, a 30-year-old who brings a series and basically watches it for 4 hours, which I think he doesn't need to do, he could be doing something else. He's too young for this. [Nurse, female, 38 years old, 16 years of professional experience]

Weaknesses of IEG

Complexity

Participants identified the technological complexity of using exergaming devices and platforms in clinical settings as a significant limitation. Several noted that limited space in some dialysis centers could hinder the installation and positioning of such equipment. They emphasized the importance of maintaining unobstructed access around the patient, particularly the area between the patient's vascular access site and the dialysis machine. Regarding design and installation setup, health care providers expressed a preference for exergaming devices and platforms to be wireless and equipped with internal or built-in power supplies. For positioning, they favored designs that could be securely attached to the external structure of the dialysis bed using a fastening system, allowing for quick and easy detachment by health care staff when necessary.

Because those beds are really designed for the patient to fit in, and maybe have something next to them. So, depending on how big the device would be, I'm afraid it would be a bit restrictive in terms of placement, right? [Nephrologist, male, 45 years old, 16 years of professional experience]

Accessibility and Users' Experiences

With regard to other limitations, health care providers expressed 2 broad groups of factors that may influence patients' engagement with IEG. The first group relates to technological accessibility and digital experience. Participants noted that patients undergoing hemodialysis, particularly those with limited access to digital technologies and minimal previous experience using them in daily life, may be skeptical, dismissive, or uninterested in IEG. They also noted that socioeconomic background and prior digital experience, particularly the frequency and quality of that experience, were strongly associated with patients' capacity to accept and adopt digital technologies in health care settings. The second group comprises individual patients' characteristics affecting technology use. Participants identified impaired visual, auditory, and cognitive functions as significant barriers to engaging with digital technologies, potentially hindering patients' ability to participate in exergaming during dialysis sessions. Interestingly, there was inconsistency among care providers regarding the role of age in patients' acceptance of exergaming technologies. Some mentioned that IEG is unsuitable for older patients undergoing hemodialysis, while others perceived no age-related disadvantages. The remaining participants acknowledged that older age could present a barrier but emphasized that many older patients are fully capable of using and benefiting from digital tools.

In my opinion, there are older patients who will find it harder to handle [exergaming device/platform] than a mobile phone. So, this will be more difficult for them. But sometimes we are surprised that even an 80-year-old grandmother has her [own] phone and can use it well. So, it would probably need to be assessed individually first. I can't say definitively yes or no for everyone. [Nephrologist, female, 34 years old, 8 years of professional experience]

Well, we have a computer available for patients if they are interested. We have internet in the hall [dialysis room] if patients are interested, but almost no one used it.... But I don't know if it would work like 'here you go, play.' And of course, they have to be... physically and mentally fit to do something like that [IEG]. [Nurse, female, 54 years old, 36 years of professional experience]

Opportunities of IEG

Uncertainty

Most of the health care providers were unable to suggest specific types and settings that could be used to tailor exergaming interventions to better suit the clinical environment, as well as the needs, expectations, and limitations of both health care providers and patients undergoing hemodialysis. The limited ability of health care providers to identify external modalities for tailoring exergaming interventions to the hemodialysis setting indicated an opportunity for future research, technological innovation, and stakeholder engagement to support the implementation of IEG. To enhance the usage of intradialytic exercise and exergaming, care providers identified several opportunities: increasing health care providers' awareness and knowledge related to the planning and organization of such interventions; ensuring either permanent or temporary access to exercise specialists for patients undergoing hemodialysis; and fostering international networks to support the exchange of best practices and shared experiences in this field.

You are asking me a difficult question, and I don't know, at the moment I don't know, I haven't thought about it [variations of intradialytic exercise], what and it would probably be the same with everyone [of participants]… because basically, when we think about it, we are always dealing only with the patient's health condition. [Nurse, female, 38 years old, 16 years of professional experience]

Dialysis Culture

Intradialytic exercise is not currently integrated into routine hemodialysis care in Slovakia. According to health care providers, exercise during dialysis, regardless of its form, is not recognized as a standard component of health care services. They reasoned that the health care system, particularly its legislative and organizational frameworks, has not yet been

XSL•FO
RenderX

adapted to support the integration of such services into clinical practice. Drawing on experiences shared by participants during their visits to dialysis centers abroad, they provided suggestions and proposed strategies for implementing effective IEG interventions. Opportunities to enhance the use of IEG include changes in dialysis culture, including creating a more family-like and relaxed clinical environment within dialysis centers; providing direct legislative support for such activities; and establishing complementary services such as nutritional and psychological counseling in routine hemodialysis care.

> *But this is not just a local problem of our [clinical] workplace; it is a systemic error. Simply put, the entire healthcare system [in Slovakia]. So we cannot sustain [nutrition status among] patients and do not exercise with them… In the [other areas of the] world, it works exactly like that: they know how many kilojoules a patient needs, what kind of diet they need, and which day after acute treatment they can start exercising.* [Nephrologist, female, 34 years old, 8 years of professional experience]

> *I can't imagine it [routine intradialytic exercise]. Because, for example, when you look at dialysis abroad, they dance and exercise with the patients, and there's a more relaxed atmosphere. Here, it's just so clinical, the dialysis, connecting and disconnecting, needles, everything sterile. It seems to me that everything has its rules, everything must be on time.* [Nurse, female, 34 years old, 10 years of professional experience]

Exergame Tips

After receiving a verbal introduction to intratherapeutic exercise interventions from members of the research team during the interview, health care providers were able to offer several suggestions regarding the setting and potential variations for implementing IEG. They proposed that patients could engage in endurance exercises such as bed bike pedaling, resistance exercises using rehabilitation equipment, and relaxation or breathing exercises during dialysis. According to them, these activities could be delivered in the form of exergaming and might be enhanced with accompanying music. Other participants suggested incorporating exergaming as a routine component of health care but recommended scheduling exergaming sessions at dialysis centers immediately after the completion of dialysis treatments, rather than during the sessions themselves.

> *Maybe they could actually pedal on those bikes, for example. I don't mean the ones used by athletes, but there are some, I don't know what they're called, where the patient sits upright, and they're actually used during rehabilitation.* [Training assistant, male, 23 years old, 1 year of professional experience]

Threats of IEG

Costs

Health care providers expressed uncertainty when identifying the entity or authority that might be responsible for funding IEG services. They expressed skepticism about the applicability and long-term sustainability of such interventions within the Slovak health care system, primarily due to the anticipated high initial financial investment and limited funding opportunities for supplementary health services. Several participants were unwilling to discuss or chose not to clearly articulate their views on the financial aspects of implementing and sustaining IEG. One participant suggested that demonstrating both the health-related benefits for patients and the cost-effectiveness of the intervention could serve as a foundation for further discussions with health care management organizations and stakeholders about securing additional financial support for such intratherapeutic services.

> *Well, for them it might actually be fun, and maybe it would make the dialysis go by faster for them, but who would fund it? Yeah, like for him [patient] it might actually be [fun], yeah, just unfortunately, who would fund it, who would take care of it?* [Nephrologist, male, 43 years old, 19 years of professional experience]

Patient Behavior

The health care providers expressed the view that due to the presence of kidney diseases and the complexity of associated health complications, patients often experience periods of frustration, demotivation, resignation, negativism, and oppositional behavior. Furthermore, care providers who participated in our study mentioned that each patient presents a unique set of personality traits, with an individual trajectory of development and expression. As a result, care providers anticipated that the introduction, familiarization, and adoption of the IEG concept would require a long-term, sustained effort and a personalized approach. They recommended avoiding strict, formal, task-oriented communication, and instead emphasized the importance of a sensitive, familiar, and pressure-free approach during the introduction and initiation of IEG. With regard to the specific nature of exergaming, health care providers mentioned that some patients might feel embarrassed due to the visibility of the activity within the shared space of dialysis rooms, as well as unfamiliarity with the exergaming technology among patients. Two participants specifically noted that differences in levels of game immersion could influence patients' engagement with exergaming. They also emphasized that psychological predispositions toward gaming addiction should be considered a potential risk associated with IEG.

Health care providers expressed concerns that patient behavior-related factors, which are largely external to the intervention and beyond the direct control of health care providers, could significantly influence patients' attitudes and willingness to engage with exergaming during hemodialysis therapy, and, as a consequence, could threaten the acceptability, usability, and sustainability of IEG.

> *As for barriers [for exergaming], what comes to my mind is addiction. Because after all, these [exergaming interventions] are games, and addiction to games is quite easy to develop, so from that perspective.* [Training assistant, female, 22 years old, 1 years of professional experience]

XSL•FO
RenderX

With regard to other potential risks, participants noted that violations of patients' personal space, privacy, and comfort during dialysis caused by exergaming activity could compromise the usage of intradialytic exercise interventions. Such disruptions could also affect patients who are not directly participating in exergaming during their treatment. Health care providers identified several sources of these intrusions, including changes to the timing of dialysis connection and disconnection procedures, alterations to the spatial layout of the clinical environment during hemodialysis, and increased noise levels or other external factors that may be perceived by patients as negative distractions during therapy.

> *I think these are some patients who... how to put it? They're kind of offended by the whole world, and they would seriously cause problems and refuse [exergaming], and maybe they would even cause problems for the other patients [whose exergaming during their dialysis] if they didn't feel comfortable in some way, and if it somehow limited them. I mean the exercise of the other patients, not their own.* [Training assistant, male, 21 years old, 1 year of professional experience]

> *If there were such interest, then the conditions would have to be created for it [IEG]. Because we have a large hall [dialysis room]. There are a lot of people there. Right? The question is how the others would react, whether it [exergaming] would disturb them.* [Nurse, female, 54 years old, 36 years of professional experience]

Resistance

We identified critical, negative, and mixed attitudes and expectations regarding IEG, including resistance to the use of digital tools. Two health care providers expressed strong opposition to the integration of exergaming into dialysis therapy. They expressed a sense of technological resistance and frustration, or overwhelm, with the increasing reliance on digital tools. In the context of intradialytic exercise, they demonstrated a clear preference for traditional, patient-centered approaches to health care, placing high value on direct, personal interaction over technology-mediated experiences. Additionally, 2 other caregivers anticipated initial resistance to IEG and raised concerns about the added responsibilities it could place on health care providers, as well as potential disruptions to the routines of dialysis nurses.

> *Well, I already think this is a bit over the top with these computers. Everyone should maybe step away from it a little, I would say. You know, it's [exergaming] not the same as when you're physically with the patient. It's not that kind of contact. It's just the computer again, and then some pedals again.* [Nurse, female, 60 years old, 40 years of professional experience]

> *I would probably be lying if I said it [IEG] would go smoothly. I'm expecting initial resistance, definitely. [It means] A load of additional work [for healthcare providers]. That's just how it is. A burden, simply because it's another [work]load.* [Nephrologist, female, 34 years old, 8 years of professional experience]

Discussion

Principal Findings

This study aimed to explore the attitudes and expectations of health care professionals regarding the concept of IEG as a strategy to support patient self-management in the domain of physical activity. It offers novel insights into the perceived strengths, weaknesses, opportunities, and threats associated with IEG, as reported by training assistants, nurses, nephrologists, and dialysis center managers.

Health care providers identified the perceived safety of IEG, along with generally positive and enthusiastic attitudes toward its use, as key strengths. However, they also highlighted the complexity of the exergaming concept, as well as closely related issues of accessibility and user experience, as potential weaknesses that could hinder its integration into health care services. In terms of opportunities, participants expressed uncertainty regarding alternative approaches to the organization and delivery of intradialytic exercise. They emphasized the need for cultural adjustments within dialysis settings to facilitate the implementation of various proposed IEG modalities in the clinical environment. The main threats identified included skepticism about the financial and resource implications of IEG, potential patient reluctance or refusal to participate due to behavioral factors, and resistance to change among health care professionals in adopting exergaming as part of routine care.

Patients' perceptions of safety play a key role in their decision to initiate and continue using technology-based physical activity interventions during dialysis therapy [74,75]. Our findings regarding perceived strengths suggest that health care providers generally view exergaming as a safe activity for patients undergoing hemodialysis. This aligns with existing evidence from studies monitoring patient safety, which consistently report no serious adverse events attributable to IEG [42,76-80]. From a broader perspective, research on exergaming interventions in patients with heart failure, stroke, or cancer similarly reports either no adverse events or only rare, exceptional cases [81-83]. Paradoxically, evidence from older adults and patients with multiple sclerosis, mild cognitive impairment, other neurocognitive disorders, and hypertension suggests that exergaming may raise concerns about physical safety. These concerns include fear of falls and general injuries, as well as occurrences of knee or back pain [16,84-89]. Such safety issues have been attributed to reduced awareness of the physical environment and insufficient guidance and support during exergaming activity [84,85,90]. Our participants expressed that, when properly introduced, clinically monitored, and technologically supported, IEG does not pose additional health risks to patients. They also expressed enthusiastic attitudes toward its use during hemodialysis therapy, which is consistent with existing evidence on positive perceptions among health care providers working with patients with dementia, cardiovascular conditions, stroke, and cancer [53,55,82,91,92]. Taken together, these insights into perceived strengths underscore the importance of promoting IEG by prioritizing

XSL•FO
RenderX

patient safety and leveraging the enthusiastic support of health care providers. Their positive perceptions can play a pivotal role in enhancing patient engagement and long-term adherence to technology-supported physical activity during dialysis therapy.

Technological limitations and a lack of design flexibility in exergaming devices and platforms may undermine their ecological validity and hinder their transferability into clinical practice [93-95]. Our participants identified several weaknesses related to the design, installation setup, and positioning of exergaming technologies within dialysis environments, collectively referred to as technological complexities. These included limited space in dialysis centers, the need to maintain unobstructed access between the patient and the dialysis machine, and preferences for wireless, self-powered devices that can be securely yet easily attached to dialysis beds. These findings are consistent with existing evidence on the general limitations and challenges of exergaming among patients undergoing hemodialysis, particularly those arising from environmental and organizational constraints [96-99]. Importantly, other authors have noted that such complexities may present challenges not only during the integration of these technologies into clinical settings but also for health care providers and end-users [55,100-105]. Our participants also identified additional barriers to IEG, including patients' digital literacy, sensory and cognitive impairments, socioeconomic factors, and differing views on the influence of age on user experience. These factors were seen as key challenges that may limit patients' accessibility and engagement with exergaming technologies [16,56,97,98,100,101,103,106]. To improve the quality of implementation, particularly the transferability and accessibility of IEG technologies in clinical practice, developers and promoters should be aware of and take into account the specific conditions of dialysis environments and patient-related limitations from the earliest stages of design and development.

Health care providers are central figures in the development, initiation, and long-term sustainability of innovative therapeutic approaches in clinical practice [107,108]. In relation to opportunities for IEG, participants expressed limited ability to tailor such interventions to clinical settings and individual patient needs, highlighting gaps in their awareness, knowledge, and experience. Nevertheless, they proposed several key opportunities to enhance implementation, including raising awareness among health care professionals, integrating exercise specialists into routine dialysis care, and fostering international collaboration to share best practices. Although intradialytic exercise is not yet a standard component of dialysis care in Slovakia, participants suggested feasible strategies to support its integration. These included legislative backing, cultural shifts within dialysis centers, and the availability of complementary services. Our evidence on health care providers' expectations and proposed opportunities aligns with existing literature, which emphasizes the importance of health care providers' competencies, the presence of support teams and services, and the need for legislative and leadership support within dialysis networks [107,109-114]. Enhancing the availability of professional competencies and providing institutional and legislative support may serve as foundational drivers for cultural change in dialysis care. Such improvements could help meet the needs and expectations of health care providers and enable broader implementation of IEG in clinical practice. A recent study highlights that implementation of innovative exercise interventions, such as exergaming, depends on addressing multilevel factors, such as patient needs, health care professional engagement, and supportive policy frameworks [105].

Underestimating external factors, particularly potential threats, during the planning of behavioral interventions can compromise their usage in clinical practice. Our participants expressed uncertainty and skepticism regarding the financial feasibility of IEG, emphasizing the need for robust evidence of its health benefits and cost-effectiveness. Patient behavior was also identified as a potential threat, with participants highlighting the importance of a personalized and sensitive approach to introducing exergaming, given the psychological, social, and environmental challenges that may influence initial engagement and long-term adherence. Additionally, some health care providers expressed resistance to the concept of IEG, favoring traditional care methods and raising concerns about technological burden, workflow disruptions in dialysis settings, and potential patient discomfort. Existing literature reflects similar concerns, with reports of uncertainty and skepticism about the availability of financial resources for exergaming [89,92,115,116], although other studies highlight its favorable cost-effectiveness and cost-efficiency [117-119]. However, cost analyses specific to IEG are currently lacking and are critically needed to inform planning and development. Patient behavior, particularly motivation, and social and emotional factors has been significantly associated with the effectiveness and adherence to exergaming interventions across diverse populations, and is recognized as both a key determinant and a potential threat [120-124]. A particularly salient concern raised by health care providers was the potential for gaming addiction, reflecting a critical awareness of unintended psychological consequences that may arise from IEG. The evidence highlighting resistant, reserved, and oppositional attitudes, as well as expectations surrounding IEG, represents a challenging yet essential insight for effective planning and development. Recommendations to overcome initial resistance include the provision of education and support from specialized professionals (eg, physiotherapists), and the active involvement of health care providers in the planning and management of the intervention [65,109,113,125]. To effectively mitigate potential risks, it is essential to conduct a thorough assessment of the resources required, prioritize individualization by addressing each patient's specific needs, and actively involve health care providers in the planning process prior to implementation of IEG.

Our study provides comprehensive evidence on Slovak health care providers' attitudes and expectations regarding the implementation of IEG in clinical practice, systematically organized into thematic quadrants of the SWOT framework. Future research exploring perceptions of IEG, including those of patients, exergame developers, and stakeholders (particularly patients' organizations, governmental and regulatory bodies), could enhance understanding of critical factors for strategic planning. Evidence on attitudes and expectations toward IEG

XSL•FO
RenderX

from respondents representing diverse health care systems, geographical regions, and socioeconomic and cultural backgrounds could strengthen the generalizability of these findings.

This study presents several key strengths. First, the sample included professionals from all levels of the organizational hierarchy within dialysis centers, from training assistants and nurses to nephrologists and senior management, providing a well-rounded and comprehensive perspective on health care providers' attitudes and expectations regarding IEG. Second, the use of prescreening enabled the recruitment of a highly diverse group of participants, varying in age, gender, and professional background. Third, all participants contributed relevant expertise through their direct involvement in implementing intradialytic exercise interventions in clinical practice. Fourth, we used an inductive approach to analyze health care providers' attitudes and expectations, followed by deductive categorization using the SWOT framework. We believe this methodological strategy yielded a practical, systematically organized, and transferable overview of the SWOT associated with IEG interventions, offering valuable insights to support strategic planning and informed decision-making.

This study has several limitations that should be acknowledged. First, despite our efforts to ensure a balanced representation across professional roles, we were unable to achieve the optimal sample size of 6 to 8 participants in the groups representing dialysis center managers and training assistants. However, the strong thematic alignment between managers, training assistants, and other professional groups suggests that their perspectives were largely reflected. Second, all participants were recruited from 2 dialysis centers affiliated with leading nephrology networks in Slovakia. As a result, the findings may be shaped by context-specific factors such as socioeconomic, demographic, and cultural characteristics, which could limit their generalizability to other dialysis settings with different health care structures. Third, our inclusion criteria required varying minimum levels of professional experience across roles. This decision was made to address the limited availability of experienced training assistants and to avoid potential bias from insufficiently experienced nurses, nephrologists, and managers. Nonetheless, this approach may have excluded early-career perspectives from some professional groups. Fourthly, our study is limited by the fact that participating health care providers had no direct experience with IEG. Therefore, the findings are based on hypothetical perceptions and expectations regarding its implementation in hemodialysis care and may not fully reflect experiences or challenges associated with its actual use in clinical settings.

Conclusions

This study offers valuable insights into health care providers' views on the implementation of IEG in clinical practice. They regarded IEG as safe and potentially beneficial for patients undergoing hemodialysis when supported by clinical monitoring and technological oversight. They highlighted the potential of IEG to enhance patient engagement and alleviate boredom during hemodialysis while noting weaknesses such as technological complexity and limitations on accessibility and users' experiences. Health care providers identified opportunities such as clarifying alternative exergame options, enhancing the availability and quality of information and support for IEG, and refining available IEG settings and modifications to facilitate implementation during hemodialysis therapy.

Although IEG is not yet standard practice in Slovakia, our findings indicate that, with appropriate planning, training, and policy adjustments, it could become a sustainable component of hemodialysis care. Health care providers acknowledged its potential benefits for engagement and well-being but raised concerns about financial feasibility, long-term sustainability, and availability of support for integration into the health care system. Common threats included uncertainty over funding and skepticism about health care system readiness, alongside worries about patients' privacy, clinical routines, staff workload, and resistance. In addition, our participants emphasized the need for a personalized approach to address patients' psychological variability and possible discomfort in shared spaces. The findings highlight the need to address both human and systemic factors in the design, development, and implementation of IEG, indicating that successful integration will require not only technological innovation but also cultural, organizational, and legislative support.

Health care providers regarded IEG as a safe and promising option for patients on hemodialysis, particularly for boosting engagement and reducing treatment-related boredom. To make this approach feasible in practice, clear guidelines, staff training, and organizational support are essential to overcome technological and accessibility challenges. With thoughtful planning and adequate resources, IEG could become an effective addition to hemodialysis care, improving patient experience and overall well-being.

Acknowledgments

We sincerely appreciate the valuable cooperation and support provided by Ivana Meszaros Skoumalova, PhD (IMS), and Denisa Kravcova (DK) during the data collection, management, and analysis phases of this study.

Abstract

Background: According to human-centered design principles, user experience and user satisfaction are key aspects when developing or providing patients and clients with assistive, rehabilitation, or training technologies. Existing tools for assessing user experience and satisfaction are often either too narrow (developed for specific technologies) or too broad, failing to capture all relevant aspects of the technology being evaluated.

Objective: The main objective of this study was to present the development process and content validation of a questionnaire that, following further validation steps, could be useful for researchers and developers in assessing the satisfaction of direct end users with assistive, rehabilitation, and training technologies.

Methods: The development of the User Satisfaction Questionnaire for Assistive, Rehabilitation, and Training Technologies (U-ART-Q) followed a multistep process: (1) literature review, (2) domain definition and item generation, (3) expert consultation, (4) linguistic validation, and (5) content validation. Initially, 72 items were generated and organized into 7 domains. After expert review and linguistic validation, the questionnaire underwent content validation by 8 experts in physiotherapy, kinesiology, and ergonomics. Each item was rated for relevance using a 4-point Likert-type scale. The content validity ratio (CVR) and item-level content validity index (I-CVI) were calculated, and items below the accepted thresholds were removed or further revised.

Results: Expert consultation resulted in the removal or merging of 20 items to improve clarity and reduce redundancy. Of the 52 items evaluated during content validation, 44 met the CVR and I-CVI criteria (CVR >0.75 and I-CVI >0.78). Eight items required additional review, and 2 items were ultimately removed. The final questionnaire comprises 10 initial screening questions and 50 content-valid items across 7 domains: design, comfort, effectiveness and usefulness, service, treatment or exercise, overall impressions, and safety. The overall average content validity index was 0.915, providing evidence of strong content validity. A macro-enabled Excel tool was developed to automate item selection and generate a PDF version of the questionnaire based on initial screening responses.

Conclusions: The U-ART-Q is a newly developed instrument for assessing user satisfaction with assistive, rehabilitation, and training technologies. Further research will focus on psychometric evaluation, reliability testing, and multilingual validation to determine whether the U-ART-Q can provide a standardized method for assessing user satisfaction. Once fully evaluated, the questionnaire could support both developmental usability testing and postmarket evaluation, facilitating evidence-based decision-making and guiding future product improvement.

Introduction

The field of assistive, rehabilitation, and training technologies is rapidly advancing, presenting both opportunities and challenges [1]. User satisfaction plays a critical role in the adoption, adherence, and effectiveness of these technologies, thereby directly influencing the user's quality of life [2]. Consequently, the reliable assessment of user satisfaction and experience is essential for the successful development, provision, and implementation of such technologies. Existing assessment tools frequently rely on generic questionnaires that may not adequately capture the specific characteristics of technologies associated with clinical and training applications. This underscores the need for instruments specifically designed to evaluate user satisfaction within the domains of assistive, rehabilitation, and training technologies. The objective of this study was to describe the development and content validation of a new questionnaire for assessing user satisfaction. The intended respondents include individuals who wear, use, or train with the technology, as well as professionals who operate or provide it, such as physiotherapists, personal trainers, kinesiologists, and other health care professionals. The proposed questionnaire aims to fill an important gap in the existing literature by providing a new instrument for assessing and providing feedback on the design, usability, and effectiveness of these technologies, ultimately enhancing overall user experience and satisfaction.

Assistive, rehabilitation, and training technologies comprise tools, devices, and systems designed to maintain or enhance individuals' functioning, participation, health, and well-being. Rehabilitative and assistive technologies facilitate the engagement of individuals with disabilities in daily activities and support caregivers by improving independence and task performance [1]. Rehabilitation technologies primarily aim to help individuals regain lost function following illness or injury, whereas assistive technologies support individuals in performing tasks that might otherwise be difficult or impossible [3]. Assistive technologies, within the scope of this study, are hardware technologies classified according to the ISO 9999:2022 classification and range from low-tech aids, such as communication boards, to advanced computer-based systems, including prosthetics, specialized keyboards, exoskeletons, and others [4,5]. Assistive technologies are often categorized by complexity and user needs as low-, medium-, or high-level systems [5]. Recent advances have expanded these categories to include wearable technologies, virtual reality, AI, and robotics, offering new opportunities to enhance independence and quality of life [1,6,7]. Some of these devices, with variations in design and intended use, are also classified as rehabilitation technologies. Examples of rehabilitation technologies include exoskeletons, robotic-assisted therapy, virtual reality rehabilitation, and electrotherapy devices, while common assistive technologies include wheelchairs, canes, hearing aids, and speech recognition software. Rehabilitation technologies can also encompass assessment and monitoring tools, such as motion capture systems and musculoskeletal modeling software, which are used in both rehabilitation and training contexts. Training technologies, on the other hand, include devices designed to maintain or improve health, well-being, and performance in individuals with or without disabilities. Examples include treadmills, stationary bicycles, rowing machines, isokinetic devices, and sport-specific systems aimed at optimizing movement patterns. Additionally, occupational training devices are used to simulate job tasks, train, and improve specific skills.

Human-centered design (HCD) is a key approach in device and system development that ensures products are usable, useful, and aligned with users' needs by integrating principles of human factors, ergonomics, and usability [8,9]. HCD enhances product effectiveness, efficiency, user satisfaction, and accessibility while reducing potential adverse effects and promoting overall well-being [9]. According to the ISO, HCD is an iterative, cyclic process comprising 4 main phases: understanding and specifying the context of use, specifying user requirements, designing solutions, and evaluating against requirements [9]. In the development of assistive, rehabilitation, and training technologies, applying an HCD approach is essential to ensure that the final product meets the needs and preferences of end users. The ultimate goal of HCD is to create technologies that are necessary, functional, and enjoyable to use.

Usability testing is a fundamental component of the HCD process used to evaluate a product's ease of use, efficiency, and user satisfaction through testing with representative users [10]. It ensures that systems are not only functional but also intuitive, efficient, and aligned with user needs [11]. By identifying usability issues early in development, usability testing helps reduce later design costs and supports the development of technologies that provide positive user experiences [12,13]. A well-designed usability study involves participant recruitment, task design, data collection, and systematic analysis to obtain both qualitative and quantitative insights that inform design decisions and improve user experience [10,14]. Well-structured usability testing is therefore essential for understanding user interactions, identifying relevant user experience factors and potential pain points, and detecting barriers to implementation and opportunities for improvement [15,16]. However, in practice, HCD and usability testing are often carried out without the iterative approach needed to fully follow the principles of the HCD process [17]. Insufficient involvement of end users in the design process can lead to poor user acceptance and approval, emphasizing the need for developers to effectively integrate user needs throughout the design cycle. Similarly, the absence of systematic usability evaluation and adequate consideration of users' needs may contribute to reduced acceptance or abandonment of assistive technologies [18-20].

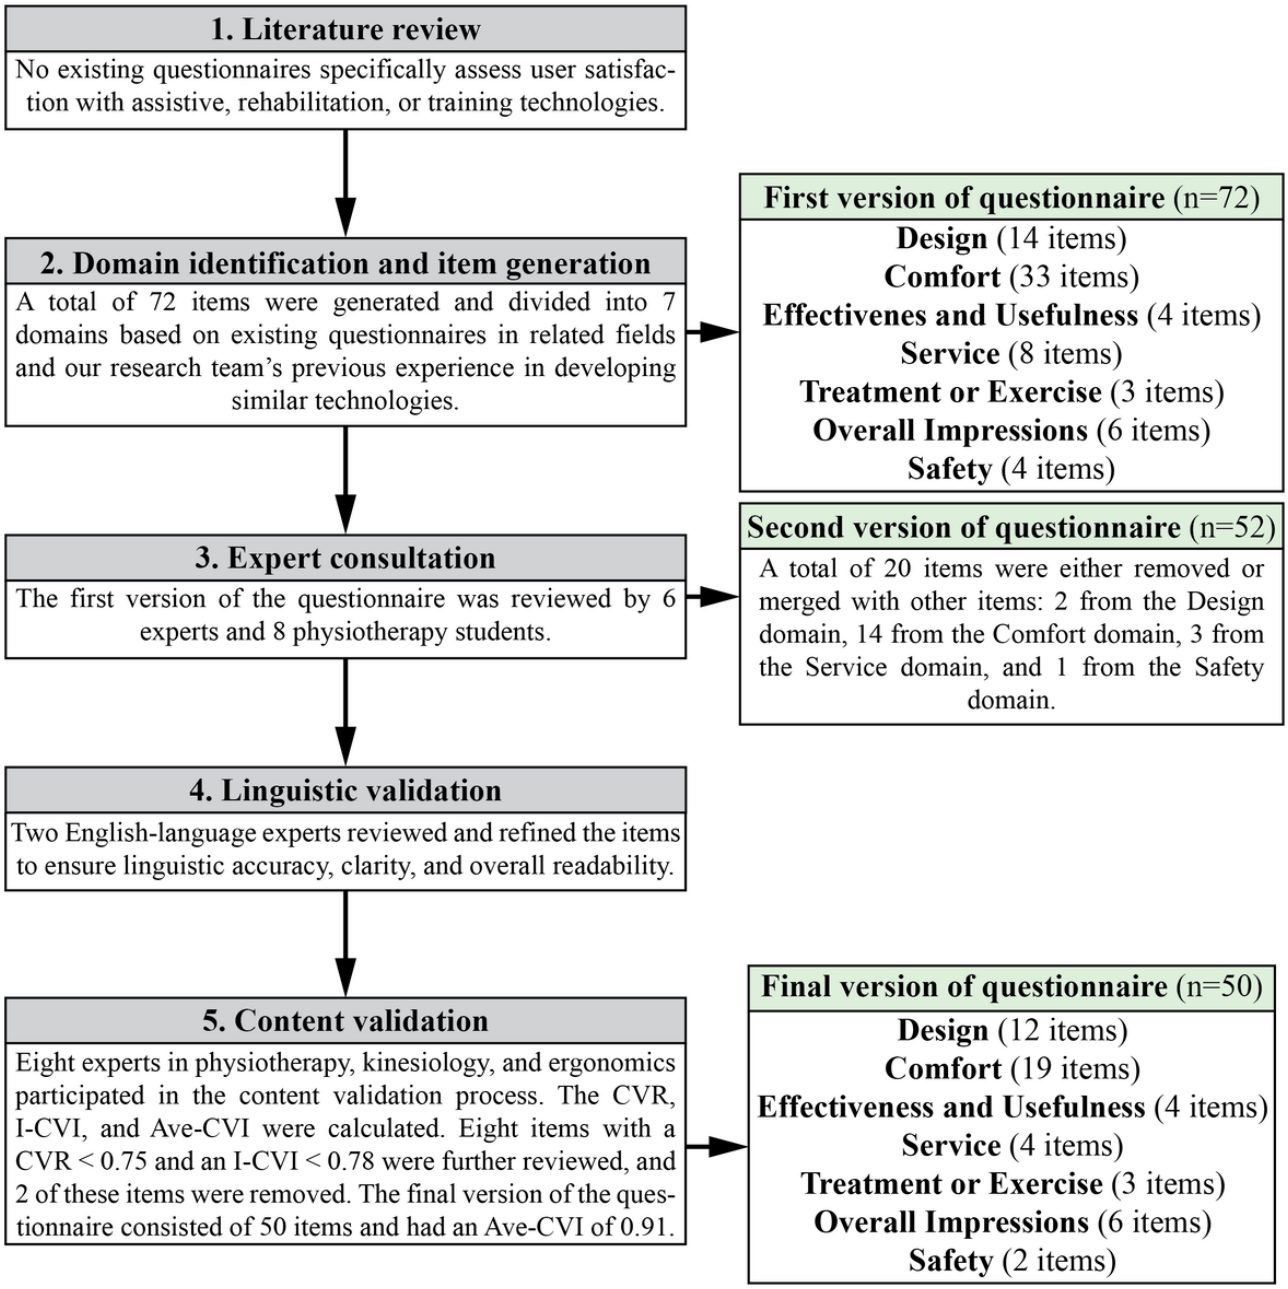
When planning and conducting usability testing, developers must determine the appropriate timing and frequency of testing within the design process, identify target end users, and establish methods for evaluating effectiveness, efficiency, and user satisfaction. Common approaches include structured and semistructured interviews, focus groups, surveys, scenario-based testing, expert evaluations, and controlled user observations [12]. Both qualitative and quantitative methods are essential for comprehensive usability evaluation and are often combined depending on the development stage and testing objectives. However, reliance on existing quantitative tools such as surveys

XSL•FO
RenderX

and standardized questionnaires can sometimes result in narrow or incomplete insights, potentially overlooking user needs and opportunities for design improvement. Conversely, qualitative methods such as focus groups and observational studies, while rich in detail, can be time-consuming and expensive. In software usability testing, common quantitative measures include task completion metrics (with or without video or screen recording) and standardized instruments such as the System Usability Scale (SUS), Usefulness, Satisfaction, and Ease of Use (USE), or NASA Task Load Index (NASA-TLX). The literature review was conducted to identify existing instruments suitable for evaluating user experience and satisfaction with hardware and devices that interact with the human body. The identified questionnaires were systematically examined with respect to their intended purpose, target technology, and domain coverage to determine if the development of the new tool was justified. The literature review yielded similar findings to previous studies: there are a large number of custom-made instruments used for satisfaction evaluation, and the identified instruments are either too general to identify specific design issues or too specific for broader application [21-23]. To overcome these limitations, a quantitative assessment tool was designed specifically to evaluate user satisfaction with assistive, rehabilitation, and training technologies. The instrument is intended to complement qualitative methods by providing a structured and potentially cost-efficient means of assessing satisfaction across individual items, broader domains, and overall device use. Following further validation steps, the questionnaire may be suitable not only for researchers and developers during the design process but also for routine commercial or clinical use of the device after development, as well as for postmarket evaluation. In these contexts, it could support the ongoing evaluation of user experience and satisfaction throughout the product life cycle, thereby informing continuous improvement and future design iterations. Additionally, it could assist researchers and clinicians in comparing user satisfaction across devices, settings, and user populations, thereby informing evidence-based decision-making in device selection and provision.

During the development process of the User Satisfaction Questionnaire for Assistive, Rehabilitation, and Training Technologies (U-ART-Q), it was considered essential to account for the distinct characteristics, intended purposes, and needs of end users of assistive, rehabilitation, and training technologies.

As emphasized in previous studies, comprehensive coverage, item clarity, and precise definition of measured constructs are crucial for creating valid and usable measurement instruments [2]. While detailed psychological definitions of satisfaction are beyond the scope of this study, user satisfaction in this context is conceptualized as a component of user experience, in line with the ISO definition: “Users’ perceptions and responses that result from the use and/or anticipated use of a system, product or service.” Satisfaction itself is defined as “the extent to which the user’s physical, cognitive and emotional responses that result from the use of a system, product or service meet the user’s needs and expectations” [9].



Methods

Overview

The development process of the U-ART-Q involved several distinct phases, including (1) literature review, (2) domain definition and item generation, (3) expert consultation, (4) linguistic validation, and (5) content validation. The detailed development process of this questionnaire is presented in Figure 1.

XSL•FO
RenderX

Figure 1. Development process of the User Satisfaction Questionnaire for Assistive, Rehabilitation, and Training Technologies (U-ART-Q). Ave-CVI: average content validity index; CVR: content validity ratio; I-CVI: item-level content validity index.

The first step in developing the U-ART-Q was to conduct a literature review to identify existing questionnaires assessing user satisfaction with assistive, rehabilitation, and training technologies. The search was conducted in the PubMed/MEDLINE, Scopus, and Web of Science databases on September 10, 2025. Database-specific search strategies were developed using combinations of terms related to satisfaction, user experience, questionnaires, development, rehabilitation, assistive technology, robotic rehabilitation, exoskeletons, prostheses, orthoses, and training technologies. The complete search strategies for each database are presented in Multimedia Appendix 1.

All retrieved records were exported to a Mendeley Reference Manager (Elsevier), and duplicate records were removed. Titles and abstracts were independently screened according to the predefined eligibility criteria. Potentially relevant studies underwent full-text review to determine final eligibility. Reasons for exclusion during the full-text assessment were documented in accordance with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) recommendations [24].

Studies were considered eligible if they reported the development, validation, adaptation, or application of questionnaires intended to evaluate user satisfaction with relevant technologies. Furthermore, studies were excluded if they focused on technologies outside the scope of rehabilitation, such as industrial exoskeletons, surgical robotics, dental technologies, and other unrelated medical devices. As our search was based only on hardware solutions, publications evaluating software or mobile apps without other hardware components were also excluded. Similarly, user interfaces without accompanying hardware components and virtual reality systems

XSL•FO
RenderX

were excluded. Additionally, studies that evaluated other constructs without measuring satisfaction (eg, quality of life, functional performance, technology acceptance without satisfaction outcomes, or clinical effectiveness alone) were excluded. Conference abstracts without full text available, editorials, letters, study protocols, dissertations, non-English publications, and studies with insufficient methodological information were also excluded.

Following full-text screening, studies were excluded for the following reasons: published study not in English language (n=9); technology outside the scope of this review (n=16); no satisfaction-related outcome measures reported (n=64); and study that does not use a questionnaire (n=3).

The complete study selection process is illustrated in the PRISMA flow diagram. All included studies are presented in Multimedia Appendix 2 (Microsoft Excel worksheet titled Studies for Extraction).

After searching the literature, we noted the existence of 117 questionnaires used to measure user experience, usability, and satisfaction with various technologies and systems. The most frequently used questionnaires were general questionnaires, such as the Quebec User Evaluation of Satisfaction With Assistive Technology (QUEST 2.0), USE, and SUS, as well as questionnaires specific to certain technologies, such as the Client Satisfaction With Device Module of the Orthotics and Prosthetics Users' Survey (CSD-OPUS), the Questionnaire for Usability Evaluation of orthopaedic shoes (QUE), the Trinity Amputation and Prosthesis Experience Scale (TAPES), the prosthesis-satisfaction subscale, and others [23,25-31]. The list of all identified questionnaires used in the evaluation of satisfaction with technologies is available in Multimedia Appendix 2 (Excel worksheet titled Identified Questionnaires).

Although a considerable number of questionnaires were identified (Multimedia Appendix 2), several limitations were noted. The identified questionnaires were either designed for a specific type of technology or failed to cover all important aspects necessary to provide detailed information on user satisfaction with assistive, rehabilitation, and training technologies. Forty-six out of 117 identified questionnaires were completely custom questionnaires, intended for the specific device or population in the study, limiting their broader applicability. Eighty-nine out of 117 questionnaires were developed specifically for the needs of the study, including custom questionnaires, modified instruments for usability testing of specific devices, newly developed questionnaires, and translations of existing questionnaires. Only 23 out of 117 questionnaires were reported in more than a single publication. Among the identified questionnaires, 58 primarily evaluated usability, user experience, technology acceptance, or overall system performance rather than user satisfaction, with satisfaction represented by only a small number of items instead of a comprehensive multidimensional construct. Additionally, none of the questionnaires appeared to cover all identified satisfaction domains. Item-level analysis demonstrated that domains with similar labels (eg, design) frequently assessed different underlying constructs and therefore did not capture equivalent aspects of user satisfaction. The identified questionnaires were also developed and used for different technology categories: 84 for assistive, 23 for rehabilitation, 9 for assistive and rehabilitation, 1 for nontechnology-specific questionnaire, and none for training technologies (Multimedia Appendix 2). Although several questionnaires have subsequently been applied beyond their original context, they were not specifically developed for these broader applications. In addition, widely used generic instruments, such as the SUS, were designed as technology-independent usability measures rather than for evaluating hardware-based technologies that directly interact with the human body and therefore do not capture several device-specific aspects identified as important in this review. Overall, while the identified questionnaires provide valuable information on specific aspects of user evaluation, no single instrument was found to simultaneously (1) assess user satisfaction as its primary outcome; (2) comprehensively cover all identified satisfaction domains at the item level; and (3) be specifically developed for application across assistive, rehabilitation, and training technologies.

Therefore, we aimed to develop a questionnaire to comprehensively assess user satisfaction across different types of assistive, rehabilitation, and training technologies. The questionnaire was specifically designed to capture the perspectives of direct end users, including both individuals using or training with the technology and professionals such as physiotherapists, kinesiologists, personal trainers, and other health care providers involved in its operation and delivery.

The second phase of the development process focused on identifying key domains and generating items to evaluate user experience and satisfaction with assistive, rehabilitation, and training technologies. The initial version of the questionnaire consisted of 72 items divided into 7 thematic domains. Item generation was guided by the preceding literature review and further informed by the research team's prior experience in developing and evaluating similar technologies. The list of all identified items and related domains during the literature review is available in Multimedia Appendix 2 (Excel worksheet titled Items and Domains). Items were generated with the intention that each item should apply to at least one type of existing assistive, rehabilitation, or training technology. However, given that such technologies can differ significantly in their fundamental characteristics, not all items are relevant for every device. To address this, a set of initial screening questions was developed to be completed by the researcher or developer prior to administering the questionnaire. The responses to these screening questions are used to generate a tailored set of questionnaire items, selected according to the characteristics of the technology and the role of the end user (eg, patient, client, therapist, or trainer). Furthermore, the researcher or developer may manually adjust the recommended item set by adding or removing questions to ensure optimal relevance for the specific technology.

After the domains were identified and the items generated, a round of expert revision was conducted. Six experts with extensive experience in the design and evaluation of assistive, rehabilitation, and training technologies and 8 master's students in physiotherapy were recruited to evaluate each item independently as either "relevant" or "not relevant." Additional

XSL•FO
RenderX

information about the experts included in the expert consultation is presented in Table 1. For any item marked as not relevant, the recruited experts were asked to provide a brief explanation for their decision. Based on the results obtained, the questionnaire was revised, and items marked as not relevant were either removed or modified. Following the revision process, the questionnaire was evaluated by 2 English-language experts to ensure linguistic accuracy, clarity, and overall readability.

Table . Additional information about the expert panel included in the expert consultation.

ID	Years of work experience	Employer	Field of research/work
E1	23	National research institute	Collaborative robotics
E2	16	National research institute	Collaborative robotics
E3	9	National research institute	Humanoid and cognitive robotics
E4	20	Clinical institution	Rehabilitation medicine
E5	27	Higher education institution	Engineering design
E6	12	Industry/private sector	Sports products development

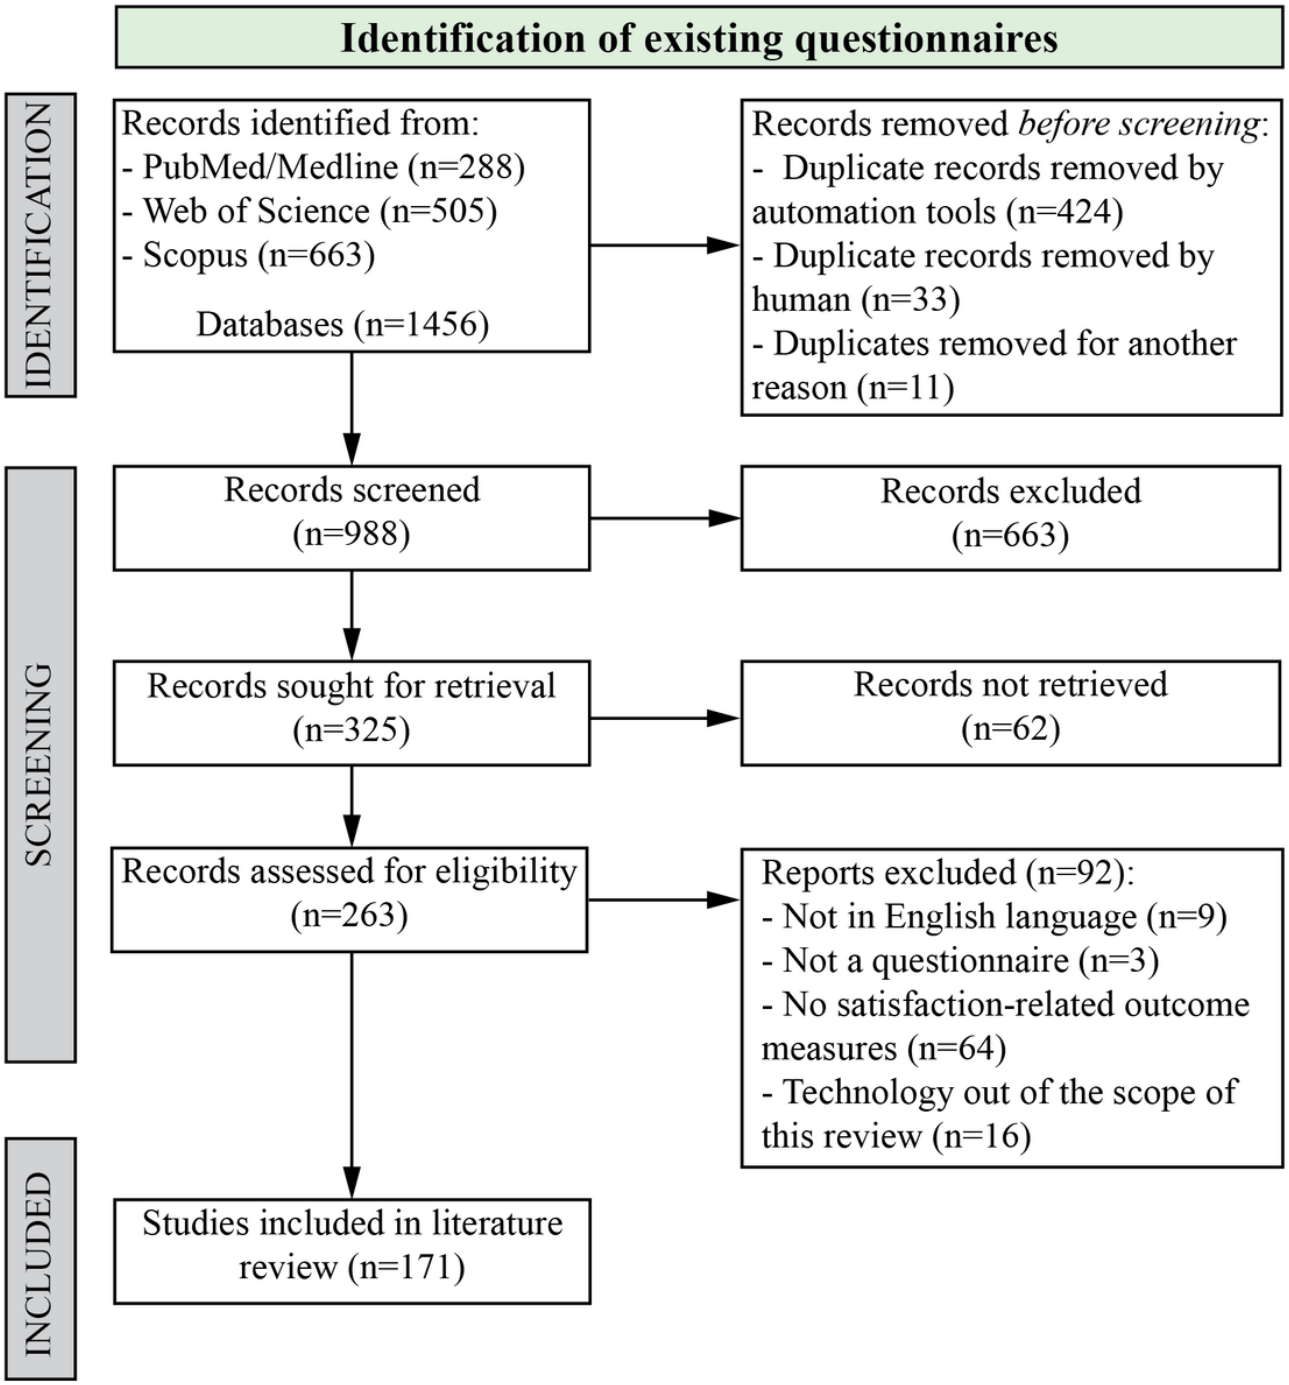
The final part of the development process was the evaluation of content validity. Content validity relates to the degree to which a sample of items constitutes an adequate operational definition of a concept [32]. To assess item content validity, another 8 experts in physiotherapy, kinesiology, and ergonomics were recruited. These experts were independent of the 6 experts involved in the previous stage of questionnaire development and had at least 5 years of experience in the development or use of assistive, rehabilitation, or training technologies. The participating experts were informed of the purpose of the questionnaire and its intended use to evaluate user experience and satisfaction with the assistive, rehabilitation, and training technologies. Each expert independently evaluated all items of the questionnaire on a 4-point Likert-type scale (1="the item is not relevant to the measured domain," 2="the item is somewhat relevant to the measured domain," 3="the item is quite relevant to the measured domain," and 4="the item is highly relevant to the measured domain"). The content validity ratio (CVR) was calculated for each item alongside the content validity index for each item (I-CVI) using equations 1 and 2, where n_4 represents the number of experts grading an item as highly relevant (grade 4), $n_{3,4}$ represents the number of experts grading an item as quite or highly relevant (grade 3 or 4), and N represents the total number of experts. Additionally, the average content validity index (Ave-CVI) was calculated as the average of the I-CVIs, representing the content validity of the overall instrument [33].

(1)CVR=(ne−N2)(N2)

(2)I-CVI=n3,4N

Items with a CVR below 0.75 and an I-CVI below 0.78 were reviewed and either revised or removed in accordance with the content validity criteria described by Lawshe [34] and Lynn [35].

Ethical Considerations



All participants received oral and written information about the study, were informed that participation was voluntary, and provided informed consent prior to participation. Participant confidentiality was ensured throughout the study. The study was approved by the University of Primorska Commission for Ethics in Research Involving Human Subjects (approval number: 4264-19-6/23) and was conducted in accordance with the principles of the Declaration of Helsinki.

Results

Following an initial literature review (the complete study selection process is illustrated in the PRISMA flow diagram Figure 2) and drawing on the research team's experience with similar technological developments, the first version of the questionnaire was developed, comprising 72 items divided into 7 domains. The identified domains were as follows: design (D), comfort (C), effectiveness and usefulness (EU), service (SE), treatment or exercise (TE), overall impressions (OI), and safety (SA).

XSL•FO
RenderX

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for the literature review.

Once the first version of the U-ART-Q was prepared, it was reviewed by 6 experts with extensive experience in the design and evaluation of assistive, rehabilitation, and training technologies and 8 master's students in physiotherapy. Based on their feedback, 2 items from design, 14 from comfort, 3 from service, and 1 from safety domain were either removed or merged with other items to reduce redundancy and improve clarity.

The refined version of the questionnaire was further reviewed and revised by 2 English-language experts to improve accuracy, clarity, and overall readability. Content validity was then assessed based on an evaluation by 8 experts in physiotherapy, kinesiology, and ergonomics. Of the 52 items, 44 met the predefined CVR values >0.75 and I-CVI values >0.78 and were therefore considered suitable for inclusion in the final questionnaire. The remaining 8 items, with CVR values <0.75 and I-CVI values <0.78, were subjected to additional review and are presented in Table 2.

XSL•FO
RenderX

Table . Items with CVR[a] or I-CVI[b] values below predefined thresholds and corresponding actions taken.

Item	CVR	I-CVI	Action
D9[c]: I am satisfied with the battery life of the assistive/rehabilitation/training technology.	0.5	0.75	Retained
D12[d]: I am satisfied with the design and appearance of the assistive/rehabilitation/training technology.	0.5	0.75	Retained
C6[e]: I am satisfied with the comfort of the contact point/points in the upper arm area.	0.5	0.75	Retained
C10[f]: I am satisfied with the comfort of the contact point/points in the wrist area.	0.5	0.75	Retained
SE2[g]: I am satisfied with the time needed to understand how the assistive/rehabilitation/training technology is supposed to operate/function.	0.5	0.75	Retained
SE4[h]: I am satisfied with the performance of the assistive/rehabilitation/training technology in the specified weather conditions.	0.25	0.625	Removed
OI3[i]: The assistive/rehabilitation/training technology is pleasant to use.	0.5	0.75	Retained
SA2[j]: I have experienced no anxiety when using the assistive/rehabilitation/training technology.	0.25	0.625	Removed

[a]CVR: content validity ratio.

[b]I-CVI: item-level content validity index.

[c]D9: item number 9 from the design domain.

[d]D12: item number 12 from the design domain.

[e]C6: item number 6 from the comfort domain.

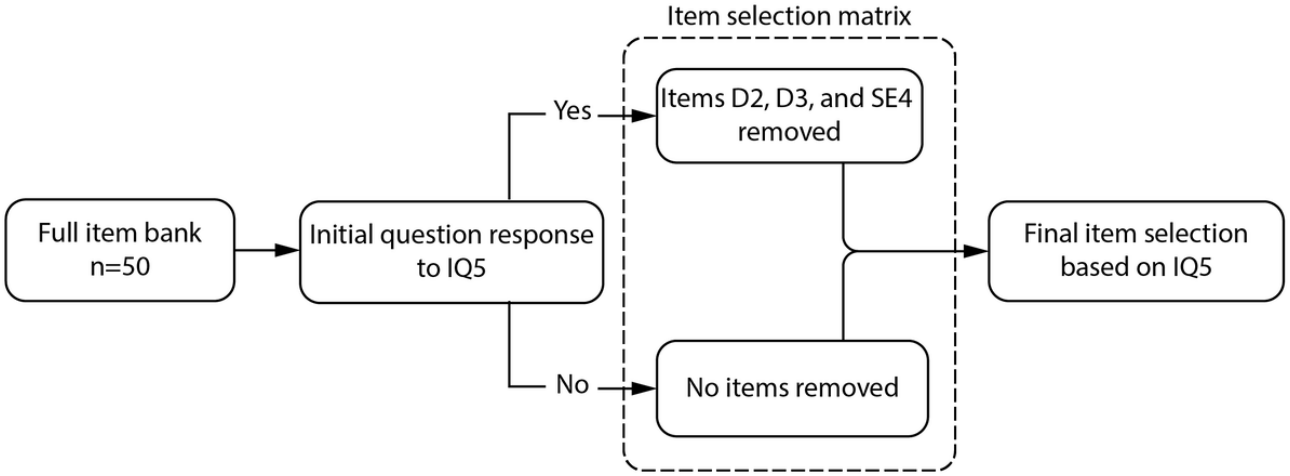
[f]C10: item number 10 from the Comfort domain.

[g]SE2: item number 2 from the service domain.

[h]SE4: item number 4 from the service domain.

[i]OI3: item number 3 from the overall impressions domain.

[j]SA2: item number 2 from the safety domain.



Following this review, 6 of these items were retained because they represented important aspects of the construct that were not adequately covered by other items. For example, although item D9, which refers to battery life, had CVR and I-CVI values below the predefined thresholds, it was retained because battery life was considered a highly relevant aspect of user satisfaction with technologies that operate on battery power [36]. Item D12, related to satisfaction with the appearance of the device, was retained, as satisfaction with appearance was identified in the literature as an important factor influencing user satisfaction, product abandonment, adoption, and long-term use [37-39]. Additionally, items regarding the appearance of the device were identified in 31 questionnaires during the literature review; therefore, this item was retained as part of the design domain. Items C6 and C10 were retained because all other items related to comfort at the contact points were rated as relevant. Because the upper arm or wrist may be the only contact points for some technologies, eliminating these items would limit the applicability of the questionnaire across different types of technologies. Regarding the retention of item OI3, the rationale was that user satisfaction encompasses the user's emotional response arising from interacting with a product or system. Therefore, perceived pleasantness represents an important affective dimension of satisfaction and was considered essential to retain in the questionnaire. The current definition of satisfaction in ISO 9241-11:2018 [40] explicitly encompasses users' physical, cognitive, and emotional responses, while ISO/IEC 25019:2023 [41] identifies user satisfaction as an emotional and hedonic outcome in which a pleasant, positive subjective experience is essential. In contrast, item SA2 was removed, even though anxiety was included as an item in some satisfaction questionnaires. The decision to remove this item was based on the fact that anxiety is a distinct psychological construct for which dedicated instruments exist, whereas

XSL•FO
RenderX

U-ART-Q is intended to assess satisfaction. There are many other standardized tools, such as the Abbreviated Technology Anxiety Scale (ATAS), Computer Anxiety Rating Scale (CARS), Technology Assisted Rehabilitation Patient Perception Questionnaire (TARPP-Q), and the General Anxiety Disorder 7-item screening tool, developed for the comprehensive assessment of technophobia and anxiety symptoms [42-45]. The item assessing satisfaction with the performance of the training technology under the specified weather conditions (SE4) was identified in only a small number of questionnaires, and insufficient evidence was found in the literature to justify its retention. Therefore, the item was removed. After removing these 2 items (SA2 and SE4), the final Ave-CVI, calculated across the remaining 50 items, was 0.915, which is above the acceptable standard reported in the literature. A complete list of all 10 initial screening questions and the final 50 items of the U-ART-Q is provided in Multimedia Appendix 3.

An additional set of 10 initial screening questions was created to determine the applicability of specific items based on the type of technology being evaluated. These initial questions are completed by the researcher who intends to use the questionnaire and are designed to identify which items are relevant, depending on the technology and the end user. Final questionnaire items are selected using the question selection matrix that is available in Multimedia Appendix 4. Each column of the matrix represents one possible response to an initial screening question, and each row represents 1 final questionnaire item. For each selected response, the corresponding matrix column is applied as a filter: items coded as 1 are retained, and items coded as 0 are excluded from the final questionnaire. Figure 3 illustrates the selection process for one of the screening questions. When the response to IQ5 is "Yes," the final questions Q4, Q5, Q39, and Q40 are removed, while all remaining items are retained.

Figure 3. Example of the item selection process for initial screening question number 5 (IQ5).

Items in the developed questionnaire are formulated in such a way that they can be graded on a 5-point Likert scale. The items can be graded as 1="strongly disagree," 2="disagree," 3="unsure," 4="agree," and 5="strongly agree."

To support the practical implementation of the item-selection process, a macro-enabled Excel tool (.xlsm) was developed and is provided in Multimedia Appendix 5. The purpose of this tool is to automatically generate the final set of questionnaire items based on responses to the initial screening questions. The tool is organized into separate worksheets. The worksheet named "Instructions" provides a step-by-step guide on how to use the Excel file to generate the final item selection. The "Initial_Questions" worksheet allows the user to select the responses to the initial questions from a drop-down list, thereby minimizing the possibility of incorrect entries. After all responses to the initial questions have been selected, the user can click the "Create_Final_Question Selection" button. The final questionnaire is then generated in the "Final_Item_Selection" worksheet. Following review, the generated U-ART-Q questionnaire can be exported as a PDF, printed, and used in practical applications.

Discussion

Principal Findings

HCD is a vital component of the product development process, ensuring that technologies are designed around the actual needs, abilities, and expectations of end users. In assistive, rehabilitation, and training technologies, HCD promotes usability, accessibility, and satisfaction by actively involving end users throughout the design, testing, and implementation phases. A key component of HCD is usability testing, which provides critical insight into how users interact with a product and identifies barriers to effective use. Failing to include usability testing at different stages of development can result in technically advanced products that do not meet user expectations, leading to poor acceptance, limited adoption, and ultimately unsuccessful implementation.

Although several relevant questionnaires were identified in the literature, none was considered fully suited to the specific purpose and scope of this study. Therefore, this study introduces the newly developed U-ART-Q and evaluates its content validity. It serves as a complementary tool for evaluating user satisfaction with assistive, rehabilitation, and training technologies. The items and domains for the initial version of the questionnaire were identified through a comprehensive

XSL•FO
RenderX

literature review. The preliminary set of items and domains underwent expert validation, which resulted in the removal or merging of 20 items to reduce redundancy and improve clarity. To further enhance linguistic accuracy, clarity, and overall readability, the revised questionnaire was reviewed and refined by 2 English-language experts. Finally, 8 additional experts with backgrounds in physiotherapy, kinesiology, and ergonomics participated in the content validation process. Out of 52 items, 44 met the predefined CVR and I-CVI thresholds and therefore met the predefined criteria for content validity. The remaining 8 items with CVR and I-CVI values below the recommended thresholds were reviewed further, resulting in the removal of 2 items from the item bank. Finally, the remaining 50-item questionnaire achieved a high Ave-CVI of 0.915, demonstrating strong evidence of content validity based on expert evaluation.

The proposed U-ART-Q represents a newly developed questionnaire with evidence of content validity for assessing user satisfaction within the domains of assistive, rehabilitation, and training technologies. To ensure its relevance across a broad range of technologies, the researcher or developer administering the questionnaire first completes a set of initial screening questions that guide item selection. This approach allows the instrument to be tailored to the specific characteristics of the technology being evaluated, making it both concise and practical for use across diverse assistive, rehabilitation, and training technologies.

The proposed questionnaire offers several important contributions to both research and practice. For researchers and clinicians, it is intended to serve as a structured and efficient evaluation tool for existing technologies, allowing user satisfaction to be compared across different devices, applications, and user groups. Its use can contribute to a more comprehensive understanding of user experience, leading to more informed decisions regarding device selection, clinical implementation, and future product improvement. For developers, the questionnaire provides a structured and standardized tool for collecting user feedback throughout the design process. It helps identify usability issues early and supports evidence-based design decisions. By systematically capturing satisfaction across multiple domains, the instrument can help optimize the development process by reducing redesign costs and improving the functionality of technologies under development. As user satisfaction and experience are closely linked to successful technology implementation, the results may also help clinical managers and other stakeholders compare available market options and support the decision-making, selection, and purchasing of technologies.

Future work will focus on further validation and practical application of the questionnaire. Pilot testing will be conducted to evaluate reliability, internal consistency, and test-retest reliability, and validated translations of the questionnaire into Serbian and Slovenian will be completed. Although a macro-enabled Excel tool (.xlsm) has been developed to support automated item selection, which is provided in Multimedia Appendix 5, the development of a mobile app or a web-based version of the questionnaire is planned to facilitate simple, time-efficient, and cost-effective administration in clinical and research settings.

Limitations

The development of the U-ART-Q has several limitations. First, the existing literature did not provide a comprehensive conceptual framework that specifically describes the multidimensional structure of user satisfaction with assistive, rehabilitation, and training technologies. Consequently, the domains and items of the U-ART-Q were informed by findings from the literature, existing questionnaires, expert consultations, and the research team's experience in developing similar technologies. Although the experts involved had substantial experience in relevant fields, expert-based evaluation is inherently subject to some degree of subjectivity. Different expert panels could have reached different conclusions regarding the relevance, wording, or importance of individual items.

Additionally, it is important to point out that the U-ART-Q is a newly developed questionnaire with initial evidence of content validity. No actual end users were included in the development or content-validation process, which represents an important limitation, particularly because the questionnaire is intended to assess user satisfaction. As such, the U-ART-Q should undergo further evaluation before it can be considered a fully validated and standardized instrument for assessing user satisfaction with assistive, rehabilitation, and training technologies. In line with recommended questionnaire-development procedures, important next steps include face validity assessment with intended users, pilot testing, evaluation of construct validity (through exploratory and confirmatory factor analysis), reliability testing, and establishment of a clear scoring system and interpretation of the results [46].

Conclusions

In conclusion, the U-ART-Q is a newly developed questionnaire with evidence of content validity. Its main objective is to support researchers and developers applying HCD principles in the evaluation and development of assistive, rehabilitation, and training technologies. The questionnaire is intended to complement existing methods of assessing user experience, including interviews, focus groups, and observational approaches. By integrating this quantitative measure with qualitative methods, the U-ART-Q can contribute to more informed, iterative, and end user–driven design processes. Future work will focus on further psychometric evaluation needed to determine whether the U-ART-Q can be established as a validated and standardized questionnaire for assessing user satisfaction with assistive, rehabilitation, and training technologies.

Abstract

Background: Communication is an essential component of participation. Communication impairment restricts full participation for children who have unintelligible speech. A vocal cord vibration switch offers an avenue for meaningful interaction to children who cannot rely on speech or voluntary limb movement but have some control of their vocal cords. Previous evaluations of the vocal cord vibration switch have been conducted primarily with adults and adolescents. However, implementation of a vocal cord vibration switch with younger, school-aged children in their natural environmental contexts can potentially foster the development of early communication skills.

Objective: This case series evaluated the appropriateness and impact of a vocal cord vibration switch, the "Hummingbird" (Holland Bloorview) with school-aged children who have complex communication needs and their mothers and teachers, using an individualized, collaborative, and iterative assistive device implementation protocol.

Methods: The Hummingbird was evaluated with 3 school-aged children, across educational and health-related contexts, over a 2-year period. Baseline, midterm, and final assessments took place at home or school in the first year with a follow-up assessment in the second year. In addition to field observations and device performance assessments by the research team, feedback from mothers and teachers was collected via questionnaires (Pictorial Children's Effort Rating Table, Quebec User Evaluation of Satisfaction with Assistive Technology, and the Family Impact of Assistive Technology Scale) to ascertain the Hummingbird's appropriateness and its impact.

Results: Appropriateness data indicated the suitability of the Hummingbird across settings. Compared to the child's prestudy devices, mother and teacher participants reported that the physical effort required by all 3 children to use the Hummingbird was lower (scores on the Pictorial Effort Rating Table decreased from 8 and 11 to scores of 4 - 6). The switch efficacy assessment of the Hummingbird indicated moderate-to-high specificity and high sensitivity at midterm and high sensitivity (0.91 - 0.94) and specificity (0.92 - 1) at final assessments. Total satisfaction scores increased from baseline (prestudy device) to the 2-year assessment for all 3 children. While data on the impact on family and communication were incomplete for 1 participant, generally favorable effects were reported. The field notes underscored the value of an individualized protocol, where the implementation and evaluation phases were adapted to accommodate the health-related characteristics (eg, seizure disorder and sleep deprivation), evolving school contextual factors (new school and teacher), and unique family environments (involving the child participant's toddler-sibling in Hummingbird sessions).

Conclusions: Overall, the Hummingbird was appropriate across home and school settings for our case study participants, all of whom had complex communication needs. The device was well-received by children and their mothers or teachers, providing an effective, setting-agnostic option for communication support. Modifications to both the device and its implementation process were required to address unanticipated health, family, and school challenges.

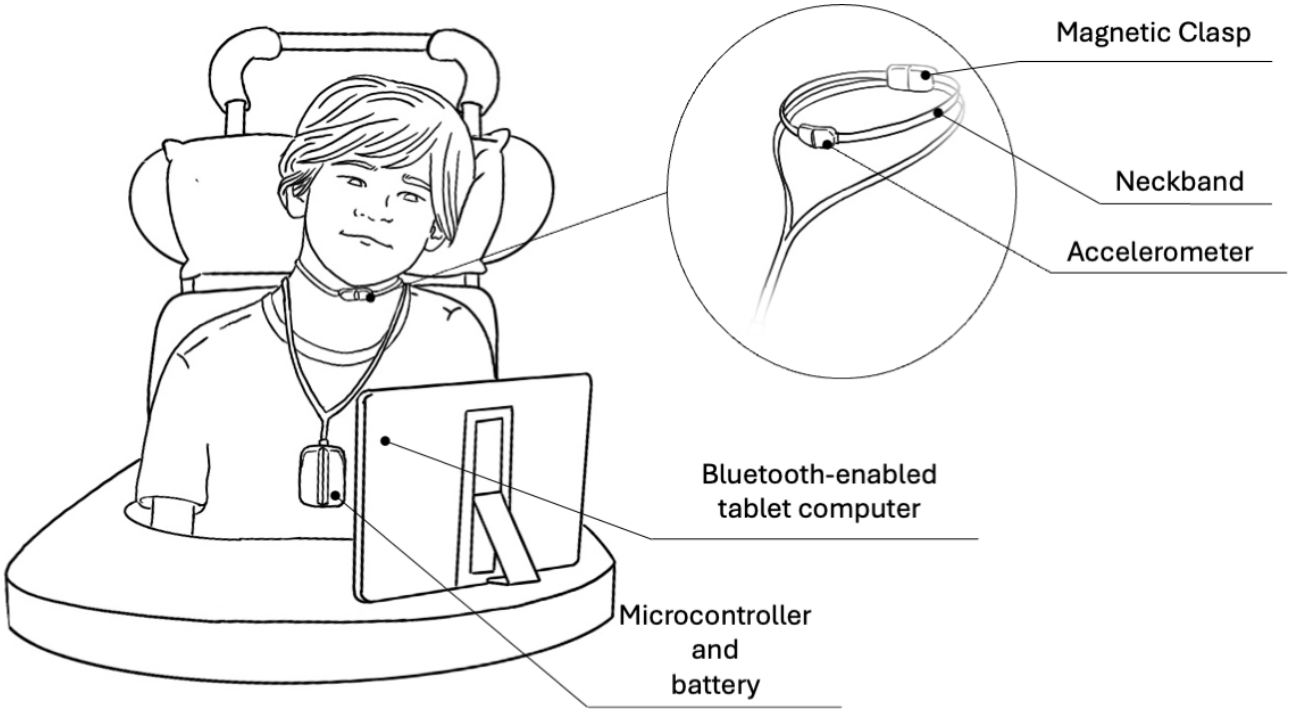
Introduction

Communication impairment is associated with limited participation in children with complex disabilities [1,2]. Participation, defined as the engagement in all facets of life, has been identified as an essential outcome for children with disabilities [3,4]. Full and effective participation demands being on an equal basis with others and transcends home, school, health, and community environments. This engagement facilitates quality of life [5] and development [6], allowing children to realize their potential [4]. While communication is one of the core components of participation, communicative impairment has been associated with participation restrictions for children with unintelligible speech [1,3,4].

Augmentative and alternative communication (AAC) systems can enhance communication and, ultimately, participation for children with complex needs [7,8]. Electronic AAC systems produce speech via technology external to the child's body [9,10]. For children who have physical limitations that restrict direct access to electronic AACs via touch, an accompanying access technology is necessary. An access technology consists of a sensor that captures the child's intent from a physical movement, vocalization, or physiological indicator and a processing unit that translates the detected intent into a corresponding control signal [11]. A vocal cord vibration switch, one type of access technology, provides an avenue for meaningful interaction to children who cannot rely on speech or voluntary limb movement but have some control of their vocal cords. This switch consists of a sensor, positioned over the vocal cords, to detect periodic vibrations resulting from the child's vocalizations, which are translated into an output signal for computer control [12].

Previous evaluations of the vocal cord vibration switch have been conducted primarily with adolescents, adults, and children older than 8 years [12-15]. Intervening with AAC as early as possible allows for the opportunity to foster children's communication skills and establish their participation potential earlier in their development [10]. School-aged children, particularly those with complex disabilities, rely heavily on their family members and teachers to facilitate social engagement. As parents and teachers play an integral part in these children's participation by defining the opportunities to participate [3], engaging them in the implementation is essential [16]. Furthermore, in previous studies, the vocal cord vibration switch was evaluated over trajectories of 4 months or less. Offering children and their communication partners more time to use the vocal cord switch with support may encourage device adoption [17,18] and enable an evaluation of their experiences later in their trajectory. Finally, these assessments focused on the function of the Hummingbird and did not address the environments in which it would be used.

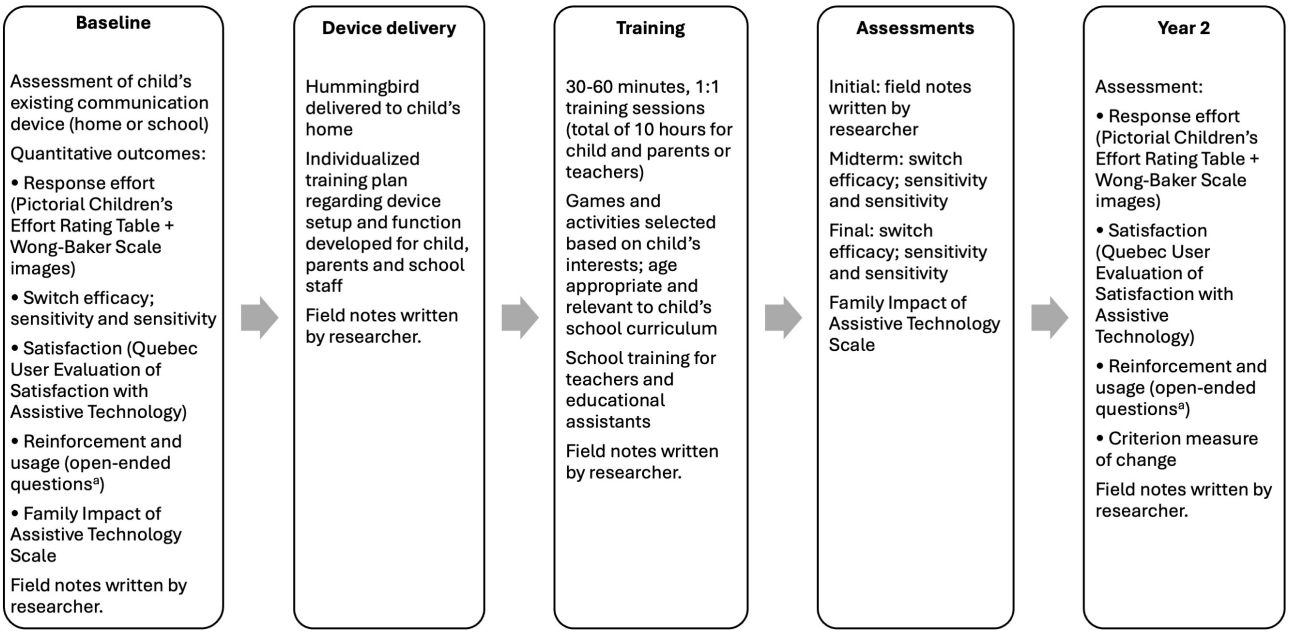
Accordingly, the purpose of this longitudinal case series was to evaluate the appropriateness and impact of the implementation of a vocal cord vibration switch with school-aged children who have complex communication needs in their natural environments (home and school), based on a collaborative, iterative, child- and family-centered protocol. Mothers' and teachers' perceptions of effort exertion, satisfaction, engagement, and psychosocial impact were measured. Device appropriateness was also assessed by the research team, and observations of process and progress were recorded in field notes. Temporal changes were measured across contexts (home and school) over a 2-year assessment period to allow for ongoing support and assessment after the initial introduction of the vocal cord vibration switch.



Methods

Overview

In this 2-year multiple case series, a vocal cord vibration switch, the "Hummingbird," was introduced to 3 school-aged children, guided by the Assistive Technology Delivery Protocol (ATDP) [19,20]. The ATDP informs the introduction and adoption of assistive technology for children who have severe disabilities and encourages device adoption by focusing on the compatibility of the technology with the needs of the users, while ensuring standardized training protocols, multidisciplinary inclusion, and an iterative assessment process. The Hummingbird consists of a dual-axis accelerometer, which is held in place on the child's neck proximal to the vocal cords using a neckband. The sensor is connected to a microcontroller box, where input vocal cord vibration signals are monitored and analyzed to detect short- or long-duration intended sounds (ie, voiced sounds or hums; Figure 1).



XSL•FO
RenderX

Figure 1. The Hummingbird device worn by a child, interacting with a computer through intentional vocal fold vibrations. The neckband is fastened by a magnetic clasp around the child's neck. A control signal is transmitted to the tablet computer whenever an intentional vocal fold vibration is detected.

For this implementation, assessments across multiple time points were conducted, including a follow-up assessment (year 2; Figure 2). In the baseline session, assessments of the child's existing communication device were conducted at home or the participant's school, according to the preference of the family. Following the baseline assessment, the Hummingbird was delivered to families at home, and an individualized training plan was developed by the research team to include the children's teachers and parents. The training plan was informed by the child's family, caregivers (personal support workers, nurses, or additional family members), and hospital-based occupational therapists or speech-language pathologists. Device training for the children occurred in 30 to 60 minute, one-on-one sessions for a total of 10 hours over a 10 to 20-week time frame and involved games and activities that were age-appropriate and of interest to the child. A school integration phase consisted of training for teachers and/or educational assistants. No researcher involvement occurred in year 2 except for a check-in to determine if the children were still using the Hummingbird and to complete a subset of the outcome measures.

Figure 2. Overview of implementation and assessment sessions. [a]Open-ended questions for reinforcement: On average, how many attempts does the child make to activate the Hummingbird before he or she is successful? Is there any delay between when the Hummingbird is activated and when the child perceives a response from the technology? Is there any delay or lack of response from the communication partner?

Ethical Considerations

The study was approved by the research ethics board of the Holland Bloorview Kids Rehabilitation Hospital (eREB0291) and each of the participating school boards. To be eligible for the study, a participant had to meet the following criteria: (1) aged at least 4 years, (2) did not have an access pathway or had an existing access pathway that was deemed inappropriate as per International Organization for Standardization (ISO) 9241‐9, (3) understand cause and effect, and (4) have voluntary control over their vocal cords in a manner that generated a measurable vibration.

Additionally, one of the parents (or guardians) of the participant as well as his or her teacher had to possess English competency at no less than a grade 6 level and had to commit to the training workshops.

Participants were recruited by self-referral via the hospital website or through a therapist or teacher. A participant was deemed competent to provide consent if the participant had a reliable access pathway associated with a communication interface (AAC device, iPad with AAC application, or computer with AAC software) that allowed him or her to express his or her complete understanding or could use partner-assisted scanning to express his or her full understanding.

If the potential participant was deemed competent to provide consent, at the initial meeting, the principal investigator or co-investigator explained the study to the potential participant and his or her legal guardian. The potential participant was subsequently asked to explain to the researcher the purpose of the study and his or her involvement in his or her own words using his or her current mode of communication. If the potential participant appeared to understand and was able to provide responses with reasonable accuracy for all questions, he or she was asked to sign consent forms for participation in the study. If the potential participant could not provide answers that were accurate with his or her current mode of communication, he or she was asked to provide assent, and his or her legal guardian was asked to provide written consent. Assent was obtained by both a researcher and the family in order to ensure that the participant understood that he or she could opt out at any time. The participant was also reminded on a weekly basis that he or she did not have to participate if he or she did not want to.

If the potential participant did not meet competency criteria, the consent process followed as described above except that the participant was asked to provide assent, and his or her legal guardian was asked to provide written consent. Where applicable, the participant's teacher and educational assistant or assistants provided written informed consent to participate in structured communication partner training. All participants were compensated for their time according to institutional research ethics board guidelines.

Appropriateness and Impact

Four concepts were measured to evaluate the appropriateness of the vocal cord switch: (1) response effort; (2) switch efficacy; (3) mother or teacher satisfaction; and (4) reinforcement and usage. Response effort refers to the amount of physical and cognitive effort required to use the Hummingbird [19]. It was measured using a modified Pictorial Children's Effort Rating Table (PCERT), consisting of effort descriptors, and a 6-level scale ranging from 0 (very easy) to 5 (very hard), with total scale scores ranging from 0 to 20 [21] and the Wong-Baker scale images [22]. The PCERT has yielded valid and reliable measures of effort with typically developing children [21,23]. In previous studies, scale scores have been moderately to highly correlated with objective measures of effort (Pearson r=0.54‐0.87), demonstrating concurrent validity of the scale at various levels of effort intensity [21], and the scale has demonstrated sufficient test-retest reliability (intraclass correlation coefficient=0.77) [23]. The PCERT was modified to use the images from the Wong-Baker pain scale, as cartoon faces ranging from happy to sad were considered more meaningful to children in wheelchairs than depictions of a child climbing stairs.

Switch efficacy represents a measure of effectiveness as defined by ISO 9241‐9; it was assessed using a switch-accessible game that required low cognitive effort and had unambiguous correct and incorrect responses for both the mother or teacher and the child [18]. The game also provided clear auditory and visual feedback to the child. Each child had 3 training sessions with the game to familiarize themselves with the task. Switch efficacy was based on researchers manually recorded data during the game and calculated using two equations: (1) specificity=true negatives/(true negatives+false positives); and (2) sensitivity=true positives/(true positives+false negatives). The specificity of a vocal cord vibration switch reflects the extent to which the device rejects the user's unintended vocal sounds (eg, a cough) while the sensitivity is the device's ability to correctly identify intended vocalizations. Based on previous evaluations of the efficacy of the Hummingbird with comparatively older children (aged >9 y), we anticipated that the 3 school-aged children in our series would achieve similar performances of specificity between 90% and 100% and sensitivity between 65% and 80% [13-15].

The Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST 2.0) was used to assess caregivers' satisfaction with assistive technology on a 5-point Likert scale ranging from 1 (not satisfied at all) to 5 (very satisfied). A total scale score and 2 subscale scores (Assistive Device and Services) are generated [24,25]. The QUEST 2.0 has been used extensively with clients of all ages, and it has been used to elicit parents' [26] and health professionals' [27] perceptions of their satisfaction with their child's assistive technology. Psychometric evaluations of the QUEST 2.0 have yielded acceptable levels of internal consistency (Cronbach α=0.74‐0.79) [28]. Furthermore, moderate correlations between subscales of the QUEST 2.0 and the Psychosocial Impact of Assistive Devices Scale [29] have been reported (Pearson r=0.34‐0.45), supporting the concurrent validity of the scale [30].

To evaluate the performance of the Hummingbird, the rate of reinforcement (attempts required to activate the Hummingbird) and the immediacy of reinforcement (delay from technology or communication partner) were assessed by asking mothers and teachers open-ended questions (Figure 2). In addition, technology usage was determined by asking them to estimate

XSL•FO
RenderX

the frequency of usage of the Hummingbird. Responses were recorded by the researcher.

The impact of the Hummingbird was assessed using two questionnaires. The Family Impact of Assistive Technology Scale (FIATS-AAC) detects the multidimensional effect of assistive device use on families with children with disabilities [31]. The purpose of this parent-reported questionnaire is to evaluate the functional effects of AAC systems on the lives of children and their families. It consists of 89 items, comprising 13 domains (7 child-related domains and 6 parent-related domains). Item scores are averaged to yield a domain score between 1 and 7. Higher scores suggest positive functional effects within a specific domain, and overall total scale scores range between 13 and 91. It has high internal consistency (Cronbach α=0.91) and test-retest reliability (intraclass correlation coefficient =0.95) [32]. Furthermore, its concurrent validity was supported as demonstrated by moderate agreement with a measure of family functioning (Pearson r=0.54) [33].

The Criterion Measure of Change Questionnaire [34] measures respondents' rating of the change in their child's communication since the commencement of Hummingbird with 3 ordinal categories (worse, no change, and better), as well as the extent and importance of this change on 7 levels ranging from a score of 1 ("a tiny bit") to 7 ("a very great deal").

Field Notes

In addition to the administration of the quantitative measures, field notes were written. These notes, which were constructed by the researchers after each interaction with the children, mothers, and teachers, were unstructured and included observations of: the performance of the technology and the child, study and child or mother or teacher progress, communication with the child's mothers, teaching staff and clinicians, and protocol implementation. The notes were compiled and analyzed using a manifest content analysis [35,36], which relies on the face value of the words written by the researcher and requires the use of preconceived categories for initiating and guiding the analysis. These categories included the following: the child's health and communication characteristics and needs, the benefits and disadvantages of the child's existing communication technology at study entry, the child's experiences with using the Hummingbird (child's likes and dislikes, successful strategies for encouraging use, and activities performed), challenges in using the Hummingbird specific to the child and mother or teacher, problem-solving, and device training and Hummingbird use at year 2. The field notes were grouped into units (sentences or phrases written by the researcher) within each of these categories, and then further organized by concepts (eg, successful strategies) within the category (eg, experiences with using the Hummingbird). This deductive approach allowed for a rich description and provided context to the child's use of the Hummingbird at their home and school, over time.

The purpose of the field notes was to provide context, that is, to identify aspects of the technology or the environment that can improve and support the child's use of the technology. They are useful beyond the study context in that they provide perspective on the aspects of the implementation and evaluation process that may need to be customized for individual children in future studies.

The ATDP [19,20] was used as a framework to design and guide the implementation and assessment process for this case series. The choice of questionnaires and the conceptual anchors for the field notes were guided by the ATDP, specifically the extent to which the Hummingbird meets the overall communication needs of the children. According to this protocol, successful Hummingbird adoption relies on the extent to which the technology is appropriate for each individual child. Appropriateness is defined as the efficiency, effectiveness, and satisfaction associated with the Hummingbird. Furthermore, the impact of the Hummingbird on the child and the family is essential to its success. The extent to which the Hummingbird is aligned with the characteristics of the children, mothers, and teachers is ultimately dependent on achieving a good match between the child and the Hummingbird within their given environment (school and home). The likelihood of this match is strengthened by the guidance of the ATDP.

Results

Herein, the field notes are presented among the results from the quantitative measures to provide context and detail. The clinical and demographic characteristics of the 3 child participants appear in Table 1.

Table . Demographic characteristics of child participants.

Child	Age[a] (y)	Sex	Diagnoses	School	Sensory function (vision; hearing)	Cognitive function
Eve	7	Female	Hydrocephalus	Special education classroom	Some impairment; no impairment	Some impairment
Jameel	5	Male	Cerebral palsy spastic quadriplegia	Home-schooled	No impairment; no impairment	No impairment
Zach	6	Male	Global developmental delay and epilepsy	School	Cortical visual impairment; no impairment	Significant impairment

Field Notes: Participant Description and Rationale for Hummingbird Introduction

At the start of the study, Eve was aged 7 years and attended a congregated public school for children with physical disabilities. In school, she used button-type switches (BIGmack button device) [31] with her hands, requiring a lot of assistance, demonstrating little accuracy, and experiencing a lot of fatigue. Her fatigue increased as the day progressed. Eve could control her head movements but had difficulty maintaining a steady head position, which resulted in her head dropping forward or to the side. She would vocalize when excited, happy, or upset. Accompanied by facial expressions, these vocalizations were used by parents and teachers to attempt to interpret what she was trying to communicate. She was able to verbalize the words "mama," "papa," and "hi," and communicate with facial expressions and sounds that only familiar communication partners could understand.

Jameel enrolled in the study at the age of 5 years and was home-schooled. At that time, he had been attempting to use a Tobii eye-gaze system [32], but the high tone of his muscles made it difficult for him to hold his head in one position, even with physical head support. As such, he found it challenging to maintain a dwell long enough for the eye-gaze system to activate the desired choice on the screen. Jameel had good voluntary control of his voice. The Hummingbird was considered a potentially appropriate device for him, as it does not require head stability, and he possessed the vocal control for activation. It was hoped by his parents that he would be able to combine the eye-gaze system and the Hummingbird.

Zach was aged 6 years and attended a specialized school for children with disabilities at the start of the study. It was difficult for Zach to control his limbs and head, and he experienced frequent seizures. He had previously tried to use button-type switches (BIGmack button device) by controlling them with his hand and head, but he found them too tiring. He was able to indicate 'yes' using a simple non-word vocalization ('ah'). This vocalization had been used to elicit answers using partner-assisted scanning and a communication book. However, his family reported that the pictures in the communication book were challenging for him to discern due to his cortical visual impairment. Zach's family expressed a desire for an appropriate technology for him so that he could demonstrate his comprehension and answer questions in the classroom, as it was otherwise difficult for him to display his capacity for learning and understanding class material. Zach did not have the first-year final assessment for the FIATS because he was not using the Hummingbird at home, only at school during the first year. The Criterion of Change was also missing for this participant.

Field Notes: Observations During Sessions

Eve really enjoyed music and as such, it was used as the initial basis for her switch training. She began with errorless activities where she had to activate the Hummingbird to hear the next verse of a song and moved on to timed options where she would activate her Hummingbird to sing a repeating line from a song at the correct time. She often needed prompting to "wait" for the correct time to activate, but this need for prompting reduced over time. There were several interruptions to Eve's participation in the study as she changed schools and school boards multiple times throughout the study. After consultation with one teacher, choice-making during circle time activities was chosen as the focus for classroom training for Eve.

Jameel progressed very rapidly from simple cause and effect exercises to games that required precise timing. At the start of the study, he was working with his mother (who was also his home-school teacher) and an educational assistant, with a home visit approximately once per week from a member of the research team. One of the main challenges for Jameel was finding activities that motivated him; he could easily become bored with an activity that was presented in a repetitive fashion. This made evaluation of the switch efficacy quite challenging—after just 1 or 2 trials of a game, he sometimes refused to play more. Despite his excellent performance with the Hummingbird, the study progressed more slowly for Jameel due to personal and family illnesses, leading to a hiatus of approximately 4 months. Even after the break, however, Jameel quickly regained proficiency in the use of the Hummingbird. In addition, Jameel's family had been limiting their use of the Hummingbird to prevent Jameel's toddler sibling from pulling and/or breaking the device wires. Jameel started using a wireless version of the Hummingbird, which became available midway through the study, and his use of the Hummingbird increased after this change. With the new wireless Hummingbird, Jameel was playing games in addition to controlling switch-activated toys that also engaged his sibling.

During Hummingbird training, Zach was motivated by music, astronauts and space, and any activities involving his family members. He was also motivated by helping others, so the research team would reframe simple games as him "helping" the character move through the story or activity. Auditory cues were used as often as possible to reduce his need to rely on his vision; bright colors on a dark background were used as these were easiest for him to see. Zach had sleep difficulties, which often required him to sleep during the day. Occasionally, he would fall asleep during his sessions or struggle to stay awake. On the days when he was well-rested, the time required for him to coordinate a response to scanning choices was 2 to 3 seconds, compared to 15 seconds when fatigued. In addition, he had frequent absent seizures. At times, the research team was unsure if he was processing his answer or temporarily unaware of the task due to seizure activity. Zach would begin a session in an alert state but could then become fatigued partway through. On good days, a quick "warm-up" using a short errorless game, followed by the actual task, seemed to give shorter response times. When he was fatigued at the start, the researchers tried to preserve his energy as much as possible for the actual task.

Appropriateness and Impact: Response Effort (PCERT)

Table 2 presents effort levels, as reported by a mother or teacher, for the baseline assessment when the child was using their baseline or non-Hummingbird device and those for the year 2 assessment. The reported perceived effort required to use the Hummingbird by all three of the children was lower than the effort required for their previous device. The largest temporal

XSL•FO
RenderX

change was for the physical effort required by Jameel's mother, decreasing from the maximum effort of 5 to 2.

Table . Response effort scores[a].

	Eve		Jameel		Zach	
	Baseline[b]	Year 2	Baseline[c]	Year 2	Baseline[b]	Year 2
Respondent	Teacher	Teacher	Mother	Mother	Mother	Teacher

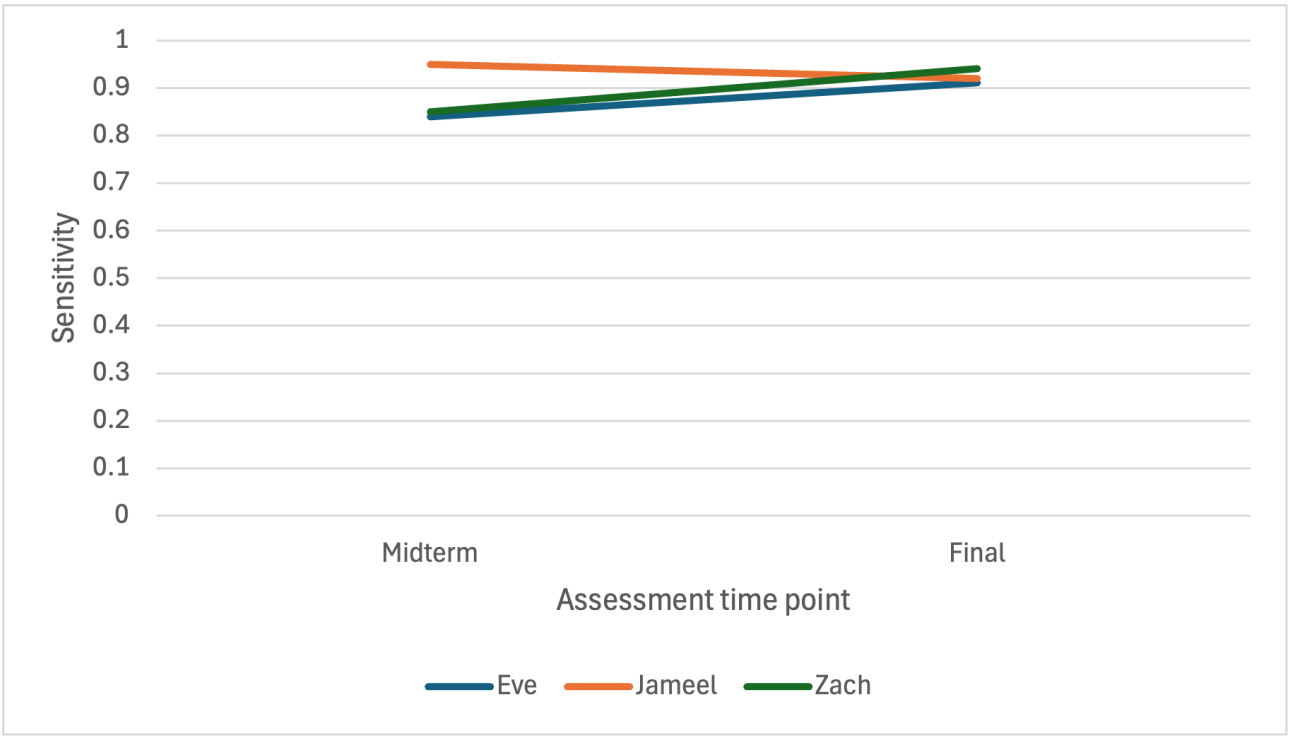
Hummingbird-Switch Efficacy



Figures 3 and 4 display switch efficacy at the midterm and final assessments for all 3 children. The Hummingbird demonstrated very high specificity (0.9 and 1) and sensitivity (0.8 and 0.9) for Eve at both the midterm and final assessments. For Jameel, specificity at the midterm was moderate (0.7) but increased in the final assessment (0.9). Finally, very high sensitivity at both midterm (0.9) and final (0.9) assessments was obtained for Zach, and a relatively low specificity at the midterm (0.5), which improved to a very high level for the final assessment (0.9).

Figure 3. Switch specificity at midterm and final assessments.

XSL•FO
RenderX

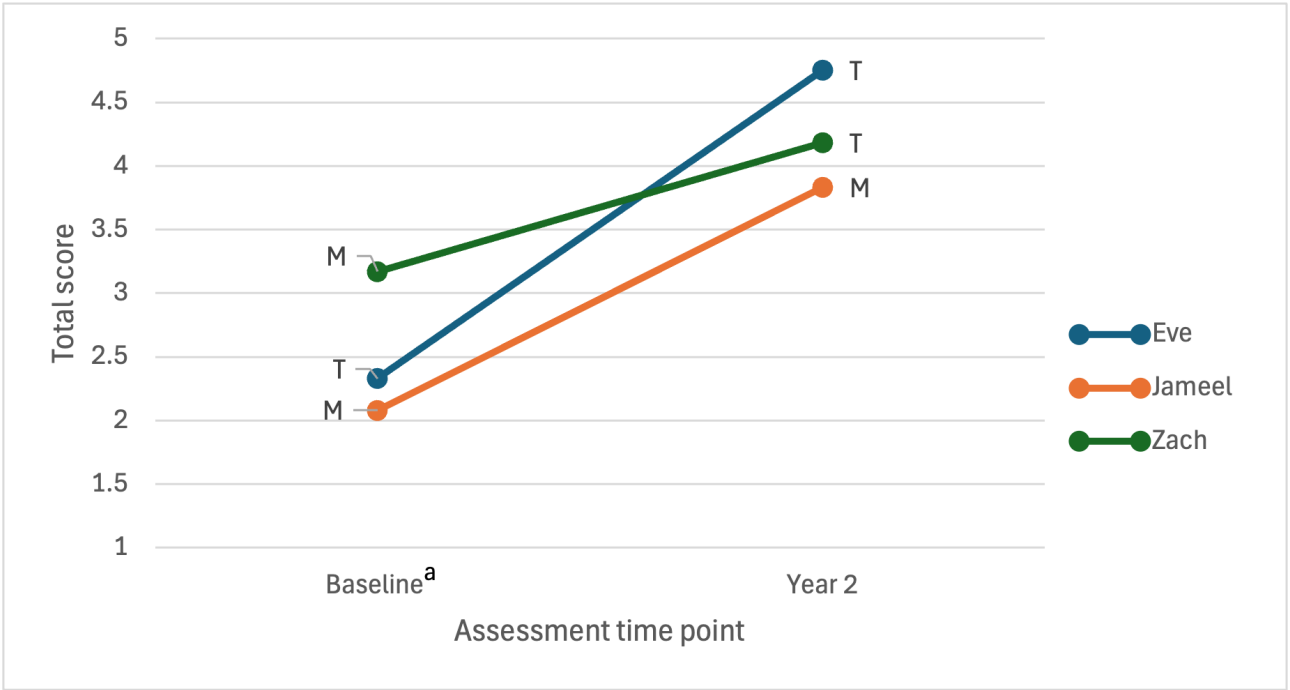


Figure 4. Switch sensitivity at midterm and final assessments.

Quebec User Evaluation of Satisfaction With Assistive Technology

Satisfaction ratings by teacher or mother participants increased from baseline (using a non-Hummingbird device) to year 2 for all 3 participants (Figure 5). All 4 respondents (2 teachers and 2 mothers) rated "easy to use" and "effectiveness" as being one of the top 3 most important items. "Professional service," "comfort," and "dimensions" were each reported by 2 respondents.

Figure 5. Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST 2.0) total scores for baseline and year 2 (Hummingbird; 1="not satisfied" to 5="very satisfied"). [a]Eve and Zach using the BIGmack button device, and Jameel using the Tobii eye-gaze at baseline. T: teacher report; M: mother report.

Rate and Immediacy of Reinforcement

The immediacy of reinforcement with the Hummingbird was consistent across the 3 participants, with no delay from the technology during their year 2 evaluation (Table 3). The usage of the Hummingbird, as reported by mothers and teachers, was lower than that of her previous device for Eve. Due to inconsistency in reporting, comparative usage is difficult to

XSL•FO
RenderX

determine for Jameel and Zach. In Table 3, immediacy of response *from the technology* refers to whether there was a delay between activating the device and the intended output (ie, the Hummingbird responding via message output). On the other hand, immediacy of response *from the communication partner* refers to any delay between the time the child used the Hummingbird to communicate (eg, made a choice or requested something) and the time at which their communication partner acknowledged the message. In this latter context, no delay meant that the communication partner (eg, mother or teacher) acknowledged the message and desired action as soon as the child "says" it.

Table . Reinforcement and device usage at baseline and year 2 assessment.

	Eve		Jameel		Zach	
	Baseline (BIGmack)	Year 2 (Hummingbird)	Baseline (Tobii)	Year 2 (Hummingbird)	Baseline (BIGmack)	Year 2 (Hummingbird)
Respondent	• Teacher	• Teacher	• Mother	• Mother	• Mother	• Teacher
Usage	• 2 times per day for 30 minutes each • Weekly total: 420 minutes	• 3 days per week for 25 - 40 minutes each • Weekly range: 75 - 120 minutes	• 5 days per week for 10 - 30 minutes • Weekly range: • 10 - 150 minutes	• Varied from: once daily for 5 days per week for months to not being used for months • Weekly rate: 5	• 2 times per day at home and school • Weekly rate: 14	• Minimum 1 time per day for a few minutes to share a short message • Weekly minimum: 35 minutes
Rate of reinforcement	• On some days, 2 attempts and other days, 3 - 4 attempts to hit switch—depends on mood+health	• Activates every time	• 1 attempt for playing games • Many attempts for communication	• With practice, 2 attempts	• Needs prompting or hand over hand to start, then uses without difficulty	• 1 attempt when device is working properly (ie, tuned to the user's vocal fold vibration), otherwise several attempts
Immediacy of reinforcement	• No delay	• No delay from either technology or communication partner	• Delay from technology when used for communication • No delay from communication partner	• No delay from technology	• Delay in activating—quicker for the child to vocalize than hit the button	• No delay

Impact

Table 4 presents scores for Eve and Jameel for baseline and final assessments, as reported by their mothers. An increase in scores over time indicates gains (positive functional effects) in dimensions from baseline to final for Jameel. The "face-to-face communication" domain increased from 2.4/7 at baseline to 5.1/7 for the final assessment. The "doing activities" domain also increased from 2.6 to 3.8. No temporal change in the overall score was observed for Eve. Only 2 domains increased for Eve over time, namely, scores from 3.6 to 4.3 for "contentment" and scores from 3.8 to 4.3 for "family roles," otherwise, her domain scores decreased (doing activities and security) or remained the same.

In year 2, the Criterion Measure of Change Questionnaire, which rates a child's communication on 3 ordinal categories (worse, no change, and better), indicated that both Eve's and Jameel's communication was rated "better" than when they entered the study (baseline). The extent of this improvement was quantified as 2/7 and 4/7, and the importance of this change as 3/7 and 7/7 for Eve and Jameel, respectively.

XSL•FO

Field Notes: Observations at Year 1 Completion

By the end of the training phase, both Eve and her teacher were comfortable with choice-making activities. Eve really enjoyed vocalizing to talk or sing along, so the Hummingbird switch was only vigilant (ie, turned on) when she was being asked to make a choice. At those times, she could calm herself and wait for the option she wanted. This selective use of the Hummingbird was adopted to avoid the frustration of excessive accidental activations when she wanted to expressively communicate through her vocalizations. Eve would become excited for sessions and wanted to vocalize a lot. If she was in an excited state, the researcher would give her time at the beginning of the session to just play, activating her switch as much as she wanted, before asking her to relax and calm herself to do the activity. The teacher also waited patiently for her to reach her calm state before presenting her with choices.

By the end of the first year, Jameel was using the Hummingbird with the eye-gaze system and appeared to find it easier than using the Hummingbird alone with a scanning-based communication grid on a tablet. His mother reported that it was easier for him to combine the 2 access methods rather than relying solely on switch scanning with his communication grid on his tablet. He was exploring spelling and sentence building using predictive text, with the assistance of his educational assistant. Depending on his level of motivation for an activity, he could often use his set-up to select from multiple choices independently. At this point, Jameel's toddler sibling had also spontaneously begun to model for him, attempting to get his attention by humming and pointing at the Hummingbird while saying, "My turn!"

Zach's sleep difficulties and seizures made some of the evaluations difficult. When the research team was unsure whether Zach was processing his answer or temporarily unaware of the task due to seizure activity, more frequent indirect prompting was used when the time to produce a response seemed especially prolonged. Indirect prompting included presenting Zach with a visual cue or picture, telling him that something was expected (eg, "Now what?" or "What's next?") and using body language (eg, questioning hand motion). The team learned to carefully observe signs of increased effort, as Zach could start a session alert but become fatigued partway through. During some of the switch efficacy testing sessions, he struggled with fatigue and falling asleep; his behavior during those sessions did not reflect the team's observations in other sessions.

Discussion

Principal Findings

This case series evaluated the appropriateness and impact of a vocal cord vibration switch with children aged 5 to 7 years across home and school settings, according to the ATDP. Despite some challenges related to the children's health and environment such as fatigue, school changes, and illness, the results from this evaluation lend support for the use of the Hummingbird for school-aged children with complex communication needs. Overall, the implementation of the

XSL•FO
RenderX

Hummingbird with 3 school-aged children was successful, and mothers and teachers responded positively to supporting its use at home and school.

Appropriateness and Impact

In our case series, we observed higher sensitivity rates at both midterm and year 2, and similar percentages of specificity compared to 2 previous evaluations of the Hummingbird that were conducted over a shorter evaluation period with children who were primarily older. In 1 study with 2 children aged 5 and 9 years, the average specificity of the Hummingbird was 98.1% and 98.8%, respectively, and the average sensitivity was 73.3% and 80%, respectively [15]. Furthermore, previously reported sensitivity percentages for a child aged 12 years using the Hummingbird were 60% and 65% at 8 and 16 weeks, respectively, and specificity percentages similar to ours were reported at >90% [20]. Switch efficacy levels with children aged 5 to 7 years in our study are similar to those observed with older users, thus supporting the use of the Hummingbird with a variety of age groups. For the youngest participant, Jameel, who was aged 5 years at study entry, the Hummingbird correctly identified his intended vocalizations at a higher or similar rate as older users. As with any efficacy evaluation, the results can be affected by dynamic factors specific to the child or user at the time of any given assessment; for example, fatigue was such a factor for 1 participant in our case series as well as for 1 child in a previous implementation [15].

We observed that mothers' and teachers' response effort scores on the PCERT decreased for all 3 children from baseline, indicating that the perceived physical effort exerted by the child was lower when using the Hummingbird compared to their prestudy communication device. It is noteworthy that this decrease in effort was observed during the year 2 assessment when regular support and contact with the research team had concluded. Ease of use of an AAC has been reported in previous studies as an important determinant of parent satisfaction [39] and device use [40]. Furthermore, literature indicates that parents report device abandonment when the effort to use the device is too demanding [17].

Measuring parents' and teachers' satisfaction is essential, given that dissatisfaction with an AAC system is 1 factor leading to device abandonment [17]. Our satisfaction results suggest that the mothers and teachers in our evaluation had a higher level of satisfaction with the Hummingbird compared to the child's previous device. Teachers' and mothers' satisfaction ratings increased from baseline to the year 2 assessment for all 3 children (scores ranging from 3.8-4.8). Similarly, in a previous case study, an individual aged 19 years also reported higher satisfaction with the Hummingbird (score=4.6) compared to a sound-based device [12]. Furthermore, in another assessment of the Hummingbird with a girl aged 12 years with cerebral palsy, similar QUEST 2.0 scores (4.0 and 3.5 at 8- and 16-wk postdevice introduction, respectively) were reported by her occupational therapist [20]. Our data thus support the applicability and usability of the Hummingbird with younger children than previously documented.

Device reliability is an important factor in preventing device abandonment [41]. In this case series, the quality of reinforcement evaluation indicated that, overall, the children were able to activate the Hummingbird more reliably, with fewer attempts and no delay compared to their previous prestudy device. The assessments during year 2 of the study revealed that all 3 children had continued to use the Hummingbird after the main study period.

Family impact scores on some of the FIATS domains for Eve and Jameel did not change from baseline, using their non-Hummingbird device, to the final assessment after months of using the Hummingbird. Overall, Jameel's total scale scores indicated a moderate increase in the positive functional effects with the Hummingbird (from 40/91 to 53/91) and no change in total functional effects for Eve. Perhaps because Jameel was home-schooled, his mother may have observed more of an effect on family functioning. In addition, Jameel's sibling started to play games with him while he was using the Hummingbird, which may have resulted in a greater overall impact on family functioning.

It is critical that AAC systems are designed for the individual to optimally facilitate communication and promote sustained user engagement [18]. In this study, personalization involved changes to the Hummingbird itself as well as to the process aspects of the protocol. The field notes provided insight into the characteristics of the children and their environments and permitted an iterative approach whereby adjustments to the training, implementation, and evaluation processes were made during the study. For example, the researcher (or researchers) explored different activities with each child; for example, Zach excelled when engaging in activities that involved helping people. A wireless version replaced Jameel's original Hummingbird to address the needs of his family environment. These customizations encouraged engagement in subsequent sessions with the three children as well as offering a guide to the implementation process in future work.

Previous research in the broader AAC literature has supported the importance of training communication partners; effective partner training promotes the communication abilities of individuals with complex communication needs [18,42]. Despite this important element, most studies have excluded AAC training for parents and siblings of children with multiple disabilities.

Value of Multisite Inclusion and Individualized Implementation Approach

Challenges are inherent in the implementation process of a device for children who have complex, co-existing conditions that compound their existing activity limitations. In our case series, the child participants differed from one another as they had a variety of health, social, family, and school context characteristics. The successful longitudinal implementation of the Hummingbird with these 3 school-aged children resulted from a comprehensive, individualized approach, including adjusting and modifying both the technology and the protocol, to meet the needs of the child and the child's environment. For example, changing to a wireless device for Jameel was essential to encourage continued use of the technology when his brother was present.

XSL•FO
RenderX

As purported by the ATDP, training and support by the team ensure a child-specific approach that recognizes and adapts to the technology user, including elements of their physical and social or family environment. Of priority to our implementation was the inclusion of key players from each of the child's environments. Furthermore, based on the ATDP, device training and implementation were individualized and embedded into the participants' daily lives and natural environments, while evaluation was semipersonalized, such as affording the child the choice of a game. Inclusion of the school setting in the implementation, attention to training, and quality of service delivery are indicators of users' and caregivers' satisfaction as well as device adoption [42-46].

Contextualization Within Existing Literature

The development and initial evaluation of the vocal cord vibration switch have been described previously [13-15]; these previous evaluations were conducted over shorter time periods (0.5 - 4.0 mo), primarily with adolescents, adults, and children older than 9 years and focused on the physical aspects of the Hummingbird, its reliability, and the ease of set-up for parents and teachers. The results from these earlier assessments informed a more formalized switch training process, the design of the neckband and its positioning, and the decision to use a questionnaire assessing family impact in the case series. In contrast, this case series measured the impact of long-term use in the child's natural environment.

Fundamentally, our findings indicate that the Hummingbird can afford a pathway through which a child can access switch-controllable technology, inclusive of communication, mobility, and environmental devices. From the perspective of the International Classification of Functioning, Disability and Health for Children and Youth framework [3], our results suggest that via the Hummingbird (environmental facilitator), children's vocal cords (body structures) can be accessed by amplifying vocal fold vibrations (body function) to expand independent, intentional switch control (activities) within their given setting (environmental participation conditions). Environmental conditions included barriers such as a child's fatigue during sessions and school changes, as well as motivators such as music or a sibling joining in on a game. In turn, such technology-facilitated switch activations can augment children's participation in communication, interpersonal interactions, education, and directing their own care (specific participation domains).

Limitations

The assessment time points did not always follow the intended trajectory. For reasons of illness and family health issues, which reflect the reality of many families with children with multiple disabilities, some of the assessments were not conducted at the intended times and/or were not completed. Furthermore, some of the questionnaires were not completed at certain time points, resulting in missing data for the FIATS and the Criterion of Change for Zach. However, given the case series design, the results were interpreted individually rather than by making quantitative comparisons across participants. Furthermore, in instances where 1 assessment was missed, data from other time points were available, permitting nonetheless a temporal view of children's and families' experiences. Future studies may consider a different measure of family impact catered more toward children who are developing basic communication skills, such as expressing preferences.

For some data collection questionnaires, 2 different respondents (ie, mother and teacher) provided the assessment for a given child participant, based on who was present in the assessment session and where it took place (home or school). For both the response effort and QUEST 2.0 measures, scores were provided by a child's mother at 1 session and a teacher at the subsequent session. This may have confounded the potential temporal changes in an outcome. Nonetheless, we arrived at a comprehensive assessment of the Hummingbird by deploying a variety of measures to capture the perspectives of multiple key informants in the training, use, and assessment phases of our protocol. Subsequent studies may consider mixed methods designs and associated integrated analyses that allow for informant-specific data sources [47].

Usage reporting was varied. Mothers' reports regarding the usage of both the child's prestudy device and the Hummingbird were unstructured (Table 3). As a result, the usage data varied in terms of how mothers reported use by units of time. To overcome this limitation, future research may consider invoking automatic logging of Hummingbird usage to objectively capture time and duration of use, the number of activations, and the functional application.

Conclusions

Across home and school environments, the Hummingbird was appropriate for 3 school-aged children with complex communication needs as indicated by their low response effort, high scores on switch efficacy and immediacy of reinforcement, and strong caregiver satisfaction. The impact was generally favorable in familial and communication realms for the 2 participants with complete data. Participants encountered unanticipated health, family, and school challenges during the study, which necessitated modifications to the device and the implementation protocol. Future studies should consider a more expansive set of impact measures in light of these real-world circumstances.

Acknowledgments

The authors would like to thank the families and children for generously participating in the protracted protocol of this study.

Funding

This research was supported by the Accessible Technology Program, Ministry of Innovation, Science & Economic Development Canada (Grant #511898). The study was funded for a 2-year period for CAD $311,111.

Abstract

Background: Physical inactivity among people with disabilities and older adults is a persistent public health concern, particularly those from racial minority groups living in underserved communities where structural barriers limit access to exercise opportunities. Technology-driven exercise programs offer scalable solutions, but the contextual factors that influence their uptake, fidelity, and sustainability remain underexplored.

Objective: This study applied the Consolidated Framework for Implementation Research (CFIR) to identify barriers, facilitators, and lessons learned during the implementation of 2 technology-driven group exercise programs—synchronous online fitness and active virtual reality gaming—delivered to predominantly African American older adults with disabilities and/or chronic health conditions in an underserved community.

Methods: Using a multimethod design, we conducted semistructured interviews and focus groups with program participants, staff, and administrators (n=15) and administered implementation surveys to program deliverers (n=9). Qualitative data were analyzed deductively using CFIR domains and constructs, while survey data provided descriptive context.

Results: Both programs achieved high acceptability and appropriateness scores, with feasibility rated slightly lower for virtual reality. Themes mapped to 4 CFIR domains (innovation, outer setting, inner setting, and individuals). Qualitative analysis identified adaptability, affordability, engaging design, and community support as key facilitators, while barriers included technology and space constraints, resistance to new technology, and sustainability challenges.

Conclusions: Technology-driven exercise programs can expand access to physical activity in underserved communities when they are adaptable, affordable, and socially engaging. Addressing multilevel barriers, including resource limitations, technology hesitancy, and long-term sustainability, is critical to scaling and sustaining these interventions.

Introduction

Despite the known health benefits of being physically active, people with disabilities report high levels of physical inactivity. Reports worldwide indicate that approximately 54% to 91% of adults without disabilities meet physical activity recommendations, compared with only 21% to 60% of people with disabilities [1]. In the United States, 1 in 4 adults is living with a disability [2], and sedentary people with disabilities are 3 times more likely to report primary health conditions such as heart disease, stroke, diabetes, or cancer compared to active people with disabilities [3]. Furthermore, physical inactivity exacerbates loneliness and social isolation, which are also associated with adverse health outcomes, including heart disease and stroke [4]. Of concern is that individuals with disabilities are not only physically inactive but often experience higher levels of social isolation and loneliness than persons without disabilities [5]. Together, these disparities underscore the urgent need for effective, inclusive strategies to promote physical activity among people with disabilities.

Barriers to physical activity for people with disabilities span multiple levels of the socioecological model, including individual (eg, lack of knowledge, physical limitations, pain,

XSL•FO
RenderX

and fatigue), interpersonal (eg, lack of social support), institutional or organizational (eg, lack of accessible fitness facilities and exercise equipment), community (eg, poorly designed outdoor spaces and street connectivity), and systemic (eg, limited or no transportation) factors [1,6-10]. These multifactorial barriers limit opportunities for people with disabilities to engage in effective and sustainable physical activity and are further compounded in underserved communities—those characterized by racial and ethnic health disparities, high poverty rates, low insurance coverage, and limited health care and physical activity resources—underscoring the need to address physical activity barriers within the socioecological framework [11,12].

Technology-driven physical activity [13] and health promotion programming can help eliminate many of these barriers by delivering accessible, scalable interventions that foster social engagement and a sense of community [14-17]. Recent systematic reviews and meta-analyses demonstrate that mobile and wearable technologies, telehealth-delivered exercise, online fitness programs, and interactive gaming platforms can increase physical activity levels and improve body composition and physical function, with consistent benefits shown across home-based and community settings [18-20]. Telehealth programs have shown improvements in physical functioning even among individuals with frailty, cognitive challenges, or mobility limitations, highlighting the value of remote delivery for populations facing barriers to traditional exercise access [21]. Adherence to technology-based exercise is generally favorable when programs are accessible, engaging, and designed to meet participant needs [22]. Interactive and game-based technologies further extend reach and appeal: virtual reality (VR) exergame programs have been shown to improve balance, mobility, and functional outcomes in older adults, including those living in long-term care, while enhancing enjoyment and motivation to be active [23-25]. Work by Malone et al [15,26] demonstrates that adults with mobility impairments can engage with adapted exergaming systems—such as modified Wii Fit balance boards and gaming mats—to achieve greater energy expenditure and report high enjoyment, suggesting these technologies can reduce barriers and support participation in meaningful movement. Additionally, online membership–based fitness programs have shown feasibility and preliminary effectiveness for increasing physical activity in people with mobility impairments [27]. Collectively, this body of evidence supports the use of technology-driven physical activity interventions as accessible, engaging, and adaptable options for promoting physical activity and supporting health in populations traditionally underserved by conventional exercise models.

Although technology-mediated exercise shows promise, evidence of efficacy and feasibility alone is insufficient to ensure successful deployment in resource-limited settings. To translate and sustain such programs in underserved settings, it is essential to examine multilevel determinants of implementation. Implementation science offers a structured approach to understanding and addressing contextual factors that influence the uptake, fidelity, and sustainability of health interventions [28]. The Consolidated Framework for Implementation Research (CFIR) provides a comprehensive, validated taxonomy for assessing contextual factors that influence implementation success across 5 domains: outer setting, inner setting, innovation, implementation process, and individuals [29,30]. Using a framework like the CFIR ensures that barriers and facilitators are identified and addressed in a structured, reproducible manner, strengthening both the science and practice of health promotion program delivery in underserved settings. The CFIR has been used to identify implementation barriers and facilitators of physical activity interventions for older adults and people with disabilities [31-33], and in a systematic review of community-based physical activity interventions [34]. However, research on technology-driven exercise interventions in underserved communities remains limited.

To address this gap, this study used the CFIR to identify facilitators, barriers, and lessons learned during the implementation of 2 technology-driven group exercise programs (synchronous online fitness and VR exergaming) delivered to older adults (aged >60 y) and individuals with disabilities and/or chronic health conditions living in an underserved community. Our primary aims were to (1) characterize the CFIR constructs that most strongly influenced each program's implementation outcomes and (2) compare implementation team member perspectives (program staff, administrators, and participants) on technology-specific and context-specific challenges and enablers. By leveraging a validated implementation framework, this work examines how technological and contextual factors shape program delivery in underserved communities and informs strategies to translate and sustain effective technology-based exercise in traditionally under-resourced settings.

Methods

Study Design and Setting

Overview

This study followed a multimethod research design, whereby the core of the research was qualitative, utilizing in-depth interviews and focus groups, and was supplemented by a minor quantitative component in the form of a brief survey provided to program staff and administrators. We chose both methods not for the purpose of triangulation or formal mixing of qualitative and quantitative paradigms, but rather for complementarity and expansion [35], allowing the survey data to offer a broader, descriptive overview of factors associated with the Lakeshore Online Fitness (LOF) and VR program implementation and the rich qualitative data to provide deep context.

This research was a retrospective evaluation of 2 technology-based interventions deployed between July 2022 and October 2022 at a neighborhood recreation center located in an underserved community (population <5800; ≈50% Black, ≈15% Hispanic or Latino; ≥25% living below the federal poverty line; 1 in 4 uninsured; 1 in 4 with a disability). The synchronous online fitness program was deployed in partnership with a local nonprofit organization that provides physical activity, recreation, and sport programs for people with physical disabilities and chronic health conditions (Lakeshore Foundation). For the VR program component, content- and age-appropriate (ie, limited

XSL•FO
RenderX

violence or foul language) active video games were identified by research staff. The LOF and Get Active with VR programs were delivered on-site at the municipal recreation facility building. Program recipients were current members of the recreation center's senior programs who met the following eligibility criteria: (1) aged 18 years or older, (2) self-reported a physical disability or health condition, (3) aged 60 years or older regardless of health condition, and (4) were not enrolled in any other physical activity program. All successfully screened participants provided informed consent prior to enrollment. Sessions for both programs were held twice a week, lasted 60 minutes, and included a warm-up, main activity, and cooldown. Participants completed 6 weeks of each program (LOF or VR) in a randomized crossover design using alternating assignments to either the LOF (Figure 1) or VR program (Figure 2).

Figure 1. Participants engaging in the "Lakeshore Online Fitness" program.

XSL•FO
RenderX

Figure 2. Participants engaging in the "Get Active with Virtual Reality" program.

Lakeshore Online Fitness

Online classes were delivered via Zoom (Zoom Communications, Inc) from Lakeshore to the municipal recreation facility [27,36]. Exercise dose was based on the predetermined length of online classes provided by Lakeshore, and frequency was based on scheduling needs at the recreation center. An instructor from Lakeshore taught all classes, and a community facilitator (staff or volunteer) and research team member oversaw the on-site group activity.

Get Active With Virtual Reality

Oculus Quest 2 headsets were used for the VR program. A community facilitator and research team member oversaw VR classes. For each session, program recipients would choose to play a predetermined game individually or competitively against other participants. Exercise dose and frequency were matched to those of the LOF program.

Study Participants

This research study used convenience sampling techniques to identify factors related to program implementation. Our sample size was determined by the availability of respondents and met minimum guidelines for thematic analysis [37,38]. We gathered input from individuals who (1) participated in the LOF and/or VR programs and (2) played a role in program implementation and/or delivery. Invitations for interviews were extended to program recipients who completed the LOF and VR programs (n=10). Invitations for focus groups were extended to 2 LOF instructors, 2 Lakeshore Foundation administrators, 1 recreation center administrator, 1 recreation center program staff member, and 2 community volunteers (n=9). The recreation center staff member's primary role was to help with the physical setup for LOF, assist participants during classes, and take down program equipment. Both community volunteers were recruited through the University of Alabama at Birmingham Center for the Study of Community Health to act as community liaisons, assist with classes, and identify potential new locations for implementation of the programs. These volunteers also helped with the physical setup for the VR program, assisted participants during classes, and took down program equipment.

Ethical Considerations

The University of Alabama at Birmingham Institutional Review Board approved this study (IRB-300008762), and all program participants provided written informed consent before taking part, which included agreement to participate in the study and permission for their images to appear in photos used in the study. Program participants received US $15 for completing the interviews. Data were stored on encrypted, password-protected servers accessible only to the research team.

Data Collection

Quantitative

Administrators, program staff, and volunteers involved in implementing the LOF and VR programs were invited to complete an online survey assessing accessibility, appropriateness, and feasibility of the two programs in October 2023. The Acceptability of Intervention Measure (AIM), Intervention Appropriateness Measure (IAM), and Feasibility of Intervention Measure (FIM) surveys were completed by all

XSL•FO
RenderX

9 relevant staff members and administrators. The AIM assesses the "perception that a given treatment, service, practice, or innovation is aggregable, palatable, or satisfactory," the IAM evaluates the "perceived fit of the innovation to address a particular issue or problem," while the FIM measures the ease at which a "new treatment or innovation can be successfully used or carried out within a given agency or setting." [39] Each measure consisted of 4 thematic questions, with 5 responses ranging from completely disagree to completely agree on a 5-point Likert scale [40]. Outcomes for the LOF and VR programs were assessed separately. Scores for each scale range from 4 to 20 and were classified as low (<12), medium (12-15), and high (>15) [40].

Qualitative

Program participants took part in one-on-one, semistructured interviews at the recreation center in January 2023 after completing the intervention. A CFIR-informed interview guide, developed in collaboration with the study principal investigator (LAM) and interviewer (WNN), was used to gauge perceptions of the most important factors influencing implementation of the 2 programs for older adults and people with disabilities in underserved communities. Interview guide questions focused on the individual, innovation, and inner setting domains of the CFIR (Multimedia Appendix 1) [29].

A separate CFIR-informed focus group guide was developed to capture staff members' opinions about barriers, facilitators, and lessons learned from implementation of the programs (Multimedia Appendix 2). Focus group questions covered the innovation, outer setting, inner setting, and implementation process domains of the CFIR [29]. Two semistructured, in-depth focus groups and 1 interview were carried out. The first focus group (n=3) included the recreation center program staff member and two community volunteers who helped set up and deliver the LOF and VR programs. The second focus group (n=3) comprised LOF fitness instructors who delivered the LOF program and 1 Lakeshore Foundation senior staff member. The focus group with recreation center staff and volunteers was conducted in person at the community center where participants completed the programs, while the focus group with LOF program deliverers and senior staff was carried out in person at the Lakeshore Foundation in November 2023. One Lakeshore Foundation senior staff member was unable to attend the focus group session, so they completed a follow-up, one-on-one, semistructured interview online in December 2023. Interviews and focus groups were completed with 79% of program participants and relevant staff and volunteers.

Data Analysis and Rigor

Survey data and participant characteristics are summarized using descriptive statistics. Means and SDs are reported for the continuous variables (ie, age and AIM, IAM, and FIM surveys), while categorical variables (ie, race and sex) are presented as frequencies and percentages.

All qualitative data were coded and organized using NVivo 14 (Lumivero). In the first stage of analysis, the Zoom recordings were transcribed verbatim using a professional transcription service (Landmark Associates, Inc), with time stamps at the beginning of each response and speakers labeled as interviewer or interviewee to ensure clarity and anonymity of the content. The first author became familiar with the data by listening to the audio recordings and repeatedly reading the transcripts. The data were then analyzed using a deductive content analysis approach, following the 3-phase guide outlined by Elo and Kyngäs [41], which includes preparation, organization, and reporting. During the preparation phase, it was decided that sentences, phrases, and themes from the transcripts would serve as the units of analysis to capture both detailed content and broader thematic patterns. Both manifest (explicit, surface-level content) and latent (underlying meanings) content were coded, allowing for a more nuanced understanding of factors influencing implementation. A deductive approach was chosen to align the identified themes with the CFIR domains and constructs, facilitating a theory-driven analysis of implementation factors.

In phase 2 of the qualitative analysis, a structured categorization matrix based on the 5 CFIR domains and 39 constructs was developed to guide organization and interpretation of themes. The first author then reviewed the data for content and coding based on correspondence with the predetermined domains and constructs. In phase 3, results were synthesized by identifying the most frequently reported themes. To ensure accurate alignment with CFIR constructs, the first and second authors reviewed and refined the synthesized results, confirming that each theme was appropriately categorized and all relevant data were considered. Integration occurred during the interpretation phase, where the survey results were used to provide supplementary context and illustration for the core qualitative themes. In this analysis, the main findings remain rooted in the qualitative evidence and are organized by facilitators and barriers, specific CFIR domains, and subthemes that correspond to the CFIR constructs [29].

To ensure quality and rigor, the evaluative markers coherence, transparency, and substantive contribution were selected from Smith and Caddick's [42] ongoing list and can be found in Table 1. At the time of data collection, the first author (WNN) was a predoctoral student in health behavior with formal training in qualitative research methods. With nearly a decade of experience working with individuals with chronic health conditions and no prior involvement in the study's program delivery portion, she brought an outsider perspective. The second author (LAM) has been involved in several qualitative studies related to physical activity and disability and served as a "critical friend" throughout the process. This role involved reviewing the first author's interpretations of the data and providing feedback on the accuracy and consistency of the coding and categorization process. Rather than reach an agreement, this collaborative, reflective approach was intended to generate nuanced and multifaceted interpretations of meaning.

XSL•FO
RenderX

Table . Evaluative markers chosen for quality and rigor.

Marker	Definition	Application
Coherence	The way that different parts of the interpretation create a complete and meaningful picture.	Demonstrated through the alignment of the research questions, methodology, and validated theoretical framework to guide the evaluation.
Transparency	Honesty about the research process.	Maintenance of an audit trail through detailed notes and critical friend throughout analytical process.
Substantive contribution	The extent to which a study makes a meaningful impact on our understanding of what is being researched theoretically, conceptually, practically, or methodologically.	Offers a theoretical understanding of factors influencing the implementation of technology-driven community programs.

Results

Implementation Surveys

All administrators, program staff, and volunteers involved in implementing the LOF and VR programs (n=9, 100%) completed the surveys. Results from the AIM, IAM, and FIM surveys are provided in Table 2. Overall, both programs attained high ratings across all 3 domains. However, one-third of respondents (n=3, 33.3%) rated the VR program's feasibility as medium (FIM score <15) rather than high.

Table . Acceptability, appropriateness, and feasibility measure results.

	LOF[a] program, mean (SD)	VR[b] program, mean (SD)
AIM[c]	16.89 (1.62)	17.56 (2.74)
IAM[d]	16.33 (1.58)	16.56 (2.70)
FIM[e]	16.78 (1.64)	16.22 (2.86)

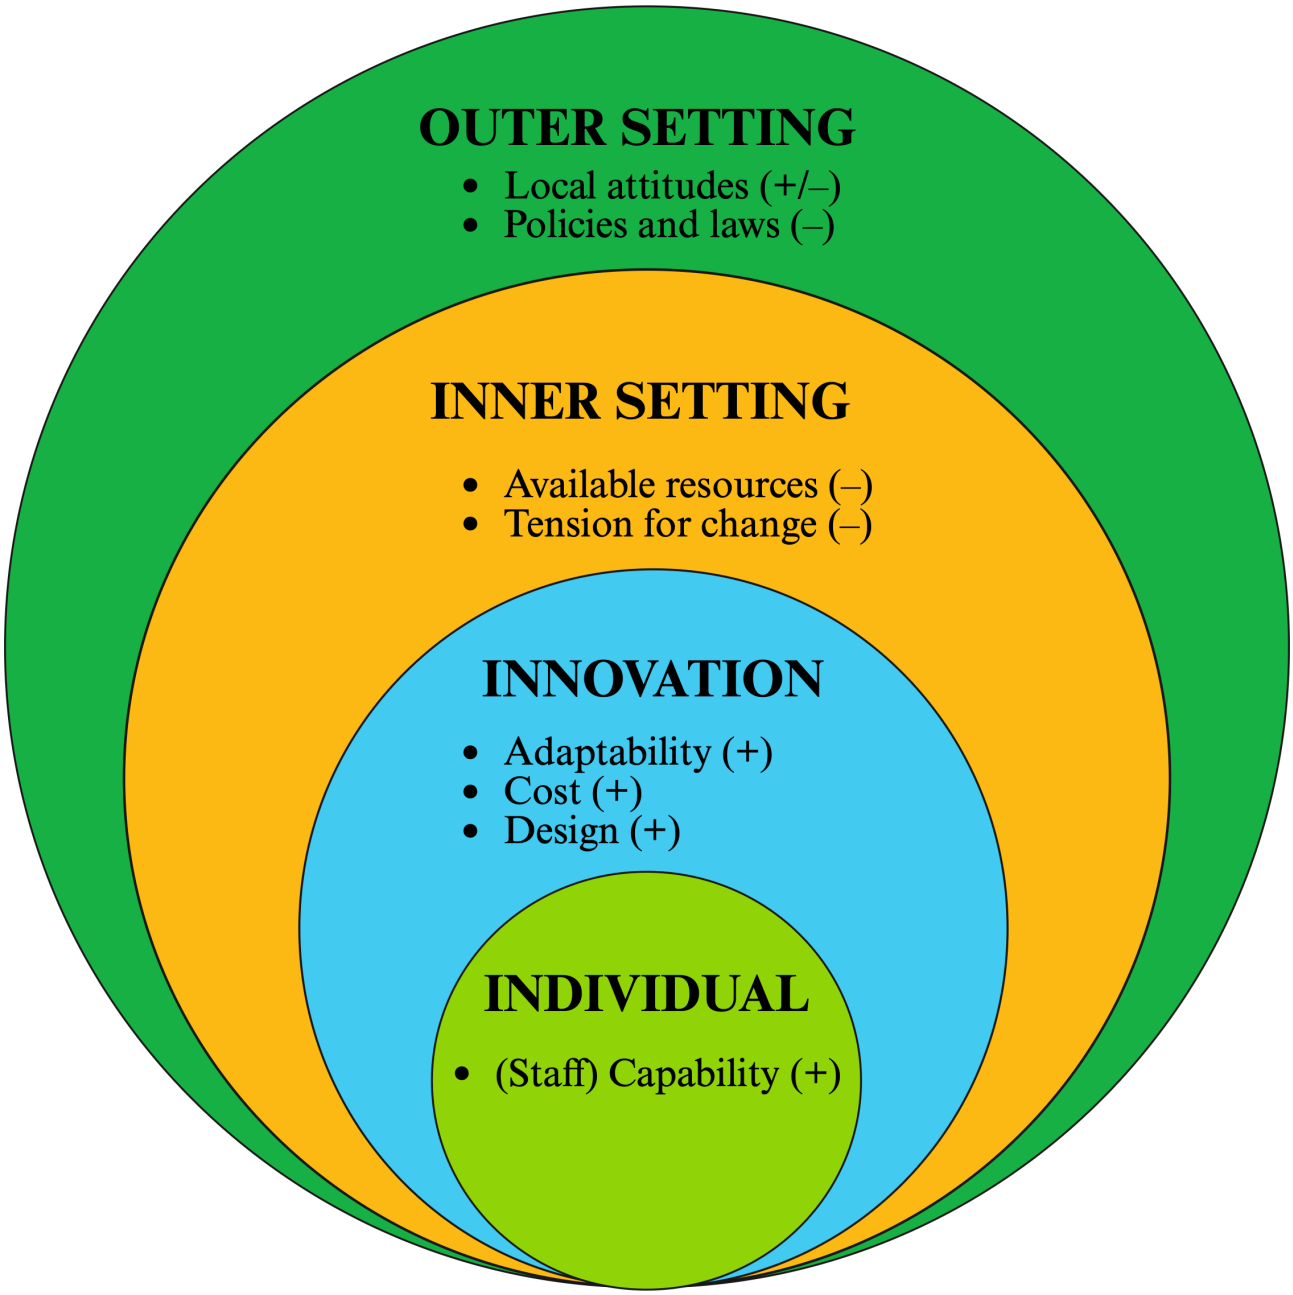
[a]LOF: Lakeshore Online Fitness

[b]VR: virtual reality

[c]AIM: Acceptability of Intervention Measure

[d] IAM: Intervention Appropriateness Measure

[e]FIM: Feasibility of Intervention Measure



Interview and Focus Group Results

A total of 15 individuals took part in the interviews (mean 41.3 min, SD 16.1 min; range 24 - 63 min) or focus groups (mean 49.3 min, SD 7.1 min), including 8 of 10 program participants, 1 recreation center staff member, 2 community volunteers, 2 fitness instructors, and 2 administrators [1]. Interview participants (n=8) were primarily Black or African American (n=7, 87.5%) and female (n=5, 62.5%) participants with a mean age of 65.0 (SD 14.0; range 44 - 86) years. The majority of interview participants had hypertension (n=6, 75%) and arthritis (n=4, 50%), with 37.5% having both concurrently. Focus group participants were primarily White (5 /7, 71.4%) and male (4/7, 57.1%) individuals; age was not collected. Program participants completed 78.3% and 85.4% of LOF and VR sessions, respectively.

Qualitative data analysis identified 4 overarching domains and 8 constructs that represented key facilitators and barriers to implementing the LOF and VR programs. The results mapped to CFIR domains and constructs are depicted in Figure 3.

XSL•FO
RenderX

Figure 3. Implementation barriers and facilitators coded into Consolidated Framework for Implementation Research (CFIR) domains and constructs. "–" indicates barriers, "+" indicates facilitators. Created in BioRender [43].

Key Facilitators to LOF or VR Implementation

Six subthemes based on 5 CFIR constructs were identified as facilitators to program implementation. These constructs belonged to 3 CFIR domains ("innovation," "outer setting," and "individuals") and are described in more detail under the "Innovation," "Outer Setting," and "Individuals" subsections below.

Innovation

Overview

The innovation domain comprises features of an intervention that might influence implementation. Key facilitators related to program characteristics centered on the adaptability, cost, design quality, and packaging constructs. Implementation team members praised both the LOF and VR programs for their flexibility, allowing for modifications to accommodate diverse physical abilities. The low cost of equipment and free access at the community center made both programs accessible and affordable, while the socially interactive and engaging design enhanced motivation and enjoyment for program recipients.

Flexible LOF Exercises (Adaptability)

All program recipients and deliverers noted the flexibility of the LOF program for participants with diverse physical abilities, such as low mobility, dexterity limitations, low vision, or stroke-related impairments. Participants with dexterity limitations mentioned the ease of modifying the LOF program components to facilitate engagement, "Once I could pick up the weights, when the resistance ball isn't—none of it bothered me, it was just putting it in my hand" (program recipient 04). Instructors adjusted exercises to participants' needs without full

XSL•FO
RenderX

information on their abilities but noted that experience was essential for making these on-the-fly adaptations.

VR Program Technology Considerations (Adaptability)

Recreation center staff and volunteers emphasized the importance of the VR program's adaptability to diverse settings, such as standing versus seated sessions to support group activity and ensure participant safety:

> *I think if they were standing up, they would likely free roam. They're in their virtual world, and they can't see where they're going or what they're doing. When you start moving, you just movin'. They might be bumping into each other. I think sitting was the perfect thing to stay in the circle and not bump each other. I think that was good.* [Community volunteer 01]

Although some participants initially struggled with dexterity, this issue was resolved quickly by the research staff, who modified the VR equipment for one-handed use.

Program Access and Affordability (Cost)

Program deliverers felt that the LOF program's low-cost exercise equipment, such as balls, bands, and lightweight dumbbells, would make the program relatively simple to replicate in other locations:

> *In theory, the way this works is we're bringing a lot of the expense to them. We're bringing the TV. We're trying to cut away as much of the red tape as we can. What we really need is for them to say, yes, here's a room. Here's somebody to turn on the TV. Here's somebody who can hover in there to help with stuff, but you guys do the hard part of buying the TV and having the expertise to teach the class. It's just [a] partnership.* [Administrator 01]

Program recipients appreciated that both programs were free and available at the community center, citing affordability and ease of access as key facilitators of engagement. They acknowledged that many older adults and people with chronic health conditions in their community lacked transportation to attend paid physical activity programs, but that, "…they would be happy to do exercise like that, long as they don't have to leave the building'' (program recipient 09).

Socially Interactive and Engaging Design (Design)

This subtheme pertains to participant perceptions of the quality of the materials associated with the LOF and VR programs. Program recipients valued the socially supported, group-based nature of the LOF program, which enhanced motivation. "We did those stretch band things. We did the balls and the dumbbells…I liked it. I liked being on the equipment" (program recipient 02). They found the competitive and interactive elements of the VR program particularly motivating, as these elements allowed them to compete against others or themselves, "We had a competition going together shooting games and stuff like that, bowling, and stuff like that" (program recipient 03). These program components made physical activity more enjoyable and immersive:

> *I like the [VR] headset because you get the feeling of really being in there. That's the part I really like. The sceneries are so beautiful. You really did, you felt like you had actually stepped into a space age, or a tennis court or baseball diamond.* [Program recipient 08]

Outer Setting: Social and Community Engagement (Local Attitudes)

This subtheme reflects the degree to which sociocultural values (eg, shared responsibility in helping recipients) and beliefs (eg, convictions about the worthiness of recipients) encourage the outer setting (eg, the city the program was implemented in) to support implementation and/or delivery of the intervention." [30,31] Those involved in program implementation and delivery felt that, "Having a community champion like the assistant mayor" (administrator 01) was crucial to the program's success, as their advocacy facilitated connections with community leaders and strengthened local engagement. Positive reactions from program recipients further affirmed the programs' value and energized program deliverers. These groups noted that this enthusiasm made the program more enjoyable for the staff and was a key indicator of its success:

> *Just seeing them enjoying made me feel good, because they [were] enjoying something. It's not like they [were] forced to do it or "Okay, we're in this program here at the rec, so this is part of it. We have to do it." "No, this is a program that I enjoy. I'm glad when it start[s]. I hate when it end[s]. We just want to have fun." They all got along. That was a good thing.* [Community volunteer 01]

> *...it was fun to coach, because you could see them move and you could see 'em doing things and it seemed like they really enjoyed it and then when it ended, they would clap and say thank you, and all that and give you that reassurance.* [Fitness instructor 01]

Individuals: Staff Training and Role Clarity (Capability)

Effective implementation required clear role distribution and adequate staffing to assist participants, manage technology, and troubleshoot issues onsite. Program deliverers felt that staff with strong interpersonal and problem-solving skills and at least some knowledge of exercise were beneficial to LOF and VR program success:

> *So, ideally, it would be someone with fitness experience…[but] minimally, it has to be, in my opinion, someone who is consistent, dependable, and someone that we could train.* [Administrator 02]

> *It was a very easy setup and once the class was going, you were hands off. If someone didn't really seem like they knew what they were doing, you would try and mimic what the instructor was doing. I don't really feel like there was too much training needed for that portion of it.* [Recreation center staff 01]

Key Barriers to LOF or VR Implementation

There were 4 barriers identified from the interviews and focus groups, with subthemes divided evenly between the inner and outer setting domains.

XSL•FO
RenderX

Inner Setting

Overview

Barriers to LOF and VR program implementation within the inner setting domain (eg, the organization in which the intervention is being implemented) [30,31] centered on the available resources and tension for change constructs. The LOF and VR programs at the recreation center faced technical and spatial challenges, and program recipients expressed dissatisfaction with the limited accessible physical activity options in their area, highlighting the need for sustainable community resources to address underlying infrastructure deficits.

Technology and Space Challenges (Available Resources)

This subtheme reflects "the degree to which resources are available to implement and deliver the intervention" [30,31] Addressing technical and spatial barriers, including technology setup and space constraints, was essential to successful implementation of the LOF and VR programs at the recreation center. Stable Wi-Fi, reliable equipment, and adequate space were critical to overcoming these challenges and ensuring successful program delivery. Program users reported minimal technical issues:

> *The only [LOF program] technical issue I think we had—well, then it wasn't an issue—was that we could not hear what she was sayin', but we could see what she was doin', so we still continued because we could see her doin' the exercises.* [Program recipient 05]

> *One day the [VR program] computer wasn't acting right for some. … [But] we never had to miss a day because of the technical difficulties.* [Program recipient 08]

However, program providers felt that LOF program delivery was complicated by spatial constraints at the recreation center:

> *I think the biggest complaint with the [LOF] class was we just didn't have enough space… Sometimes we had 10 people, and so we had all the chairs. It was like they couldn't fully put out their arms, or [they'd] be running into each other and stuff like that. … I feel like just the size of the room was the biggest issue.* [Recreation center staff 01]

> *You could see 'em moving and everything, but you weren't able to read people's eyes, you saw gross movements, but you didn't see the finer movements.* [Fitness instructor 01]

LOF instructors noted that participant monitoring could be enhanced with larger screens and/or additional cameras, "…so you can see people a little bit closer, 'cause we were at a distance, and you really couldn't see their faces" (fitness instructor 01). Instructors also emphasized the importance of standardized and simplified technological setups on their end to minimize the burden of adjusting to new rooms, equipment, and lighting conditions.

Need for Infrastructure and Resource Support (Tension for Change)

This subtheme aligns with the CFIR construct "tension for change," where implementation team member recognition of significant gaps creates momentum for implementation efforts [30,31]. Program recipients expressed a strong desire for more accessible physical activity options in their area, noting that the absence of such resources created what they perceived as an urgent community need: "There aren't no other [free physical activity opportunities] here...People, they go out down there to the community store and buy 'em a can of beer or a pack of cigarettes" (program recipient 04). Participants highlighted both the immediate value of the LOF and VR programs, "Well, me and my other two siblings, we got high blood pressure, so we need somethin' to motivate us" (program recipient 02), and emphasized the need for additional community resources to support these programs long-term:

> *...Cause we don't have nothin' there. I needed it. ...Those people need it. They really need somethin' like that…* [Program recipient 09]

The emphasis on sustainability concerns further reflected program recipients' insight that temporary interventions, while beneficial, would not address the fundamental infrastructure deficits underlying their community's physical activity challenges.

Outer Setting

Key barriers to LOF and VR program implementation within the outer setting domain centered on the local attitudes and policies and laws constructs. Resistance to new technology and sustainability challenges were identified as barriers to implementing and sustaining the LOF and VR programs.

Resistance to New Technology and Approaches (Local Attitudes)

Program recipients, administrators, recreation center staff, and volunteers all mentioned resistance to adopting new technology and program approaches. Some program recipients expressed concerns that others in the community might resist the VR program due to discomfort with wearing headsets, influenced by cultural and personal preferences: "...I don't think they would like it 'cause just puttin' stuff on their face…" (program recipient 09). Similarly, recreation center administration initially doubted participants' willingness to engage with the LOF and VR programs, reflecting skepticism about the programs' acceptance and feasibility:

> *When we said, well, how about this group take the class, [senior staff] at the rec center were like, y'all are out of your minds. They are never going to participate in this* [Administrator 01]

Sustainability Challenges (Policies and Laws)

This subtheme reflects the "degree to which legislation, regulations, professional group guidelines and recommendations, or accreditation standards support implementation and/or delivery of an intervention" [30,31]. One administrator felt that relying solely on grant funding made long-term sustainability of the LOF program uncertain, especially without a financial

XSL•FO
RenderX

model for continued implementation, "So how do we deliver it when it's not through a grant, and how do we try to align as closely to the way that we would onboard members now, but on the online, which is different" (administrator 02). This administrator also noted liability and membership issues, including the need for waivers and consistent liability protocols, as barriers to continuing the LOF program at the community center, "...Because we can't deliver any product without some kinda safeguard set up...and I don't believe we ever figured that out" (administrator 02). Similarly, program deliverers expressed concerns about the VR program's long-term feasibility due to equipment maintenance, cultural unfamiliarity, and staff burden—factors that align with the relatively lower feasibility scores reported in the FIM survey.

Discussion

Key Findings and Contributions

This study applied the CFIR to explore barriers and facilitators influencing implementation of two technology-driven group exercise programs—an online platform (LOF) and VR gaming—delivered to predominantly African American older adults living in an underserved community. Through semistructured interviews, focus groups, and implementation surveys, we identified factors across 4 CFIR domains (innovation, outer setting, inner setting, and individuals) that collectively influenced the programs' uptake, delivery, and sustainability. Our findings highlight that successful implementation was shaped by a combination of program adaptability, affordability, social engagement, and community support, while sustainability and resource constraints emerged as persistent barriers.

A key contribution of this study lies in demonstrating how technology-enabled interventions can create structured exercise opportunities in community centers that previously lacked formal fitness programming. Unlike settings where technology supplements existing exercise classes, the recreation center in this study had no structured physical activity programs prior to implementation. Technology served as the catalyst for introducing accessible, engaging, and adaptable exercise options, addressing a critical gap in underserved communities where traditional programs are often unavailable due to resource limitations. This approach aligns with growing evidence that technology-based interventions can overcome environmental and logistical barriers by delivering scalable, customizable programs that promote physical activity and social engagement among older adults and individuals with disabilities [18-20]. By leveraging online platforms and VR gaming, the programs provided not only exercise opportunities but also novel experiences that enhanced enjoyment and motivation—factors shown to improve adherence in populations facing mobility and transportation challenges [15,23,26].

Facilitators of Implementation

Adaptability emerged as a key facilitator across both programs. The ability to adjust exercises and technology to accommodate diverse physical abilities allowed for broad participation, even among individuals with mobility limitations and dexterity challenges. These findings align with previous research highlighting the importance of customizable interventions that support engagement among populations with heterogeneous physical limitations [44,45]. Affordability and ease of access were also critical enablers, extending beyond equipment costs to include transportation and membership fees, which are common deterrents among people with disabilities [1]. By eliminating these costs, the programs created equitable access to structured exercise opportunities, reinforcing prior evidence that cost-sensitive solutions are vital for program sustainability in resource-constrained settings [46].

The socially interactive and gamified design of both programs further enhanced motivation and enjoyment. LOF's group-based format fostered camaraderie, while the VR program's competitive elements introduced novelty and fun, supporting the value of incorporating social and gamified components into technology-based group physical activity programs for older adults and people with disabilities to sustain engagement [47]. Future implementation of technology-driven exercise interventions should leverage these design principles to strengthen both physical and psychosocial outcomes in this population.

Finally, community support amplified program success. Advocacy from community champions (eg, city leaders), enthusiastic endorsement from community volunteers and recreation center administrators, and visible program recipient enthusiasm strengthened buy-in among staff and volunteers, creating a sense of shared ownership. This is consistent with previous research emphasizing the role of community advocacy in successful implementation of health promotion programs in underserved areas [45] and suggests that early identification of community champions should be integral to implementation planning.

Barriers to Implementation

Despite these strengths, several barriers impeded implementation. Technology and space limitations were the most immediate obstacles. Unstable Wi-Fi, suboptimal camera setups, and inadequate physical space complicated LOF program delivery and monitoring, while the VR sessions required careful configuration to ensure safety, highlighting the need for robust infrastructure and standardized protocols [45,46,48]. Resistance to new technology reflected cultural and personal discomfort, particularly with VR headsets, and skepticism among staff about program feasibility. While program recipients spoke highly of the VR program, initial hesitancy underscores the importance of tailored program orientation and gradual exposure to technology to build confidence and acceptance [45,49,50].

Additionally, sustainability challenges stemming from reliance on grant funding and unresolved liability protocols raised concerns about program continuity. Administrations cited liability and membership protocols as unresolved issues for the LOF program, while survey responses from program deliverers reflected reservations about the VR program's feasibility. This underscores the need for alternative funding strategies (eg, partnerships with local health departments and sliding-scale fees), infrastructure development, and policy alignment to support long-term program continuation. Without such planning,

XSL•FO
RenderX

even well-received programs risk discontinuation once initial funding ends.

Implications

Our findings suggest that technology-driven exercise programs can reduce health disparities in underserved communities when they are adaptable, affordable, socially engaging, and supported by community champions. However, implementation efforts must anticipate and address resource constraints, technology resistance, and sustainability challenges. Multilevel implementation strategies, including investment in digital infrastructure, community advocacy, targeted orientation to reduce technology hesitancy, and sustainable financing models, are essential to scale and sustain such interventions. Future research should explore strategies for scaling these programs, such as partnerships with local organizations, integration into existing community services, or development of cost-sharing models. Programs should engage community champions from inception, build standardized technical protocols, and test these programs across diverse geographic and demographic contexts.

Strengths and Limitations

Study strengths include its use of a validated implementation framework (CFIR), integration of multiple implementation team member perspectives, and use of both qualitative and quantitative methods to identify barriers and facilitators to program implementation. However, the current study has limitations that warrant consideration. Our sample, though achieving 79% participation among relevant implementation team members, was relatively small and drawn from a single, predominantly African American community, which may limit generalizability. Additionally, racial distribution differed between data collection formats: interview participants were predominantly African American, while focus group participants were primarily White. This imbalance may have influenced the range of perspectives captured. Implementation team member perspectives were collected several months after program delivery, which may not have captured immediate perspectives of program sustainability or technology acceptance. Nonetheless, the rich qualitative insights underscore the value of incorporating ongoing implementation team member evaluation and feedback into program design.

Conclusions

Technology-enhanced group exercise interventions hold considerable promise for reducing physical inactivity among underserved older adults and people with disabilities. The results of our CFIR-guided analysis suggest that, while adaptability, low cost, and social engagement facilitated uptake, the LOF and VR programs presented technical, infrastructural, and policy-related barriers. The findings of this study contribute to the growing literature on technology-enabled health interventions for aging populations and people with disabilities and offer insights into implementation strategies in underserved, resource-limited settings.

Acknowledgments

The authors wish to acknowledge Eric Evans for his initiative on the virtual reality portion of this project and to thank Ashley Wright for her expertise and assistance with program delivery. The authors also extend our appreciation to the Lakeshore Foundation fitness instructors and senior leadership, community volunteers, and staff at the Parks and Recreation Department. Without their time, dedication, commitment, and resources, this project would not have been possible. The authors thank Emily Delzell for her editorial review and assistance in the preparation of this manuscript.

Abstract

Background: Exercise therapy is fundamental to rehabilitation for knee osteoarthritis and anterior cruciate ligament (ACL) reconstruction, yet adherence to prescribed exercise typically declines once clinical supervision ends. Digital rehabilitation platforms offer a promising means of supporting sustained exercise adherence, but qualitative evidence on how patients experience these platforms in real-world clinical practice remains limited, particularly in non-Western health care contexts.

Objective: This study aimed to explore how patients with different knee conditions experienced the Healthy Knees digital rehabilitation platform in Hong Kong and to identify the factors shaping their platform engagement and exercise adherence.

Methods: A qualitative design was adopted using reflexive thematic analysis. Fifteen adults (9 with ACL, 6 with osteoarthritis) who had been prescribed the Healthy Knees web-based platform at Prince of Wales Hospital participated in semistructured, in-person interviews (30 - 45 min). Interviews were conducted in Cantonese or Mandarin, transcribed verbatim, translated into English, and analyzed inductively. Ethics approval was obtained from the Chinese University of Hong Kong and the University of New South Wales.

Results: Participants were aged 21 to 79 years, with most being male (11/15). Younger participants were predominantly patients with postoperative ACL, while older participants were predominantly patients with preoperative osteoarthritis. Three interrelated themes were identified, collectively describing the fit between the platform and participants' contexts. Content fit captured the alignment between exercise content and rehabilitation needs; participants across both groups perceived substantial overlap with existing physiotherapy, and content was often mismatched to their recovery stage. Motivational fit captured the alignment between platform support features and motivational needs; pain functioned as both a driver and a deterrent to exercise, and participants ranged from highly self-directed to reliant on external scaffolding, not following a simple age pattern. Access fit captured the alignment between the platform's delivery mechanism and participants' technological circumstances; QR code–dependent access, absence of a dedicated mobile app, and display issues created friction that led several participants to migrate to alternative resources, maintaining exercise adherence while abandoning platform engagement.

Conclusions: Adherence to digital knee rehabilitation was shaped by the degree of fit between the platform and users' contexts across content, motivational, and access dimensions. When access fit failed, participants often substituted alternative exercise resources rather than ceasing exercise entirely, highlighting a distinction between platform engagement and exercise adherence. As the sample's clinical and demographic characteristics were closely linked, these findings should not be interpreted as diagnostic comparisons between ACL and osteoarthritis populations but as patterns shaped by the recovery phase and age. These findings suggest that digital rehabilitation platforms should incorporate adaptive content aligned with the recovery stage, integrated feedback mechanisms, and reduced access friction to sustain platform engagement within an ecosystem of competing alternatives.

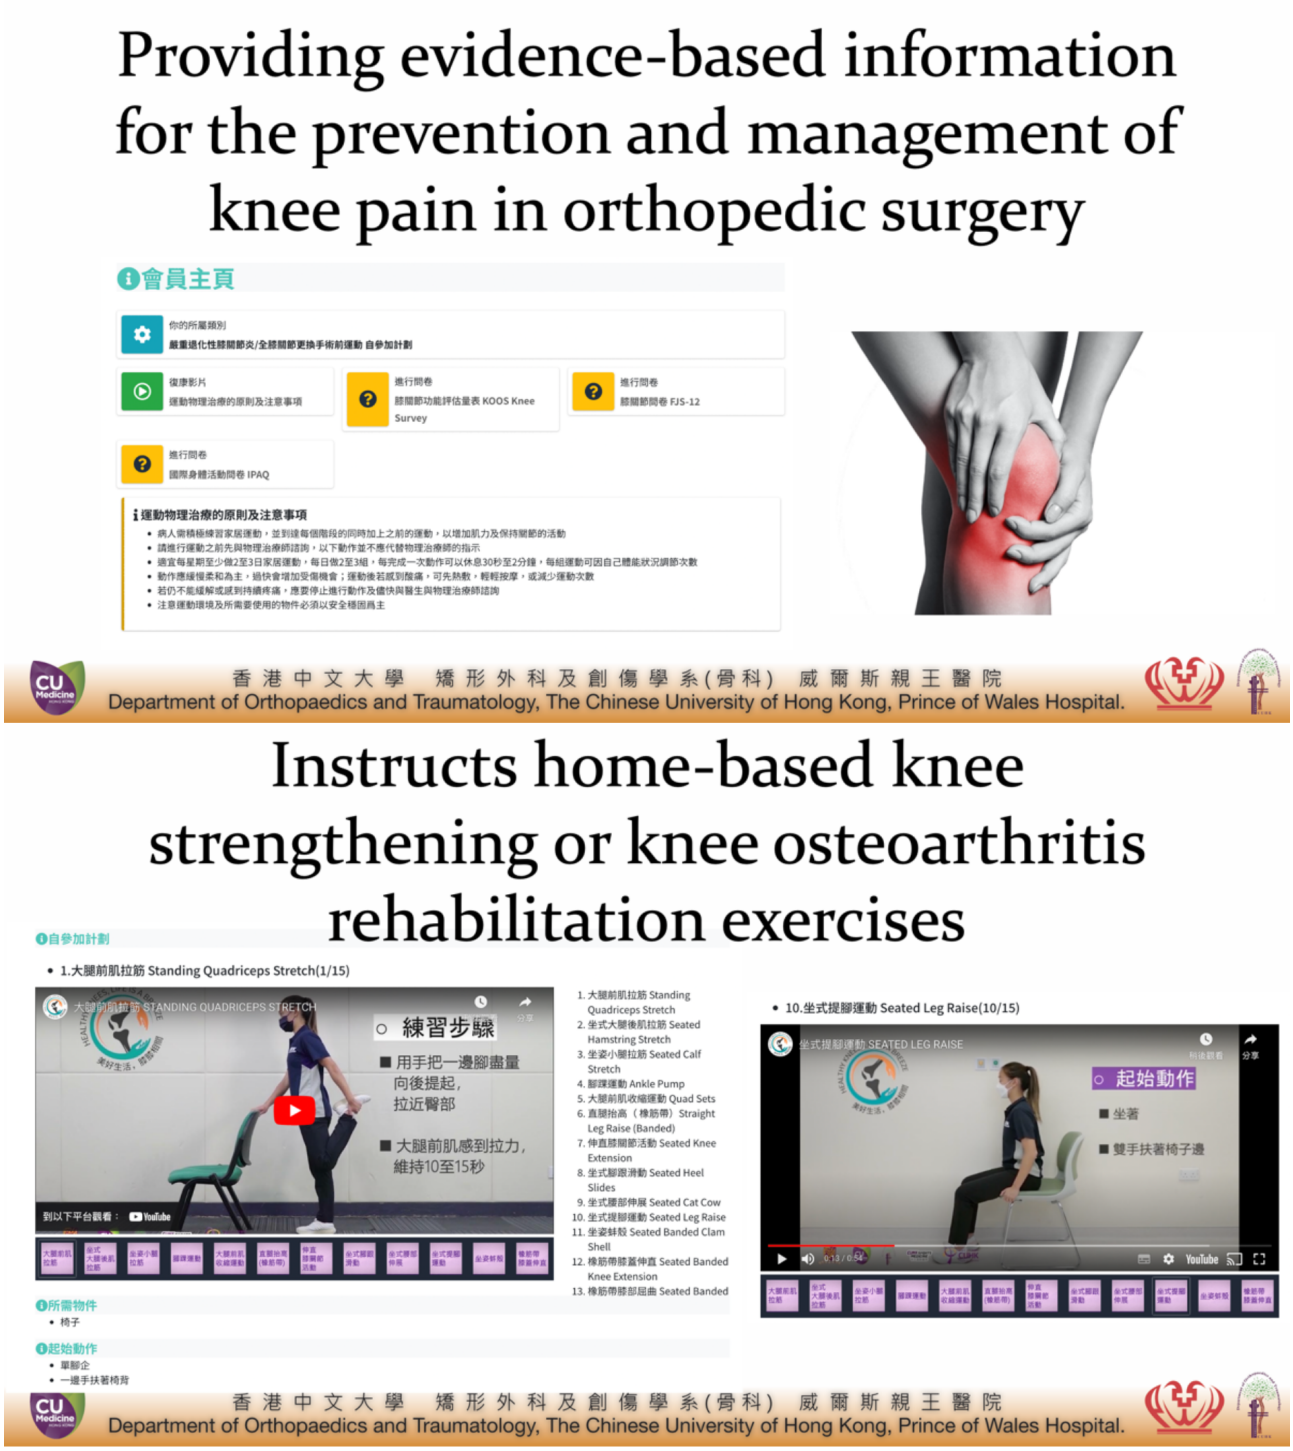
Introduction

Exercise is widely recognized as a key approach in managing knee osteoarthritis and improving recovery following knee surgeries, such as total knee replacement (TKR) and anterior cruciate ligament (ACL) reconstruction [1]. Therapeutic exercise programs are critical in reducing pain, improving joint function, and enhancing overall quality of life for individuals with knee impairments [2].

Despite the proven benefits of these programs, maintaining exercise for patients remains a significant challenge. Exercise adherence usually declines once clinical supervision tapers off [3]. A decline in exercise can lead to suboptimal recovery outcomes, prolonged rehabilitation periods, and increased health care costs [4,5].

Digital rehabilitation interventions—including web-based platforms and mobile apps—have emerged as promising tools to support sustained exercise adherence beyond the clinic [6]. These platforms can offer flexible access to exercise guidance, structured programs, and remote monitoring capabilities [7]. Yet, the effectiveness of such interventions depends on whether patients engage with and adhere to them in practice [8]. Adherence itself is a complex, multidimensional phenomenon: the World Health Organization has argued for a systems approach that considers socioeconomic, health system, condition-related, therapy-related, and patient-related factors, rather than treating nonadherence as a patient-driven problem [9]. Understanding how digital rehabilitation interventions are experienced in real-world settings—and why users persist with, adapt, or abandon them—is therefore essential for informing intervention design [10].

A growing body of quantitative research has examined digital rehabilitation for knee conditions, with evidence suggesting that digital adjuncts can improve short-term adherence, though benefits may diminish over time [11]. However, qualitative research exploring patients' lived experiences of digital knee rehabilitation remains limited, particularly in non-Western health care contexts. Existing qualitative work has identified broad themes such as the importance of personalization, usability, and motivational support [6], but it is not well understood how patients with differing clinical and demographic profiles experience digital knee rehabilitation platforms in practice, nor how their experiences shape adherence in practice. There is also limited evidence from contexts such as Hong Kong, where long public hospital waiting times for elective orthopedic surgery [12], significant physiotherapy workforce shortages, and the growing availability of alternative digital health resources create a distinctive landscape for digital rehabilitation adoption.



The Healthy Knees intervention (Figure 1) is a web-based rehabilitation platform developed by the Department of Orthopaedics and Traumatology at the Chinese University of Hong Kong. It provides evidence-based information for the prevention and management of knee pain in orthopedic settings and delivers structured, home-based rehabilitation exercises for patients with knee osteoarthritis and those recovering from ACL surgery. The platform includes video demonstrations of strengthening and mobility exercises, educational resources on knee health, and progress monitoring tools such as patient-reported outcome surveys. The platform uses online questionnaires to monitor at-risk patients. It is accessed via a web browser using a QR code provided by the treating clinician; no dedicated mobile app is available. The platform does not include automated adherence-support features, such as goal-setting tools, personalized feedback, or social comparison functions. It is intended to support remote rehabilitation by improving access to exercise guidance outside conventional in-person physiotherapy services.

In this study, adherence refers to the extent to which participants performed the prescribed exercises after accessing them through the Healthy Knees platform. This encompasses both engaging with the platform to access exercise content and subsequently completing exercises as intended. The study did not capture objective platform usage metrics such as login frequency or session duration; rather, adherence was explored through participants' self-reported accounts of their exercise behavior in qualitative interviews. The term "adherence" is used consistently throughout this paper; where a distinction is necessary, "platform engagement" refers specifically to interaction with the digital platform, while "exercise adherence" refers to the performance of prescribed exercises.

This study qualitatively examines adherence to the Healthy Knees digital rehabilitation platform among individuals with different knee conditions in Hong Kong. The aim is to explore how patients experience the platform in real-world clinical practice and to identify the factors that shape sustained engagement and exercise behavior across different clinical profiles.

Figure 1. Healthy knees digital intervention.

Methods

Overview

This qualitative study used reflexive thematic analysis following the 6-phase process described by Braun and Clarke [13,14]. Trustworthiness was addressed using the strategies outlined by Nowell et al [15], including prolonged engagement with the data and peer debriefing. The study was planned and designed by NC, SP, JB, and MTYO. NC and SP trained MY, who conducted the interviews. The researchers, except for MTYO, who was the consulting clinician, had no prior relationships with the participants. The study was reported using the COREQ (Consolidated Criteria for Reporting Qualitative Research). The study was conducted at Prince of Wales Hospital in Hong Kong.

The research team brought diverse disciplinary perspectives to the study. NC is a digital health researcher with no clinical relationship with the participants. SP contributed qualitative research expertise and had no prior involvement with the Healthy Knees platform or its users. JB provided senior research oversight for the project. MTYO, the consulting orthopedic clinician, introduced patients to the Healthy Knees platform as part of routine clinical care and was involved in study design but did not participate in recruitment, conduct interviews, or

XSL•FO
RenderX

contribute to the analysis. MY, who conducted the interviews, was trained by NC and SP and had no prior relationship with participants. Participants were existing users of the Healthy Knees platform who were invited to participate by MY during their clinic visit. The team acknowledges that participants' awareness of MTYO involvement in their clinical care may have influenced their willingness to participate or the candor of their responses. This should be considered when interpreting the findings.

Participant Selection and Recruitment

Participants were selected using a convenience sampling strategy from patients at Prince of Wales Hospital who had been introduced to the Healthy Knees app by author MO as their consulting clinician. Participants were recruited during their clinic visits. The sample included individuals diagnosed with knee osteoarthritis, those awaiting ACL surgery, and those who had undergone ACL surgery. Inclusion criteria focused on patients who had been introduced to the Healthy Knees app. No explicit exclusion criteria were defined for this study.

Data Collection

Data were collected through in-person, semistructured interviews. A total of 15 interviews were conducted, each lasting around 30 to 45 minutes. The interviews were designed to identify the participants' experiences with the Healthy Knees app.

The research team developed a semistructured interview guide (Multimedia Appendix 1) to facilitate the interviews. The guide began with questions to collect participant demographic and clinical background information, followed by open-ended questions exploring participants' experiences with the Healthy Knees platform, their perceptions of the exercises, barriers and facilitators to adherence, motivations for exercise, and suggestions for platform improvement. Probing questions were used to elicit detailed responses. Prior to data collection, the interview guide was pilot-tested within the research team to ensure clarity and relevance. In practice, the interviewer used the guide flexibly, adapting the order and phrasing of questions in response to participants' accounts, consistent with a semistructured approach.

All interviews were conducted in Cantonese or Mandarin by MY and were audio-recorded. The audio recordings were transcribed verbatim in the original language. The first transcript was translated into English by MY. The remaining transcripts were translated by a professional translation service at Guangdong University of Foreign Studies, a university recognized for its expertise in translation studies and accredited by the International Conference of University Institutes of Translators and Interpreters. No formal back-translation or independent verification of translations was conducted; this is acknowledged as a limitation.

Data Analysis

Data analysis followed the 6-phase process of reflexive thematic analysis [13,14]. NC familiarized with the data by reading the transcripts multiple times and then generated initial codes by identifying key patterns, concepts, and recurring ideas. These codes were grouped into broader categories in the search for potential themes, which were subsequently reviewed, refined, and named to ensure they accurately represented the data and were distinct from one another. Throughout this process, NC, SP, and JB engaged in recurring discussions to critically examine the developing codes and themes, ensuring they were grounded in the data and reflected the range of participant experiences. Where individual accounts diverged from emerging patterns, these were examined closely to assess whether theme boundaries required refinement. During the final phase of analysis, the team identified an overarching pattern connecting the 3 themes, which was developed inductively rather than applied from a pre-existing theoretical framework. The coding and analysis were carried out manually without using software tools. A completed COREQ checklist is provided as Checklist 1.

Ethical Considerations

Ethical approval for the study was obtained from the Chinese University of Hong Kong (2023.29), and external approval was registered with the University of New South Wales (iRECS5785) ethics committees. Informed consent was obtained from all participants through a signed written consent form before participation. Participants were informed of the study's purpose, that participation was voluntary, and that they could withdraw at any time without affecting their clinical care. All interview transcripts were deidentified prior to analysis, with participants assigned alphanumeric codes (eg, P01) in place of identifying information, and stored securely on password-protected institutional servers accessible only to the research team. Participants did not receive any financial or other compensation for taking part in the study.

This project was funded by the Chinese University of Hong Kong-The George Institute Joint Collaborative Research Fund.

Results

Participants

Fifteen participants took part in the study (Table 1). The sample comprised 9 participants with ACL conditions and 6 with knee osteoarthritis. Most were male (11/15). Notably, diagnosis, age, and surgical stage were closely intertwined in this sample: participants with ACL conditions were predominantly younger (age range 21 - 52 y) and postoperative (8/9), while participants with osteoarthritis were predominantly older (age range 63 - 79 y) and preoperative (5/6). This overlap means that differences observed between the 2 groups cannot be attributed to diagnosis alone and may reflect age, surgical stage, or their combination. Throughout the "Results" section, participants are described by their experiential profile (eg, "younger, postoperative participants") with the associated diagnosis noted in parentheses.

Table . Participant demographics[a].

Characteristic	ACL[b] (n=9)	Osteoarthritis (n=6)	Total (n=15)
Surgery status, n			
Presurgery	1	5	6
Postsurgery	8	1	9
Sex, n			
Male	8	3	11
Female	1	3	4
Age (y), range	21 - 52	63 - 79	21 - 79

[a]Detailed clinical variables, such as Kellgren-Lawrence grade for knee osteoarthritis and time since surgery for postoperative participants, were not systematically collected in this study.

[b]ACL: anterior cruciate ligament.

Analysis of the interview data identified 3 interrelated themes that collectively describe the fit between the Healthy Knees platform and participants' contexts. These themes—content fit, motivational fit, and access fit—capture the dimensions along which the platform aligned or misaligned with participants' rehabilitation needs, motivational profiles, and technological circumstances. Across the 3 themes, adherence was shaped not by any single factor but by the degree of alignment across all 3 dimensions.

Content Fit: Alignment Between Platform Exercises and Rehabilitation Needs

This theme captures the extent to which the Healthy Knees exercise content matched participants' perceived rehabilitation needs at their particular stage of recovery. Three patterns emerged: perceived redundancy with existing physiotherapy, temporal mismatch between platform content and recovery stage, and difficulty calibrating between exercises and physical capacity.

Perceived Redundancy With Existing Care

Across both groups, a recurring finding was that participants perceived substantial overlap between the Healthy Knees content and the exercises they were already receiving through physiotherapy or other sources. This perception reduced the platform's added value and contributed to disengagement:

> *I saw that the exercises were similar to those in physical therapy, so I didn't persist.* [P01, male, 76 years, osteoarthritis, preoperative]
>
> *They're the same by 70% to 80%. The physiotherapy exercises consist of stretching routines.* [P09, male, 45 years, ACL, preoperative]
>
> *I am not interested because they're very basic.* [P04, male, 26 years, ACL, postoperative]

Even among participants who found the content acceptable, the platform was often seen as confirming what they already knew rather than offering new guidance. One older participant noted:

> *I've received these conservative treatments and know how to perform these movements. However, I just do them depending on my own abilities.* [P05, male, 77 years, osteoarthritis, preoperative]

Similarly, 1 postoperative participant who had progressed well under the guidance of her personal coach found the platform content comparable to what she was already doing (P08, female, 63 years, osteoarthritis, post-TKR). This pattern was cross-cutting, appearing in younger postoperative and older preoperative participants alike, suggesting that redundancy with existing care was a common barrier regardless of age or diagnosis.

Temporal Mismatch Between Content and Recovery Stage

Among younger, postoperative participants (predominantly ACL), a distinct pattern emerged in which the platform content was seen as appropriate for a particular recovery stage—but not for the stage the participant was at when they accessed it.

> *These exercises are suitable for those who need rehabilitation training immediately after surgery. However, I was not at the rehabilitation stage when I accessed this platform.* [P13, male, 38 years, ACL, approximately 1 year postoperative]

One participant discovered the platform 6 months after surgery, by which time she had already resumed her preinjury physical activities daily and found the early-stage content no longer relevant: "I searched for related videos on YouTube...there weren't many videos in this respect on YouTube and were not so detailed as this platform" (P14, female, 21 years, ACL, postoperative). Another attempted the exercises immediately after injury but found them too painful:

> *I tried to follow your videos to do home exercises immediately after starting the rehabilitation at home. However, doing those movements was so painful that I failed.* [P02, male, 52 years, ACL, postoperative]

A notable counter-case was P07 (male, 35 years, ACL, postoperative), who reviewed later-stage content and found it genuinely challenging:

> *The jumping with the BOSU ball and the single-leg jump are challenging. But I think they are movements at the final stage of the rehabilitation program on your platform. I have not reached that stage currently.*

XSL•FO
RenderX

This suggests that the platform does contain progressive content, but participants who entered at the wrong recovery stage were unlikely to discover or reach it.

Difficulty Calibration

Perceptions of exercise difficulty diverged along the age and surgical-stage lines in this sample. Younger, postoperative participants (predominantly ACL) consistently found the exercises to be below their capacity and preinjury activity levels:

> *Your platform is good. Maybe as an athlete I might think the exercises on the platform are easy, but they are still useful for the elderly.* [P04, male, 26 years, ACL, postoperative]
>
> *Your exercises are too basic for them, but are adequate for me.* [P06, male, ACL, postoperative]

Older, preoperative participants (predominantly osteoarthritis) more frequently reported that specific exercises exceeded their physical capabilities:

> *This movement is challenging for me, but if I find it beneficial, I will strive to do it even despite difficulties. However, the third and fourth movements are beyond my capacity.* [P05, male, 77 years, osteoarthritis, preoperative]
>
> *There were a few exercises that I couldn't do at all, such as bending my feet, stilting my feet.* [P01, male, 76 years, osteoarthritis, preoperative]

However, this pattern was not universal. P11 (male, 79 years, osteoarthritis, preoperative) found all exercises within his capacity, and P08 (female, 63 years, osteoarthritis, post-TKR) noted that exercises initially difficult became manageable over time: "At the beginning, I found some movements difficult, but now I can do them." One participant's experience highlighted a potential safety concern: after stretching for one to two minutes rather than the recommended 10 to 30 seconds, he experienced adverse effects: "I've done them for a week and stopped after my muscles hurt. Maybe I didn't follow their recommended duration" (P09, male, 45 years, ACL, preoperative). This suggests that without adequate guidance on exercise dosage, some users may inadvertently overexert.

Motivational Fit: Alignment Between Platform Support and Motivational Needs

This theme captures how participants' motivational profiles interacted with the platform's support features (or lack thereof) to shape adherence. Two patterns emerged: the complex role of pain as both a driver and deterrent of exercise behavior, and the spectrum between self-directed motivation and reliance on external scaffolding.

Pain as a Double-Edged Motivational Driver

Across both groups, pain emerged not simply as a barrier to exercise but as a motivational force operating in 2 opposing directions. For some participants, the presence of pain drove continued engagement; for others, it triggered disengagement.

Among older, preoperative participants (predominantly osteoarthritis), pain served primarily as a motivator through fear of functional decline. Despite finding exercises difficult, P01 (male, 76 years, osteoarthritis, preoperative) persisted because he feared deterioration: "Not really fond of exercises, but if I don't exercise, my physical function may deteriorate soon." P11 (male, 79 years, osteoarthritis, preoperative) continued exercising because exercises directly alleviated his symptoms: "After doing these exercises, the pains of thighs can be alleviated to some extent." P05 (male, 77 years, osteoarthritis, preoperative) adopted a selective approach, performing exercises that were tolerable and skipping those that caused excessive discomfort:

> *I will skip the movements that are totally beyond my capacity. But I definitely will do these stretches.*

Among younger, postoperative participants (predominantly ACL), the relationship was more paradoxical. P06 (male, ACL, postoperative) explicitly described reduced pain as a reason to stop exercising: "When I feel the therapeutic effect without pain, I tend to skip exercises, otherwise I'm motivated to do more exercises." In this case, the absence of pain—which would typically signal recovery—actually undermined adherence by removing the perceived need for continued exercise. By contrast, P09 (male, 45 years, ACL, preoperative) stopped exercising because pain from overexertion deterred him: "I've done them for a week and stopped after my muscles hurt."

The Healthy Knees platform did not include features to help participants interpret pain in the context of their recovery—for instance, distinguishing expected postexercise discomfort from signals to reduce intensity. In the absence of such guidance, participants developed their own heuristics, with some persisting through pain and others withdrawing from exercise entirely.

Self-Direction Versus External Scaffolding

Participants varied considerably in the degree to which they could sustain exercise independently, and this variation did not follow a simple age or diagnosis pattern.

Several participants described strong internal motivation. P04 (male, 26 years, ACL, postoperative) reported no need for external prompts due to his athletic background. P10 (female, 74 years, osteoarthritis, preoperative) exercised 45 minutes to 1 hour daily, combining exercises sourced from a physiotherapy platform (HA Go) with a community exercise group led by a retired coach:

> *I think at least if you have some kind of this kind of platform or introduce some patient, at least they have the knowledge to know and then they have the freedom whether to follow is up to their decision.*

Her case challenges any simple association between older age and low self-direction.

Others, however, described difficulty maintaining routines without external structure. P03 (male, 21 years, ACL, postoperative) was candid:

> *I don't think I have that high level of self-consciousness. I will have greater drive to perform workouts with companions than alone.*

P06 (male, ACL, postoperative) attributed his nonadherence to "laziness," and P01 (male, 76 years, osteoarthritis, preoperative)

XSL•FO
RenderX

described a cycle of initial effort followed by abandonment: “I can do it for 10, 20 times, and then I gave up.” One participant (P08, female, 63 years, osteoarthritis, post-TKR) resolved this by building a structured external routine—weekly sessions with a coach supplemented by independent practice at home—effectively creating her own scaffolding outside the platform.

Two younger, postoperative participants independently raised the idea that progress tracking and feedback features could bridge the gap between self-direction and external support. P15 (male, 34 years, ACL, postoperative) described this in detail:

> *If I have the record about what exercises I do at what time, the results, are they good or bad, or easy to do? Then I will have more motivation. With something to feedback.*

P13 (male, 38 years, ACL, postoperative) similarly suggested staged content with expected milestones so users could gauge their progress. While this pattern was observed in only 2 participants, both arrived at a convergent suggestion: that the platform’s lack of feedback mechanisms left a motivational gap that neither purely self-directed nor externally prompted approaches could fill.

Access Fit: Alignment Between Platform Design and Users’ Technological Context

This theme captures how the design and delivery mechanism of the Healthy Knees platform interacted with participants’ technological circumstances to shape engagement. Two patterns emerged: access barriers created by the platform’s delivery format and competition from alternative exercise resources that participants found easier to use.

Platform Access Barriers

The Healthy Knees platform is accessed via a web browser using a QR code provided on a printed pamphlet during a clinic visit. It has no dedicated mobile app, no saved login, and no bookmark prompt. Several participants described how this access mechanism created friction that disrupted or prevented engagement.

The most direct account came from P08 (female, 63 years, osteoarthritis, post-TKR), who lost the pamphlet and was unable to return to the platform:

> *Sometimes it was impossible to access your platform without scanning the QR code … I lost the pamphlet; without the QR code, I couldn’t log into the website.*

Rather than abandoning exercise, she switched to YouTube videos and sessions with her coach.

P01 (male, 76 years, osteoarthritis, preoperative) faced a more fundamental barrier: he did not have a mobile data plan, relying on a pay-as-you-go card, and could only access the platform via home Wi-Fi. A nurse assisted him with initial access during his clinic visit, but sustained engagement required connectivity he did not routinely have:

> *My phone doesn’t have internet access. I didn’t sign a service contract.*

P03 (male, 21 years, ACL, postoperative)—a younger participant with no digital literacy difficulties—identified the format itself as the problem and suggested a solution:

> *Maybe it would be more convenient to change your platform into an app. Users can view video as soon as they access the app.*

He noted this would also benefit older users: "Some elderly users may not be able to find the QR code each time, but can always check videos on the app with one click.”

One participant reported a technical display issue that compromised usability:

> *I have an issue with your website on my mobile phone. Only the latter half is visible; the upper portion remains hidden … It’s an iPhone issue.* [P06, male, ACL, postoperative]

These barriers were not exclusively a function of age or digital literacy. While older participants faced additional challenges around connectivity and device familiarity, younger participants also encountered friction from the platform’s web-based, QR code–dependent format. The common thread was that the access mechanism placed the burden of re-entry on the user, and when that burden exceeded a threshold—whether through a lost pamphlet, absent connectivity, or a display bug—engagement ceased.

Competition With Alternative Exercise Resources

A distinctive finding was that when the platform’s access mechanism failed or when content was perceived as insufficient, participants did not simply stop exercising. Instead, many migrated to alternative resources they found more accessible or better suited to their needs.

The most frequently cited alternative was HA Go, a mobile app provided by the Hospital Authority that offers exercise content with daily reminders. P05 (male, 77 years, osteoarthritis, preoperative) described it as functionally comparable to Healthy Knees: “HA Go app has similar functions to your platform and can remind users to do exercises every day.” P10 (female, 74 years, osteoarthritis, preoperative) used HA Go as her primary exercise resource and had not engaged with Healthy Knees at all, supplementing the app with a community exercise group:

> *They gave me also another platform that is belonged to the physiotherapist. And then I follow that kind of exercise. I think there’s some improvement for me.*

P11 (male, 79 years, osteoarthritis, preoperative) similarly used HA Go rather than Healthy Knees for his daily exercise routine, responding to its SMS text messaging reminders.

YouTube was another common alternative. P14 (female, 21 years, ACL, postoperative) searched for ACL recovery exercises on YouTube during her home rehabilitation, though she noted the content was “not so detailed as this platform.” P08 (female, 63 years, osteoarthritis, post-TKR) turned to YouTube after losing access to Healthy Knees. P01 (male, 76 years, osteoarthritis, preoperative) took a different approach entirely, purchasing a stretching board and devising his own exercise routine based on prior physiotherapy knowledge.

XSL•FO
RenderX

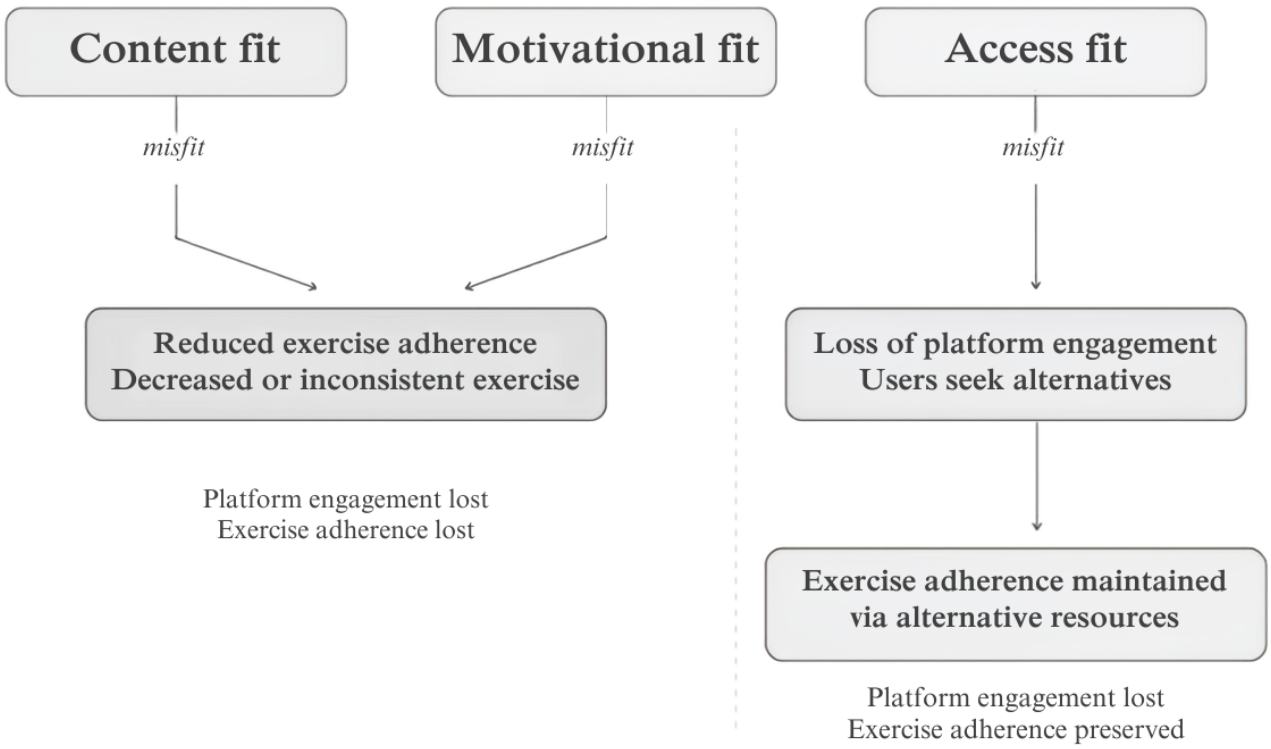
This pattern of substitution has important implications. It suggests that the participants in this study were not, on the whole, lacking in motivation to exercise—rather, the Healthy Knees platform was competing for their engagement within an ecosystem of alternative resources, some of which offered lower access friction (HA Go's app format, YouTube's familiarity) or more personalized guidance (personal coaches, community groups). Nonengagement with the platform, in these cases, did not equate to nonadherence to exercise.

Table 2 summarizes the 3 themes describing the fit between the Healthy Knees platform and participants' rehabilitation contexts.

Table . Summary of themes describing the fit between the Healthy Knees platform and participants' rehabilitation contexts.

Theme	Description
Content fit	The degree to which the platform's exercise content matched participants' rehabilitation needs, including perceived redundancy with existing physiotherapy, temporal mismatch between content and recovery stage, and difficulty calibration relative to physical capacity.
Motivational fit	The alignment between the platform's motivational support features and participants' needs, including the dual role of pain as both a driver and deterrent of exercise, and the spectrum between self-directed motivation and reliance on external scaffolding.
Access fit	The alignment between the platform's delivery mechanism and participants' technological circumstances, including access barriers created by the QR code–dependent web format and competition from alternative exercise resources such as HA Go and YouTube.

Across the 3 themes, a common pattern emerged inductively during analysis: adherence to the Healthy Knees platform depended on the degree of fit between the platform and the participant's context across content, motivational, and access dimensions. When fit was adequate across all 3 dimensions, participants maintained both platform engagement and exercise adherence. When any single dimension was misaligned—whether through content that did not match the recovery stage, insufficient motivational scaffolding, or access friction—adherence was disrupted. Notably, the consequences of misfit differed by dimension: content and motivational misfit tended to reduce exercise adherence overall, while access misfit more often redirected exercise behavior toward alternative resources, disrupting platform engagement while preserving exercise adherence. Furthermore, fit was not static: participants' alignment with the platform shifted over the course of their recovery, with content that was initially appropriate becoming redundant or insufficient, and motivational needs evolving as pain and functional capacity changed. These patterns, including the temporal dimension of fit and its implications for platform design, are developed further in the Discussion section.



Discussion

Principal Findings

This qualitative study explored adherence to the Healthy Knees digital knee rehabilitation platform among 15 participants in Hong Kong. Three themes were identified—content fit, motivational fit, and access fit—which together describe the alignment between the platform and participants' rehabilitation needs, motivational profiles, and technological circumstances. The central finding is that adherence was not determined by any single factor but by the degree of fit across all 3 dimensions. When fit was adequate across content, motivation, and access, participants maintained both platform engagement and exercise adherence. When any single dimension was misaligned, adherence was disrupted—but the nature of that disruption differed: content and motivational misfit tended to reduce exercise adherence overall, while access misfit more commonly redirected exercise behavior toward alternative resources, preserving exercise adherence while disrupting platform engagement. These predominant patterns are depicted in Figure 2.

XSL•FO
RenderX

Figure 2. Relationship between the 3 fit dimensions and divergent adherence patterns.

Fit as an Organizing Framework for Understanding Digital Rehabilitation Adherence

The concept of fit that emerged from this analysis resonates with established adherence frameworks while offering a more specific account of how adherence operates in digital rehabilitation contexts. The World Health Organization's multidimensional adherence model identifies 5 interacting dimensions—socioeconomic, health system, condition-related, therapy-related, and patient-related factors—and emphasizes that nonadherence is a systemic issue rather than a patient-driven problem [9]. Our findings align with this principle: participants' nonadherence reflected mismatches in the intervention design, health care delivery context, and access mechanisms, not simply a lack of motivation. The fit framework extends this perspective by specifying the dimensions most salient in a digital rehabilitation context and by revealing that different types of misfits produce qualitatively different patterns of nonadherence.

Our findings can also be situated within the Capability, Opportunity, and Motivation Behavior (COM-B) model of behavior change [16], which posits that capability, opportunity, and motivation must all be present for a behavior to occur. Content fit maps broadly onto capability—participants needed exercises that were appropriate to their physical capacity and recovery stage. Motivational fit maps onto motivation—participants varied in the degree to which they could sustain exercise without external scaffolding. Access fit maps onto opportunity—the platform's delivery mechanism either enabled or constrained the possibility of engagement. Consistent with previous applications of COM-B to rehabilitation contexts [17], our findings suggest that interventions addressing only 1 component—for example, providing exercise content without motivational support or accessible delivery—are unlikely to sustain adherence. However, the fit framework adds a temporal dimension that COM-B does not explicitly address: fit is not static but shifts as users progress through recovery, meaning that a platform well-suited to a participant at one stage may become misaligned at another.

Content Fit and the Challenge of Perceived Redundancy

A striking cross-cutting finding was that participants across both groups perceived the Healthy Knees content as substantially overlapping with exercises they were already receiving through in-person physiotherapy or other digital resources. This finding suggests that providing evidence-based content alone may be insufficient to drive engagement; rather, as the person-based approach to digital intervention development argues, content must offer perceived added value from the user's perspective to sustain use [18]. The temporal mismatch finding—in which participants accessed the platform at a recovery stage for which the content was either too advanced or no longer relevant—has important design implications. Previous work on digital rehabilitation has emphasized the importance of tailoring exercise content to the individual [19], but our data suggest that tailoring must account not only for diagnosis and physical capacity but also for the timing of platform introduction relative to the patient's rehabilitation trajectory. The experience of participants who discovered the platform months after surgery, when its early-stage content was no longer relevant, illustrates how the window of optimal content fit can be missed entirely. Conversely, participants who attempted exercises immediately

XSL•FO
RenderX

postinjury found the content too demanding, suggesting that premature introduction can be equally problematic.

The safety concern raised by one participant, who overexerted during stretching exercises and experienced adverse effects, highlights the limitations of a platform that provides exercise demonstrations without guidance on dosage or adaptation. Digital rehabilitation platforms that lack real-time feedback or clear dosage parameters may inadvertently place responsibility for safe exercise progression on the user, which is consistent with concerns raised in the wider literature on unsupervised home-based exercise [20].

Motivational Fit and the Dual Role of Pain

The finding that pain operated simultaneously as a motivator and a deterrent adds nuance to existing understandings of adherence in musculoskeletal rehabilitation. Previous research has identified pain as a barrier to exercise adherence [21], but our findings suggest a more complex dynamic in which the presence or absence of pain served as an implicit indicator of need. For some participants, feeling pain signaled that exercise was necessary; for others, the absence of pain removed the perceived rationale for continued effort. This paradox has been observed in medication adherence research, where symptom improvement is a well-documented trigger for discontinuation [9], but it has received less attention in the digital rehabilitation literature.

The spectrum between self-directed motivation and reliance on external scaffolding also challenges simple demographic assumptions. Some of the most self-directed exercisers in the sample were older preoperative participants, while some younger postoperative participants described significant difficulty maintaining routines without companions or external prompts. This finding is consistent with research suggesting that health literacy, prior exercise experience, and self-efficacy may be more important predictors of sustained engagement than age alone [22]. The convergent suggestion from 2 participants that progress tracking and feedback features could support adherence aligns with evidence that self-monitoring is among the most effective behavior change techniques in digital health interventions [23].

Access Fit and the Ecosystem of Alternative Resources

The finding that participants migrated to alternative exercise resources rather than ceasing exercise entirely is perhaps the most distinctive contribution of this study. Recent work on engagement with digital health interventions has drawn a useful distinction between microengagement—interaction with the digital tool itself—and macroengagement—engagement with the target health behavior [8,24]. Our findings illustrate this distinction empirically: several participants maintained macroengagement (exercise adherence) while abandoning microengagement (platform engagement), substituting YouTube videos, the HA Go app, personal coaches, or self-devised routines.

This pattern of substitution reflects the competitive landscape in which digital rehabilitation platforms operate. In Hong Kong, the Hospital Authority's HA Go app provides a widely available, app-based alternative with built-in reminder features. YouTube offers a vast library of rehabilitation exercise content. Personal coaches and community exercise groups provide social support and accountability. The Healthy Knees platform, delivered via a QR code–dependent web browser with no dedicated app, no saved login, and no automated reminders, faced a significant access disadvantage relative to these alternatives. This is consistent with broader evidence that the usability and convenience of digital health tools are critical determinants of sustained engagement, particularly when users have readily available alternatives [25].

The Hong Kong Context

Several features of the Hong Kong health care system shaped the adherence patterns observed in this study. Waiting times for elective orthopedic surgery in the public system can extend to several years [12], meaning that participants with preoperative osteoarthritis in this study were managing their condition over prolonged periods with limited physiotherapy access. Participants described physiotherapy sessions conducted at long intervals that felt insufficient, with limited opportunities for 1-on-1 attention. This context makes digital rehabilitation particularly relevant as a means of bridging gaps in formal care—but it also means the platform must sustain engagement over long waiting periods, a challenge that the current static content model is unlikely to meet.

The cost differential between public and private physiotherapy in Hong Kong is substantial. Participants in this study were drawn from a public hospital where physiotherapy resources were described as limited. Digital platforms offer a potential solution to this resource constraint, but our findings suggest that a platform perceived as duplicating rather than extending existing care will not be adopted, regardless of its clinical quality.

While these health care system factors are specific to Hong Kong, several of the adherence patterns observed in this study may extend to other contexts. Context-specific findings include the reliance on a QR code–based web platform as the primary access mechanism and the availability of HA Go as a readily accessible alternative provided by the Hospital Authority. However, the challenge of perceived redundancy with existing physiotherapy, the temporal mismatch between static platform content and evolving rehabilitation needs, and the tendency for users to substitute alternative resources when access friction is high are likely relevant wherever digital rehabilitation platforms operate alongside established care pathways.

Strengths and Limitations

This study has several strengths. To the authors' knowledge, it is among the first qualitative studies to explore digital knee rehabilitation adherence in Hong Kong, providing context-specific insights into a health care system with distinctive resource constraints and cultural characteristics. The postimplementation design captured real-world experiences of participants who had used the platform in practice, rather than hypothetical responses to a prototype. The inclusion of both ACL and osteoarthritis participants allowed comparison across different experiential profiles, revealing both cross-cutting and group-specific patterns.

XSL•FO
RenderX

Several limitations must be acknowledged. Diagnosis, age, and surgical stage were closely intertwined in this sample: participants with ACL were predominantly younger and postoperative, while participants with osteoarthritis were predominantly older and preoperative. Consequently, differences observed between groups cannot be attributed to diagnosis alone, and may reflect age, perioperative stage, or their combination. Detailed clinical descriptors—such as osteoarthritis severity grading, time since surgery, or concomitant injuries—were not systematically collected, which limits the degree to which findings can be linked to specific clinical characteristics. Future research should include such variables to enable more precise stratification.

The study used a convenience sample drawn from a single hospital, potentially limiting transferability, although there is no reason to expect patients at this site to differ substantially from those at other public hospitals in Hong Kong. The platform did not capture objective usage data (eg, login frequency, session duration), so all engagement information is based on participants' self-reported accounts. Transcripts were translated from Cantonese or Mandarin into English, which may have introduced minor shifts in meaning despite efforts to ensure accuracy through the use of a professional translation service. Data collection did not pursue theoretical saturation, and with 15 participants, some perspectives may not have been captured. While our sample included diverse demographic and clinical profiles, future research with larger and more varied samples is needed to explore additional viewpoints.

Conclusions

Adherence to digital knee rehabilitation is best understood not as a property of the individual or the platform, but as a product of the ongoing fit between the 2 across content, motivational, and access dimensions. This fit is dynamic, shifting as users progress through recovery. Digital rehabilitation platforms that offer static content through high-friction access mechanisms risk losing users to more accessible alternatives—without necessarily losing them to inactivity. Designing for sustained fit, particularly through adaptive content, integrated feedback, and reduced access friction, may be more effective than targeting adherence as an isolated behavior. Future research should test this framework longitudinally and with objective usage data to identify when and how fit breaks down across recovery trajectories.

Abstract

Background: Digital social media aids are features that enhance accessibility to social media for users with disabilities. One group of adults with disabilities who have reported barriers to social media access is adults with traumatic brain injury (TBI). Results of previous studies showed that adults with TBI want to engage in social media but encounter significant barriers to doing so, due in large part to TBI-related cognitive and communication challenges. We previously collaborated with adults with TBI to develop 5 aids to increase social media access. Aids were implemented as Chrome extensions that modified user interface functions and visuals on Facebook. The present study was the next step: testing the use of the 5 aids by a novel group of adults with TBI longitudinally and in naturalistic settings.

Objective: This study aimed to determine (1) how participants perceived each aid (ie, in terms of satisfaction, usability, likes, and dislikes), (2) how aids influenced participants' well-being, and (3) which aid features participants rated as most and least useful.

Methods: We recruited 39 adult Facebook users with TBI to take part in an approximately 1-month-long within-subject evaluation study of Facebook browser aids. Each aid was used for 3 days, followed by an evaluation and a subsequent 2-day no-aid use period. Participants evaluated each of the 5 unique browser aids in a randomized order.

Results: Users reported the aids to be beneficial, especially aids that reduced visual clutter and information overload. Users also reported increased life satisfaction after using the aids (P=.02).

Conclusions: These results provide proof of concept for the types of digital aids that could improve access to social media for users with TBI. We advocate including aids like these across all social media platforms so users with TBI can access the benefits of engagement in social media with fewer barriers.

accessibility; assistive technology; human factors; social media; TBI; traumatic brain injury

Introduction

Overview

Moderate or severe traumatic brain injury (TBI) can cause cognitive and communicative challenges that profoundly affect a survivor's activities of daily living and social networks [1-3]. Social media platforms have the potential to help individuals with TBI maintain and expand their social networks, join communities with people sharing similar experiences post injury, and acquire relevant information [4,5]. These platforms can also create spaces and opportunities for self-expression and identity

XSL•FO
RenderX

construction post injury [6]. Individuals with TBI, however, report significant challenges when using social media platforms.

Building upon the existing literature on TBI-related social media challenges [6,7], our team designed and developed an accessibility toolkit to provide cognitive and communication support for individuals with TBI [8]. The toolkit includes 5 browser extensions that modify the Facebook interface for greater accessibility and usability. Here, we build on this prior work by testing how these tools perform during real-world, longitudinal use.

Cognitive and Communication Impairments After TBI

TBI can cause a myriad of impairments in cognition, communication, and social interaction, as well as sensorimotor and psychological functions [1-3,9]. The most commonly impaired cognitive functions are executive functions and memory [2,10]. Executive function impairments can limit the individual's ability to manage thoughts and feelings and self-regulate behaviors [11]. Memory impairments are typically in working memory, the ability to hold and manipulate information temporarily, and declarative learning, the ability to consciously encode new information. The combination of these impairments often leads to difficulties in higher-order cognitive functions, such as reasoning and decision-making [12,13].

Social cognition impairments have been well documented in adults with moderate to severe TBI, including deficits on affect recognition and Theory of Mind tasks [14-22]. While researchers continue to debate whether these impairments are secondary to impairments in executive function (eg, if impaired cognitive flexibility limits the ability of a person with TBI to take another person's perspective) [23-25], there is consensus that performance on social cognition tasks is impaired and that these impairments contribute to negative social outcomes after TBI [26].

Cognitive impairments typically translate into communication challenges [25,27], including difficulty understanding long or complex verbal information, either written or spoken; failure to understand abstract or figurative language, like sarcasm or slang; and expressive language that is less informative, appropriate, efficient, or complete than would be expected in a given context [25,28]. Speed is also a factor in communication, as everyday communication requires rapid comprehension and expression. Speed of thinking and expressing thoughts is commonly affected by TBI [28], so even individuals with relatively strong cognitive function can have difficulty communicating at the pace of typical social interactions.

Use of inappropriate language and lack of social understanding can lead to limitations in family and friend support and cause social isolation and loneliness for individuals with TBI [1,29-33]. Psychological changes can also occur after TBI, causing negative self-perception, heightened stress and anxiety, and depressive symptoms [34,35]. Specifically, individuals with TBI can have a stronger emotional response to pessimistic information or negative experiences [8]. These TBI-related challenges can profoundly affect an individual's social connections, resulting in a lower quality of life [36].

Social Media Use After TBI

As a result of cognitive and communication impairments, individuals with TBI face significant barriers to using social media [4,8-42]. Complex user interfaces can be difficult to navigate and make some features of social media platforms less accessible [6,43]. Undesirable content in newsfeeds, such as arguments between users or posts pertaining to violence, can trigger heightened negative emotions and cause frustration for individuals with TBI, particularly individuals with impairments in emotion recognition. Advertisements in the newsfeed can easily be a source of distraction and prevent users from focusing on desirable content [8]. Because of their communication challenges, individuals with TBI can misunderstand social media posts, "misreading" the sentiment of the sender and thus responding with inappropriate comments [6,8]. These types of interactions can yield an overall worse user experience and limit the development of social connections [44].

Why Improve Social Media Access?

It could be argued that the costs of social media access for adults with TBI outweigh the benefits, as cognitive challenges associated with TBI can pose risks to users. Our view is that adults with TBI who want to access social media should have the same opportunity to benefit from that access as their uninjured peers. When accessible, social media platforms help users maintain connections with their social ties, form bonds with communities, obtain new information, and foster information exchange [4,6,38,40,45]. For individuals with TBI, social media platforms provide functions that can help them overcome TBI-related challenges [4,5,38,43], and there is evidence that individuals with TBI may even prefer to have social interactions online rather than face-to-face [39]. Specifically, social media platforms can mitigate the communication challenges caused by TBI by reducing time pressure through increased time for users to comprehend information and formulate responses [4]. Individuals with TBI can also form online support groups to exchange information related to TBI and share personal experiences [4,5]. Moreover, individuals with TBI have used social media as a space to rebuild their self-identity and social connections post injury, particularly those who face dramatic changes in their personal lives [6]. With these benefits in mind, we next discuss our team's prior work toward making social media more accessible to users with TBI.

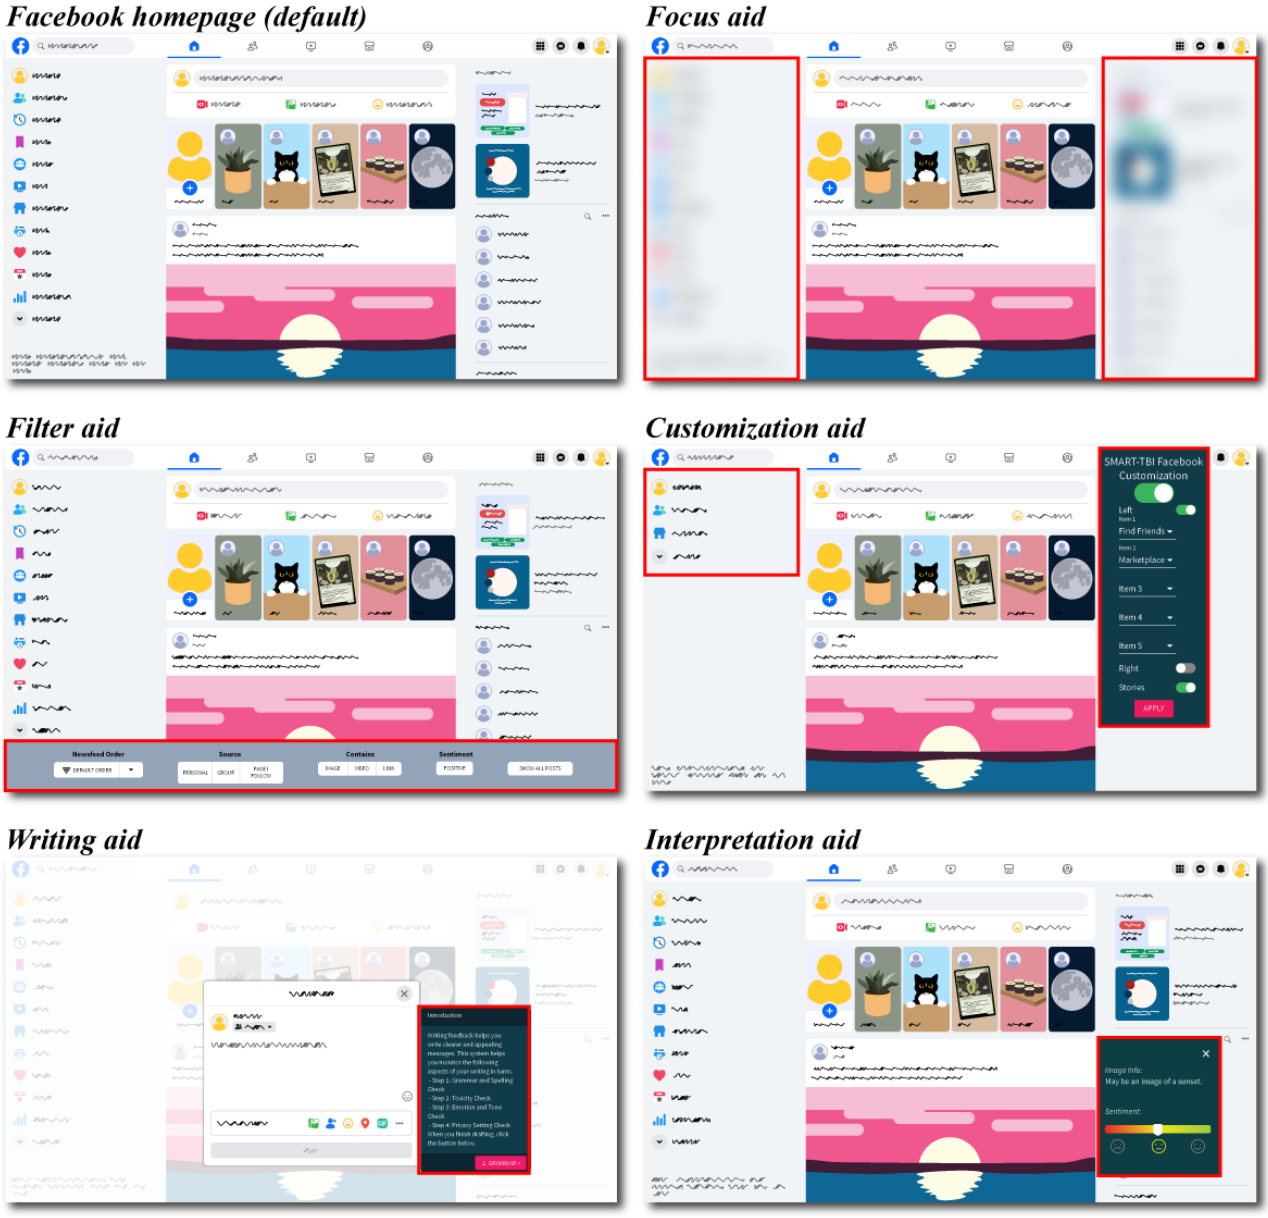
Related Work

Overview

There is a growing body of work aimed at reducing social media–related challenges faced by individuals with TBI and improving their social media experience [6,7]. For example, Brunner et al [46] developed online training and an educational toolkit for users with acquired brain injury to ensure users' safety and privacy in social media use [46]. This important work has reduced barriers and risks to using social media but has focused on training persons with TBI rather than changing the platforms themselves. Our research team focused on the latter: developing tools that address these specific challenges and improve the social media experience for users with TBI.

XSL•FO
RenderX

Our research team sought to understand the challenges of social media use in users with TBI, with the long-term goal of reducing barriers to use and improving opportunities for communication, connection, and well-being through computer-mediated communication. In this section, we review our previous efforts toward the development and evaluation of social media aids, which have used a variety of research designs, including needs finding [5,39,47], participatory design [6], prototyping [48], and a formative study [8]. These studies culminated in our current longitudinal study assessing the effectiveness of the SMART-TBI extensions.



To begin, Zhao et al [48] conducted a preliminary study to assess individuals with TBI's perceptions of the acceptability of 4 prototype social media aids intended to support user attention, memory, social cue interpretation, and message production. These 4 support areas were chosen based on existing literature and the clinical experience of the research team. Individuals with TBI were asked to review images of the prototype aids, read descriptions of their functions, and rate the aids in terms of acceptability, ease of use, and utility. The findings of this study indicated that participants found the proposed aids easy to use and expressed interest in utilizing them regularly. This study offered foundational insights for the future development of technological support tools on social media platforms.

Building on this work, Lim et al [6] further explored the use of social media supports through a participatory design study that involved exploration, ideation, and sketching to create prototype supports. Through this study, several critical design features were identified to address challenges faced by users with TBI on social media. These features included a safe filtering mechanism for the newsfeed, a customizable interface, and prompts to support communication, among many others. The study emphasized the importance of addressing not only sensory-level support but also cognitive, emotional, and communication impairments, along with the altered sense of identity experienced by users with TBI when using social media. The generation of these prototypes allowed the research team to ground future aid development in the needs of real users with TBI.

Based on these participant-led designs, Hu et al [8] developed the Social Media Accessibility and Rehabilitation Toolkit (SMART-TBI). The toolkit consists of 5 aids: the focus aid, filter aid, customization aid, writing aid, and interpretation aid. These aids were specifically designed to address the cognitive and communication challenges faced by individuals with TBI on social media platforms. A visualization of each aid can be seen in Figure 1.

XSL•FO
RenderX

Figure 1. Social Media Accessibility and Rehabilitation Toolkit (SMART-TBI) extensions. Comparison of the default Facebook homepage and visualizations of each aid extension. Focus aid: the left and right side panels are blurred to increase focus on the newsfeed. Filter aid: a menu bar at the bottom of the interface allows users to tailor newsfeed content to their preferences. Customization aid: users can tailor the stories and the left and right side panels of the interface to meet their needs and preferences. Writing aid: users receive feedback on the posts they write, including grammar, spelling, toxicity, tone, and privacy checks. Interpretation aid: users are provided with an interpretation of a post's content. The interface differences associated with each aid are highlighted in red.

Focus Aid

This aid helps users focus on the newsfeed section of the Facebook interface by blurring other peripheral information present on the home page. This function reduces the cognitive challenge of information overload and creates a more manageable viewing experience. As a result, users with TBI are able to direct their attention toward meaningful content rather than extraneous details.

Filter Aid

Rather than limiting the amount of information on screen, this aid offers users the ability to reorganize newsfeed content in chronological order or view only positive posts. In doing so, this aid reduces cognitive challenges related to information overload and maintaining focus by allowing users to control the content they view and limit the appearance of undesirable content. IBM Watson NLP API [49] is used to analyze the sentiment of the posts and, in turn, enable positive post filtering.

Customization Aid

Similar to the focus aid, this aid helps users simplify the home page layout by offering the ability to customize which features are shown in the left column of Facebook's home page (eg, friends, groups, and events), hide the right column (eg, advertisements and contacts), or hide the stories sections of the home page. While the focus aid also minimizes extraneous information on the home page, the customization aid enables users to optimize their navigation experience by choosing which elements they prefer to view. This aid helps to address cognitive

XSL•FO
RenderX

challenges related to organization and planning, maintaining focus, and information overload.

Writing Aid

Unlike the prior 3 aids, this aid primarily focuses on communication by helping users refine their Facebook posts and comments through provided grammar suggestions, sentiment analysis (ie, tone and emotion type), toxicity analysis, and privacy settings (ie, private or public). This function allows users with TBI to better understand how others might interpret their posts and comments. As a result, this aid helps to address communication challenges related to social cognition, comprehension, word finding, and language production. Grammar errors, sentiment, and toxicity are detected using external APIs, including TextGears [50] for grammar checks, IBM Watson NLP API [49] for sentiment and emotion analysis, and Perspective API [51] for toxicity assessment. It is important to note that the writing aid runs entirely on the client side as a browser extension. To generate feedback, text is sent from the participant's browser to the aforementioned natural language processing services. These services return only numeric scores and category labels. Google APIs are used under terms that prohibit data retention and training. We also set Perspective API calls so that text is not stored. TextGears stores only the analysis result and the number of API requests.

Interpretation Aid

While the writing aid helps users with TBI understand how others might interpret their posts and comments, the interpretation aid allows users to understand the sentiment and meaning of posts written by others. This aid helps to address the communication challenge of comprehension by highlighting negative text in red and positive text in green, thereby clarifying the sentiment of the post. The same external APIs used within the writing aid are also used to analyze the sentiment of posts in the interpretation aid (ie, IBM Watson NLP API [49]).

These 5 aids are intended to directly address the specific challenges faced by users with TBI. As a result, we hope to see improvements in participant self-reports, including feelings of emotional support, social connection, self-esteem, and satisfaction with life.

Objective

We conducted a longitudinal in-the-wild study to evaluate the effectiveness of the 5 aids described above in supporting users' social and psychological well-being. A total of 39 users with TBI engaged in this study over the course of 4 to 7 weeks. Throughout the course of the study, all participants completed a prestudy interview, provided daily numerical and open-ended ratings of their satisfaction with each aid, completed evaluation surveys of each aid after each evaluation period, and completed a poststudy interview describing their experience throughout the study. Through these data, we sought to answer the following questions:

- How do participants perceive each of our 5 SMART-TBI extensions in terms of satisfaction, usability, likes, and dislikes?
- How do the aid extensions influence participants' well-being?
- What aid features are most and least useful to participants?

The contributions of this work are threefold:

- a longitudinal evaluation of our SMART-TBI extensions in participants' everyday use;
- insights into the social media experience of users with TBI, including their challenges and needs; and
- design implications for social media developers who may integrate the features of these aids into their applications.

Methods

Overview

We next describe our approach to evaluating the SMART-TBI extensions, including details on participants; measures; study materials, design, and procedure; and our analysis plan.

Participants

A total of 39 adults with moderate to severe TBI (female: n=25; male: n=14) were recruited at Vanderbilt University Medical Center (n=30) and McMaster University (n=9). At the time of the study, the participants' mean age was 41.85 (SD 11.55) years. All participants were from the continental United States and were native speakers of North American English. While some participants occasionally missed their daily Facebook usage, all 39 participants successfully completed all 5 evaluation phases of the study for a final retention rate of 100%.

Participants at the Vanderbilt site were recruited through the Vanderbilt Brain Injury Patient Registry [52], and participants at the McMaster site were recruited from among participants in previous studies who consented to be recontacted for future studies. All participants with TBI were in the chronic phase of injury (ie, >6 months post injury). All but 1 participant sustained their injuries in adulthood (ie, at or after age 18 years), and the average time since injury among participants was 8 (SD 8.37) years. Participants did not have a history of neurological or cognitive disabilities before the qualifying brain injury. TBI severity was determined using the Mayo Classification System [53]. By this system, participants were classified as having sustained a moderate to severe TBI if at least one of the following criteria was met: (1) a Glasgow Coma Scale (GCS) score of less than 13 within 24 hours of acute care admission, indicating moderate or severe injury; (2) positive neuroimaging findings; (3) loss of consciousness (LOC) greater than 30 minutes; or (4) posttraumatic amnesia (PTA) after 24 hours. Injury-related information was collected from available medical records and a semistructured interview with participants. GCS scores were available for 26 participants, with scores ranging from 3 to 15; LOC was available for 28 participants; and PTA information was available for 29 participants. Acute imaging information was available for 27 participants, with 26 containing positive findings. Causes of injury included motor vehicle accidents (n=16), falls (n=9), motorcycle accidents (n=6), being hit by a car as a pedestrian (n=3), assault (n=2), multiple concussions (n=1), or other (n=2). Multimedia Appendix 1 provides demographic and injury characteristics of our participant population.

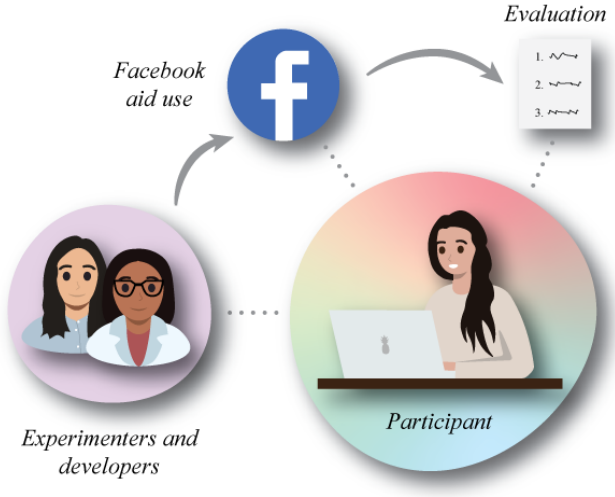
XSL•FO
RenderX

Inclusion criteria for this study included self-reported English fluency, having an active Facebook account and using it within the past year, knowing the login information for the account, and daily access to Wi-Fi.

Study Materials

The research team provided each participant with a Samsung Chromebook 4 laptop (model #XE310XBA-K01US), which was used for all study-related activities (eg, Facebook usage and Zoom meetings). To prevent lack of familiarity with a Chromebook from being a barrier to participation, the research team prepared each Chromebook with a new Gmail account, Zoom for aid activation and prestudy or poststudy calls, all 5 SMART-TBI extensions, and aid demonstration videos for each aid. Additionally, each laptop contained browser bookmarks for Facebook and other relevant applications (eg, YouTube and Gmail) required throughout the study. Each participant also received a binder with their personalized schedule, a series of "cheat sheets" describing the functions of each aid, and login information for both the Chromebook and Gmail account. Each participant was also provided with a wireless mouse and keyboard for easier navigation of their laptop and a laptop bag to hold all the study materials.

Study Design



This study used a within-subjects, in-the-wild design. The study protocol was approved by the institutional review boards of Vanderbilt University and McMaster University, and all participants provided consent prior to engaging in the study.

Participants used the developed aid extensions for 4 to 7 weeks, with the duration of a given participant depending on external factors such as travel and holiday plans. Each participant received a personalized study schedule tailored to their individual availability and preferences (eg, time of day for Zoom calls). An example schedule is shown in Figure 2.

To begin, participants attended an in-person or online prestudy session where they were introduced to the study and provided with study materials. Throughout the course of this study, participants were asked to use and evaluate the 5 SMART-TBI extensions. Each evaluation included 3 days of using an individual aid, followed by a period of Facebook use with no aids to mitigate carryover effects. The number of baseline days varied depending on individual schedules and availability, but participants were always given at least 2 days between each aid evaluation phase. The aid extension order was randomized using a balanced Latin-square design to reduce order effects. At the beginning of each evaluation phase, participants were required to complete a Zoom call to activate the necessary aid for that period. After using all 5 aids, participants attended an online poststudy session to end the study.

Participants were compensated US $20 per hour for the prestudy session, poststudy session, and each of the 5 online aid introduction sessions. For the duration of the study, participants received US $10 per day that they used Facebook for at least 10 minutes. Compensation was provided in the form of a check or Amazon e-gift card. Finally, participants who completed the study were gifted the Chromebook laptop they used throughout the study.

Figure 2. Participant schedules. Participants engaged in the study following schedules with the same structure illustrated here. Participants initially met with experimenters to complete a prestudy interview and later met with experimenters at the beginning of each aid evaluation period to activate the relevant aid. Each evaluation period consisted of 3 days during which participants used 1 of the aid extensions. Following each evaluation period, participants completed an aid evaluation survey. After all 5 evaluation periods, participants completed a final poststudy survey. Participants additionally met with the development team to discuss any technical challenges as needed throughout the study.

Poststudy interview						

Procedure

Prestudy Session

Participants were given the option of completing the prestudy session online or in person. If a participant chose the in-person option, the research team met the participant in the laboratory and gave them the Chromebook laptop to take home for the rest of the study. If a participant chose the online option, the research team mailed them their Chromebook laptop and met with them on Zoom. During the prestudy session, participants were given an overview of the Chromebook (ie, login information and bookmarks) and their study schedule (ie, evaluation days, baseline days, and survey dates). Prior to or during this session,

XSL•FO
RenderX

participants provided informed consent by signing digital consent forms.

Once a participant logged into their assigned Chromebook, they completed a prestudy interview on REDCap and a prestudy questionnaire on Qualtrics. Next, participants logged into their Facebook accounts and were informed that their Facebook usage would only register if they used the provided Chromebook. Additionally, the experimenters informed participants that data collected throughout the study would never include the specific content of their posts and would be anonymized through the use of participant IDs.

Following this initial meeting, participants began the study by completing baseline days (ie, using Facebook with no aids active) until the first scheduled Zoom meeting, during which the first aid would be activated and the evaluation phase would begin.

Aid Evaluation Phases

Throughout the course of the study, participants completed a total of 5 aid evaluation phases. Each phase began with a Zoom call with an experimenter to (1) update the laptop background to the "cheat sheet" that matched the aid being evaluated, (2) assist the participant in activating the aid and a "helper window" extension for feedback, (3) watch the demonstration video for the relevant aid, and (4) guide participants through the process of using the aid prior to individual use. Participants were asked to use the aid for 3 days and for a minimum of 10 minutes per day. Outside of the minimum usage time, participants were encouraged to use Facebook as they would during normal use. Following their daily use of Facebook, participants were asked to complete a brief feedback survey to report their satisfaction with the active aid. This survey was made available through a "helper window" extension. After 3 days of use, the active aid extension automatically deactivated. Participants were then sent an email with an evaluation survey to provide detailed feedback on the aid extension they had evaluated. This full process was then repeated for each of the remaining aids until all had been evaluated.

Poststudy Session

Following their evaluation of all 5 aid extensions, participants completed an online poststudy session with an experimenter. During this session, participants completed an interview on REDCap and a questionnaire on Qualtrics to report their experiences with the aids and well-being outcomes. Additionally, experimenters assisted participants in deleting study materials and restoring the laptop to factory settings during this time.

Measures

Overview

Throughout the course of this study, the research team collected a considerable amount of data ranging from qualitative interviews and open-ended survey questions to quantitative perception measures and Facebook usage data.

Prestudy Interview

Within this initial interview, experimenters asked participants a series of 8 open-ended questions, which centered on current social media usage and experience with assistive technology for TBI challenges. A listing of these questions is provided in Multimedia Appendix 2.

Aid Evaluation Surveys

Following each aid evaluation phase, participants completed a survey concerning their experiences with and perceptions of the evaluated aid. This survey included the full 15-item Usefulness, Satisfaction, and Ease of Use (USE) Questionnaire [54], which captures perceptions of usefulness, ease of use, ease of learning, and satisfaction. This questionnaire is a widely used metric to evaluate system usability and was chosen to capture a multifaceted perspective on participant experience with the developed aids. Five open-ended questions concerning likes, dislikes, technical difficulties, aid challenges, and design suggestions were also included. These items allowed the research team to develop a thorough understanding of participant perceptions and experiences while also providing an opportunity for participants to give open-ended feedback. All items that were developed by the research team are provided in Multimedia Appendix 2.

Daily Ratings

After a participant had used Facebook on a given day, they completed a daily rating. Participants were prompted with the question, "How satisfied are you with the Facebook aid today?" followed by the optional question, "Do you have any other comments?" The first question was answered with a star rating of 1 to 5, while the second question was answered with a free-text response.

Poststudy Interview

During the final interview, experimenters asked participants a series of 3 open-ended questions centering on their experiences with the aids throughout the study. These questions included:

- How was your experience using the aids?
- Do you have a favorite aid? And if so, which one was it? And why?
- Is there anything else you'd like to share with us?

Prestudy and Poststudy Surveys

Within both the prestudy and poststudy surveys, participants rated their feelings of emotional support, social connection (adapted from Ledbetter [55]), self-esteem [56], and satisfaction with life [57]. These ratings were intended to capture any pre-post study changes. Additionally, the poststudy survey also contained 2 additional items regarding unaddressed TBI challenges (ie, "Are there any challenges related to your TBI that were not addressed by the aids you used during this study? If yes, please explain.") and endorsements of the aids for use in everyday life (ie, "Would you use any of the aids you have used during this study in your daily life? If so, which ones would you use?"). After having evaluated all aids, these questions allowed the research team to understand the main benefits and shortcomings of all aids holistically.

XSL•FO
RenderX

Analysis

Given the complexity of this study and the high volume of data collected throughout, quantitative data were first reviewed and cleaned to remove any erroneous data (ie, duplicate surveys and extraneous daily ratings). Following this step, aggregate daily ratings were generated for each aid per participant and then for each aid across all participants. Aggregates were also generated for each perception rating collected within the evaluation surveys across all participants. Finally, paired-samples 1-tailed *t* tests were used to determine whether there were positive pre-post changes in participant feelings of emotional support, social connection, self-esteem, and satisfaction with life.

We examined several types of qualitative data, including prestudy and poststudy REDCap interview data and multiple ratings of participants' perceptions of the extensions (Table 1). We conducted inductive thematic analysis for the survey feedback under each category for each aid (ie, likes, dislikes, technical difficulties, and aid challenges) [58,59]. The primary coder and a secondary coder each coded a subset of the dataset and developed the initial codebook. Disagreements were resolved through discussion. The primary coder then coded the remaining dataset, consolidated new codes, and updated the codebook iteratively. The primary coder performed the interview analysis independently. This analysis was aided by qualitative analysis software, specifically Dedoose [60], that facilitated data management and coding consistency. Based on the final codebooks of the survey responses and the interview data, our interdisciplinary research team discussed and generated the final themes and subthemes.

Table 1. Data analysis approach. An overview of the analysis for all data collected throughout the longitudinal user study, including collection method, measures, and analysis approach.

Collection method	Measures	Analysis approach
Prestudy interview	Prior social media usage and experience with assistive technology for TBI[a] challenges	Thematic analysis
Prestudy survey	Feelings of emotional support, social connection, self-esteem, and satisfaction with life	Descriptive statistics
Daily rating	Satisfaction with the evaluated aid	Descriptive statistics
Aid evaluation survey	Quantitative perceptions (ie, usefulness, ease of use, ease of learning, and satisfaction) and qualitative perceptions (ie, likes, dislikes, technical difficulties, aid challenges, and design suggestions) of aid extensions	Descriptive statistics and open coding
Poststudy interview	Experiences with all aids throughout the study	Thematic analysis
Poststudy survey	Feelings of emotional support, social connection, self-esteem, and satisfaction with life as well as aid endorsements	Descriptive statistics and *t* test

[a]TBI: traumatic brain injury.

Ethical Considerations

The study protocol was approved by the institutional review board (IRB) at Vanderbilt University (IRB 191489) and the Hamilton Integrated Research Ethics Board at McMaster University (Project 16271). All participants provided informed consent prior to participating. Participants were compensated at a rate of US $20 per hour for the prestudy session, poststudy session, and each of the 5 online aid introduction sessions. During the study period, they also received US $10 for each day they used Facebook for at least 10 minutes. Compensation was provided by check or Amazon e-gift card. In addition, participants who completed the study were permitted to keep the Chromebook laptop used throughout the study. Participant data were deidentified through the use of codes. All identifying information present in interview data was removed during the transcription process. Additionally, all of our social media aids ran on the client side as browser extensions, and no content from any Facebook posts or comments was collected. Collected data, such as consent forms and electronic data files, were stored in either secure physical storage or university-approved servers accessible only to study personnel. In the case of Vanderbilt University, research records will be retained for at least 3 years following closure of the research with the IRB, and any HIPAA (Health Insurance Portability and Accountability Act)-related documentation will be retained for at least 6 years following the last date of use. Deidentified data collected at McMaster University will be stored indefinitely.

Results

Overview

In this section, we present the results of our longitudinal study, including themes derived from our prestudy and poststudy interviews, findings from our multifaceted aid evaluation, and the overall impact the aids had on participants.

Prestudy Interview

Overview

To begin, a total of 39 prestudy interview transcripts were analyzed using thematic analysis. Through this analysis, we identified a total of 6 themes that illustrate the varying backgrounds of our participants.

Theme 1: Facebook Usage Changes Following TBI

Overview

Our analysis revealed several subthemes that reflected reported changes in patterns of Facebook usage in relation to TBI-related challenges.

XSL•FO
RenderX

Pattern of Usage

A total of 51% (20/39) of participants noted a decrease in Facebook use following their TBI, with varying patterns of reduced engagement. Some participants ended their use immediately after their TBI and only re-engaged in a limited manner sometime later. Participant 5 stated:

> *I just got back on Facebook about a year and a half ago. If I added anyone, it was just immediate family, a pool of ten people. These people don't have Instagram, so I have them on Facebook...I rejoined because I missed seeing the progression of close people's stories.*

Others reported decreasing or ending specific activities, such as posting. For example, participant 27 explained:

> *I have stopped posting a ton of things on Facebook. I limit it to just family things and not so much on where I am, like checking in anywhere.*

Some participants expressed a preference for re-engaging with visual-oriented platforms, such as Instagram, due to their TBI-related needs or personal interests. Participant 1 mentioned, "I switched over mostly to Instagram, with it being easier to take a look at pictures." Additionally, several participants indicated a desire to limit their time online or adapt their social media use to better suit their post-TBI lifestyle. For example, participant 10 noted:

> *Not specifically due to my TBI, but I do use social media significantly less than I did before. Now I primarily use Facebook for Facebook Marketplace and to remember birthdays.*

Participants 1 and 5 also noted a switch to Instagram from Facebook post TBI, as the picture-based nature of Instagram supports their engagement.

However, 10% (4/39) of participants noted an increase in their Facebook use post TBI. Participant 18 remarked, "My Facebook use has increased since the injury, partially due to COVID since I was home more." This participant also attributed their increased use to social pressure, stating:

> *It has increased due to social norms forcing the use of Facebook to be able to be involved in community events, etc. since that is how they notify you of times and changes in events.*

Additionally, 31% (12/39) of participants did not report any specific changes in their Facebook usage post TBI. For example, one participant noted that they "use it about the same" and described themself as "not a frequent user" (P31).

Sensory Challenges

Additionally, 21% (8/39) of participants noted sensory challenges while engaging with Facebook post TBI. Specifically, vision challenges were reported to impede Facebook navigation immediately following a sustained TBI:

> *The biological part, my eyes were so bothered by the bright light. Screens were just out, completely. Scrolling was impossible. I would close my eyes as I was scrolling and then look at posts, it was a nightmare. Trying to read people's updates, I found it was frustrating and a useless experience.* [P5]

Participants also described experiencing sensory overload while on Facebook, noting, "It just goes very fast; it takes me a while to understand" (P4).

Social Challenges

Further, 10% (4/39) of participants noted social challenges while engaging on Facebook post TBI. One such challenge was reduced confidence in posting on Facebook:

> *Actually, before I was confident using it. Now, I will start to put something on Facebook and then delete it because I'm not confident about what I've posted. It's wording, punctuation, that I'm not as confident with.* [P7]

Concerns with social comparison were also expressed: "I had deleted Facebook initially. I couldn't watch everyone's updates of getting married, having kids" (P5). This sentiment was echoed by other participants who felt overwhelmed by others' lives:

> *The way I see Facebook, it's more attracting families, moms and dads, posting their pictures—blasting all of their pictures, like birthday parties—It's too much.* [P1]

Cognitive Challenges

Beyond changes in Facebook usage, many participants also noted challenges following their TBI. Changes in cognitive abilities, such as attention, memory, and understanding, were specifically noted by 8% (3/39) of participants. They shared that their "attention span" was reduced when on Facebook (P33), that they relied on written reminders to support their memory (P6), and that understanding online information was difficult at times: "Some things I don't understand. Definitely. It's difficult sometimes" (P4).

Theme 2: Use of Technology, Apps, and Tools for TBI Management

Overview

Participants described the use of various tools, apps, and technology to manage their TBI symptoms in general and specifically to support their use of online communication. The following subthemes relate to the types of supports participants indicated they used prestudy.

Cognitive Supports

A total of 26% (10/39) of participants highlighted the use of various technologies and apps to address cognitive challenges following a TBI, both in their daily lives and on Facebook, where available. These tools were primarily used to support memory and attention difficulties. For instance, participant 3 mentioned:

> *I've attempted to use a lot of apps for research on symptom management, for example like a type of exercise to do to overcome the dizziness, the cognitive impairment aspect of it, and the balance of course.*

The types of tools and apps used included timers, calendars, reminders, alarms, note-taking apps, and meditation apps. These

XSL•FO
RenderX

cognitive supports were considered essential by many participants. One participant emphasized the importance of these supports, stating, "It's kinda' like my external hard drive. When I can't rely on my brain, it's helpful for storing and recalling information" (P8). Participants also discussed the use of various cognitive retraining apps, including brain games and specific apps (eg, Peak) "to improve brain function and stamina" (P12).

Participants also noted challenges with the consistent updates to and availability of these tools on social media. For example, participant 10 expressed difficulty in keeping up with changes on social media platforms: "I also like the birthday reminders but don't currently know where to find this on Facebook; things seem to move often."

Sensory Supports

A total of 21% (8/39) of participants discussed the types of apps, tools, and technology they use online to cope with visual, sensory overload, and hearing challenges. Visual supports included setting their screen to dark mode, dimming the screen, using a larger font, and orienting the screen to photo mode. Participant 19 noted, "I like darker screens now and less clutter, so we've adapted my preferences to be darker and less clutter[ed]; email, my search engine, etc." Similarly, participant 5 stated, "I use larger font—14-16 size font," to support their vision. Additionally, one participant mentioned post-TBI auditory sensory overload and the use of "hearing aids...for anacusis and tinnitus, with active noise canceling" (P5).

Assistive Technology

Additionally, 21% (8/39) of participants described an increased reliance on the use of assistive technology in the form of devices and assistive features post TBI. For example, some described using larger devices to access social media: "My iPad and computer have purposefully lots of pixels, big screens, etc., for when my eyes get tired and it's harder to process" (P19). Specific assistive features noted included speech-to-text, text-to-speech, and AssistiveTouch. Reasons participants reported for using these features centered around the need for cognitive, physical, and communication supports. For example, one participant noted:

> *With the voice-to-text, because of the affected side [of my body], sometimes it is hard for me to write or type. So I use the voice-to-text. It also helps my speech because the injury affected my speech. In the beginning, you get a lot of therapy but then it stops. I also use the touch screen and magnifying and closed captioning a lot.* [P3]

Written Communication Supports

Some participants (3/39, 8%) also reported using spelling and grammar check tools while writing online, specifically highlighting the use of apps like Grammarly to support post-TBI cognitive challenges with writing. Participant 36 shared:

> *When I forget a word or erroneously substitute, [for example I] meant 'baseball' but typed 'basement', I like that it highlights potential errors and allows me to decide if I want to 'correct' it.* [sic]

AI

AI search tools, such as Bard AI, were described by one participant as "helpful when sifting through large amounts of data" (P2) and were highlighted for their role in facilitating information processing and retrieval post TBI.

Lack of Support

A substantial number of participants (16/39, 41%) reported not using any specific apps or technology post TBI. Participants' rationale varied, ranging from a lack of awareness about available tools to a preference for managing their interactions with technology in other ways. For instance, participant 18 stated, "[I do] not know of any tools to use," indicating a lack of awareness as a barrier to using supportive technology. Some participants preferred to manage their technology use by controlling their exposure to overwhelming stimuli. For example, participant 27 shared their strategy for handling Facebook usage: "I got back onto Facebook once I could handle it again. If I became overwhelmed using it, I would stop and come back to it later." This approach highlights a preference for self-regulation and intermittent use to avoid sensory and cognitive overload.

Theme 3: Frequent Use of Social Media and Facebook

Out of 39 direct responses regarding the frequency of social media and Facebook use, 37 (95%) participants provided detailed insights. The majority of participants (34/39, 87%) rated their use as "5," indicating they use social media "very frequently" (eg, daily or several times a day). Example comments included: "[I] check stuff daily but more app-specific preferences" (P36). Some participants noted that they are on social media "constantly, I'm on it all the time" (P2), or "on a daily basis, 2-3 hours per day, this is where I get my news now" (P1). A total of 2 (5%) participants rated their use as "4," signifying that they use social media often (eg, once a week to several times a week). One participant rated their use as "2," indicating "rare" use of social media (eg, less than once a month), stating:

> *Maybe once a month or once every two months [I use Facebook]. Then I'm only on there for a few minutes to send a message or receive one. I find it overwhelming and confusing and too time consuming for me.* [P19]

As with the frequency of social media use, the majority of participants noted that they use Facebook either "very frequently" (27/39, 69%) or "often" (8/39, 21%). One participant (P35) noted that they use Facebook "rarely," specifically "once every 3 months." Participants discussed attempting to limit their use, noting, "[I am on] daily but [for a] limited amount of time; mostly to check on community events, not for personal people [sic] networking" (P18). Another participant mentioned a specific use of Facebook to keep up with a certain demographic of friends:

> *I check it once a week primarily to keep in contact with older sergeants from my time in the Army that only use Facebook, along with some members of my family.* [P23]

XSL•FO
RenderX

Theme 4: Preferred Social Media Platforms

Participants described using multiple social media platforms in addition to Facebook, with many engaging with 2 or 3 other platforms. Instagram was mentioned most frequently (30/39, 77%), followed by TikTok (9/39, 23%), Snapchat (5/39, 13%), and several others. A visual of the reported social media platforms is provided in Multimedia Appendix 3.

One participant explained their selective use of social media platforms:

> *I was on Instagram, but I don't like it. I just find that everything is about your picture and posting, and I'm getting overwhelmed with social media. So, I just choose which one is functional for me. And TikTok, but it's getting too addictive, I like the dancing and the funny stuff. Of course, YouTube—everything you need is on YouTube. And YouTube is educational for me. I like fixing stuff so I look for how to do stuff.* [P3]

Several participants (9/39, 23%) noted that Facebook was the only social media platform they actively used. One participant shared:

> *Facebook's the only one I use. I Google things and use email, but that's about it. I don't have Instagram or TikTok or Twitter. If there are other social media platforms, I'm not really aware of them...* [P19]

Theme 5: Perceived Benefits of Social Media

Overview

Participants were asked what they generally liked about engaging on social media, specifically on Facebook. Several subthemes of liked aspects of social media emerged.

Social Connection

Most participants (32/39, 82%) reported that engaging on social media provided them with an important context for social connection. They reported using social media to connect with friends and family who live far away, converse with new people with similar interests, and stay updated with others' activities. One participant noted about Facebook:

> *After my brain injury, I like the fact that I can, it can be two in the morning or afternoon, there's always somebody, a conversation, something to see. It's very stimulating.* [P9]

General Information

A total of 26% (10/39) of participants highlighted the ease of accessing information, such as staying current with the news and learning new things. For example, one participant mentioned, "It's great for staying up to date with the news" (P24), and another added, "I use it for learning new things" (P21).

Entertainment

Several participants (6/39, 15%) described the entertainment value of watching videos, sharing memes, and passing time with humor. One participant noted, "I follow very few things on Facebook, but the ones that I do are fun things" (P7).

Professional Development

Some participants (3/39, 8%) said they used specific sites for business purposes. One participant said that LinkedIn was a "powerful tool in the business environment" (P23), allowing them to build their businesses.

Theme 6: Concerns With Facebook

Overview

While about half of the participants (18/39, 46%) reported not having any concerns with their Facebook use, the others described concerns about Facebook in 4 categories: cognitive, social, privacy and safety, and skills-related.

Cognition

Cognitive concerns included feeling overloaded and overwhelmed by information and concerns about their own overuse of the platform. For example, participant 31 noted, "It takes up too much time, too much screen time, [and] feels like it makes my attention span worse." Another participant echoed this sentiment, stating, "I have ADHD and it's a dopamine hit, so I'm prone to get on social media too much. Especially TikTok" (P21). One participant reported concerns with their long-term use of Facebook, noting, "my brain has enough challenges, and it's hard to keep up with all the changes on Facebook" (P19).

Social

Social concerns included personal and social judgments about what they and others posted, as well as social comparison. Participant 1 said, "Sometimes I feel weird about posting and people asking too much [sic] questions," and participant 30 expressed the concern that Facebook "leads to comparison of others."

Privacy and Safety

Privacy and safety concerns included concerns about data tracking, identity and information theft, scammers, hacking, and a lack of anonymity. For example, participants reported knowing their information is not private and feeling "leery" about posting or experiencing heightened anxiety online. Participants noted, "There are so many unscrupulous people" (P2) and "Predatory people are out there, and [you] need to be careful" (P9).

Lack of Skills

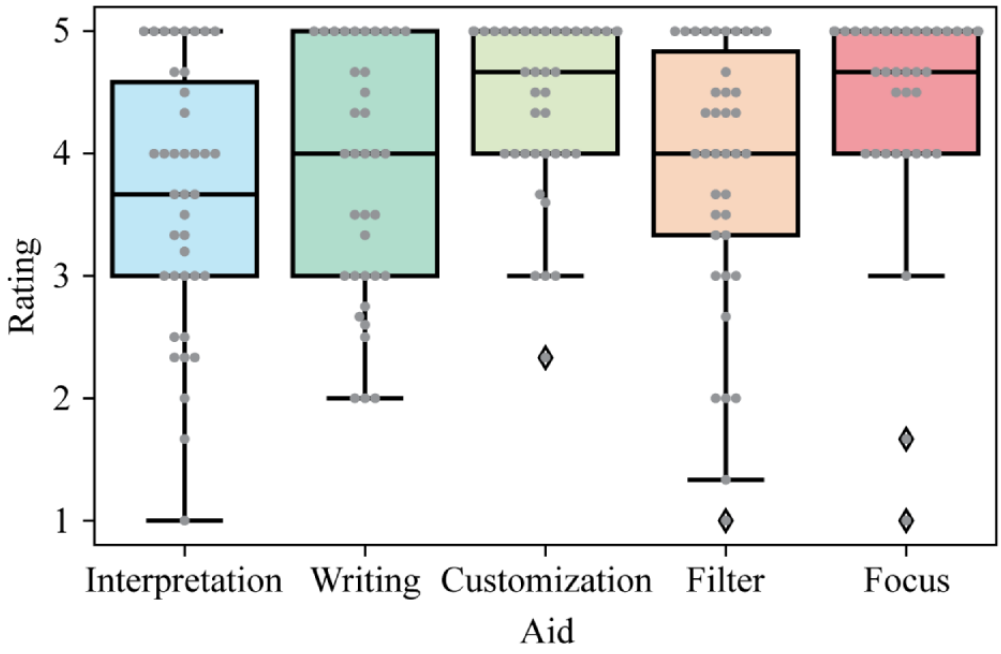
Finally, skills-related concerns centered around familiarity with using Facebook. For example, participant 7 explained why they chose Facebook because of its familiarity:

> *Because I'm used to Facebook, that's why I go there the most. Others, like Instagram, I'm not used to moving around, navigating. With Facebook, I get a pop-up message that it's there.*

Other participants expressed concerns with frequent Facebook interface updates and the resulting reduced confidence with the platform. These reports showcase the importance of consistency in allowing for a manageable social media experience.

XSL•FO
RenderX

Aid Perceptions



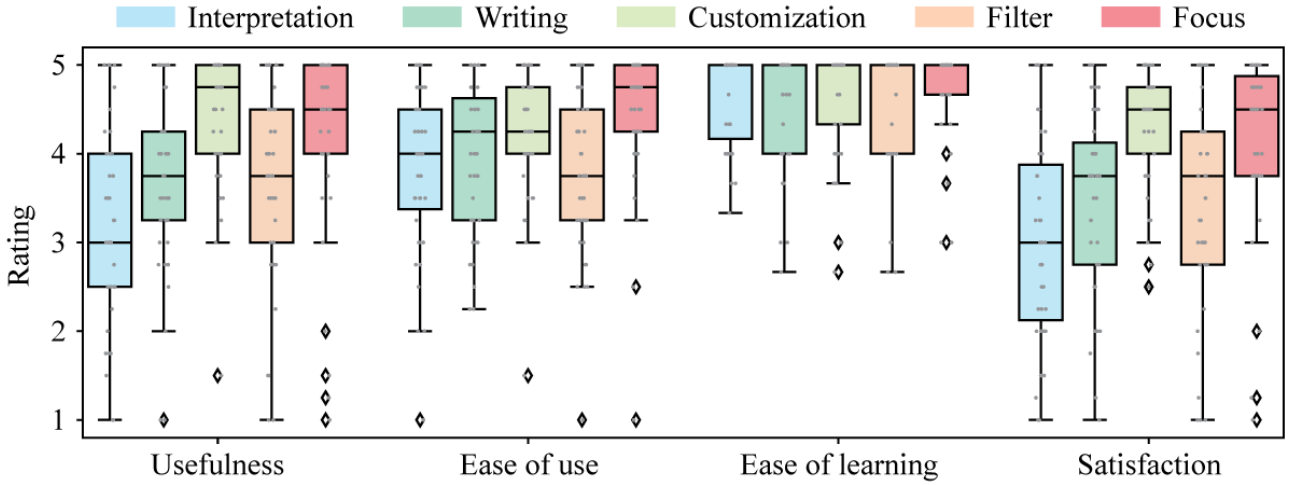
Overview

To understand how participants perceived each of our aid extensions, we investigated their daily ratings (ie, numerical and descriptive) while the aids were active and their perceptions of each aid holistically across the metrics of the USE Questionnaire (ie, usefulness, ease of use, ease of learning, and satisfaction). We also conducted open coding of participants' reported likes and dislikes, technical difficulties, and aid-specific challenges for each aid. Finally, we analyzed which aids participants reported they would like to continue using in daily life. These data allow us to understand which aid features were beneficial and where improvements can be made.

Daily Ratings

When evaluating each aid, participants were asked to provide a daily rating on each of the 3 evaluation days. While some participants provided exactly 3 ratings, others provided additional ratings or missed days. In total, 518 ratings were collected throughout the study. Due to the inconsistency in the number of ratings between participants, overall scores were calculated by first generating average scores per participant per aid and then averaging those aggregates to calculate per-aid average ratings. These ratings range from 1 to 5 stars, where 1 star indicates a poor experience and 5 stars indicate a highly positive experience. On average, participants rated their satisfaction with each aid as follows: focus, 4.45 (SD 0.89); customization, 4.41 (SD 0.71); filter, 3.86 (SD 1.09); writing, 3.83 (SD 1.01); and interpretation, 3.65 (SD 1.06). While these scores express an overall positive perception of the aids, there appear to be noteworthy divisions, with the focus and customization aids being rated similarly and most highly, followed by the filter and writing aids, and finally the interpretation aid. These scores are visualized in Figure 3.

Figure 3. Daily ratings. Aggregate daily ratings of all participants across days of aid use for each of the 5 Social Media Accessibility and Rehabilitation Toolkit (SMART-TBI) extensions.



USE Questionnaire

Following each evaluation phase of the study, participants completed the USE Questionnaire. The average ratings per aid in terms of usefulness, ease of use, ease of learning, and satisfaction can be seen in Figure 4. While there is some variation between the daily ratings and holistic postevaluation ratings of satisfaction, we see a similar pattern of perception wherein the customization (mean 4.33, SD 0.68) and focus (mean 4.17, SD 0.98) aids are rated most highly, followed by the filter (mean 3.44, SD 1.19) and writing (mean 3.44, SD 1.05) aids, and finally the interpretation aid (mean 2.97, SD 1.17). The same pattern is also present in participant ratings of aid usefulness and ease of use. There is, however, a noteworthy difference in terms of ease of learning, for which all aids scored 4.56 or higher on average (focus: mean 4.76, SD 0.51; customization: mean 4.64, SD 0.61; interpretation: mean 4.63, SD 0.51; writing: mean 4.57, SD 0.66; filter: mean 4.56, SD 0.73).

XSL•FO
RenderX

Figure 4. Usefulness, Satisfaction, and Ease of Use (USE) Questionnaire ratings. Participant ratings of usefulness, ease of use, ease of learning, and satisfaction across all 5 Social Media Accessibility and Rehabilitation Toolkit (SMART-TBI) extensions. These subscales are shown in the order in which they are presented within the full scale.

Likes and Dislikes

Overview

Along with the USE Questionnaire, participants also provided open-ended responses regarding aspects of the aids that they most liked and disliked. We collected additional feedback on aid challenges, technical difficulties, and design suggestions, though these data were much sparser, as participants often provided responses such as “none” or “see previous.” Here, we present the most common sentiments shared by participants for each aid.

Focus Aid

Participants noted that the focus aid decreased distractions within the Facebook interface, allowed for improved focus, and made their use of Facebook less overwhelming. As one participant stated:

> *[I] loved how it helped me stay focused on the news feed. [I]t made me feel less overwhelmed and [I] would probably stay on [Facebook] longer due to this.* [P30]

Participants also expressed that they would have preferred the translucent blurring effect to instead be opaque so that moving content (eg, advertisements) would not be visible. Additionally, participants noted that while it was active, the focus aid made some elements of the interface inaccessible.

Filter Aid

The features of the filter aid that participants most liked were the positive filter, the chronological-ordering filter, and the overall ability to control and customize their Facebook experience. The benefits of the positive filter are well illustrated by participant 5, who stated:

> *I liked knowing that if I was having a bad day and wanted to use the filter...I had the option to engage with Facebook without the fear of encountering any content that could be interpreted as ‘too heavy’ to handle for that day.*

This statement captures the need for both limitations on certain types of content and the ability to tailor content based on day-to-day user preferences. Participants also expressed, however, that the filter aid caused lag when scrolling through the newsfeed and that the menu bar covered certain interface elements. The lag experienced while using the aid was caused by information loading and rendering on the web page.

Customization Aid

Like the focus aid, participants reported that the customization aid enabled greater control, decreased distractions, and simplified the Facebook interface by removing clutter. These benefits were expressed by participant 12, who stated:

> *I liked how much [the customization aid] decluttered my feed since I am so easily distracted and overwhelmed by information. I liked that I could choose certain tabs to keep on the left side and hide the rest.*

While the customization aid requires users to specify which elements they would like to keep and remove, which could be a cognitive challenge, the result is a more tailored Facebook experience that ultimately could reduce cognitive load and increase the ability to focus on desired content. Depending on the user, this granular selection might be more desirable than the broad blurring of interface elements with the focus aid. The primary negative feedback about the customization aid was the inability to use the aid beyond the Facebook home page, such as blocking advertisements in the Facebook Marketplace.

Writing Aid

Participants’ most-liked features were the spelling and grammar checks and the tone and toxicity checks. As stated by participant 27:

> *I’m glad that [the writing aid] checked the toxicity and tone of the post. It made me think twice about whether or not I wanted to post a comment. I really like that it checked grammar and spelling. There’s nothing worse than bad spelling.*

XSL•FO
RenderX

This quote illustrates that participants appreciated the review of their content before posting to limit errors in both communication of intention and technical aspects of writing. While the aid had a positive impact for some participants, others reported aid inaccuracies. For example, participant 19 expressed concern, stating:

> *It wasn't very accurate...and it made me anxious—if I think I can trust something like that I might let my guard down and depend on it. When I find it's not accurate, it's disturbing.*

Interpretation Aid

Participants reported that the interpretation aid allowed for easier understanding of posts by clarifying sentiment and summarizing content. Participant 27 reported a positive experience with the aid, stating:

> *I really liked that it colored the text. I found myself not reading the red text at all and skimming through the white text. It really made the whole experience more positive and more enjoyable.*

Not all participants felt they needed the aid. Participant 29 said:

> *[The interpretation aid] wasn't something that I would use, but it is also something that I don't need. For those who struggle with perception it could be useful.*

Some participants reported disagreeing with the interpretations. As with the writing aid, participant 19 said, "I had a hard time trusting [the interpretation aid] because it didn't always agree with my interpretations of what was positive or negative."

Poststudy Evaluation

Overview

Participants were asked 3 questions at the conclusion of the study about their experience using the aids and their overall favorite aid. The following themes emerged from these data.

Overall Positive Experience Using the Aids

A total of 95% (37/39) of participants reported positive experiences using the aids. Participants appreciated the ease of learning and using the aids, with participant 24 stating:

> *I had a very good experience using the aids. They were all easy to learn how to use and didn't have too many kinks. I definitely felt like some were more specific to the symptoms I struggle with than others.*

The aids were noted to enhance engagement and enjoyment on Facebook, as evidenced by participants' comments like, "I absolutely loved the aids. I loved that they kept me more focused and less distracted. I was able to enjoy Facebook more" (P27) and "It was very helpful, and I feel like I would use Facebook more" (P35). Participants also emphasized the aids' user-friendliness, noting, "All aids were easy to use" (P22) and "The tools were really useful based on my needs" (P1), though some aids were easier to use than others. Additionally, the aids were recognized for their potential value to individuals with TBI, with one participant stating, "I believe the aids are very helpful for the Brain Injury Community" (P37), and another stating, "They each could have value depending on the user's needs" (P22). Overall, the aids were well received, contributing to increased focus, enjoyment, and perceived value among participants.

A total of 21% (8/39) of participants also reported specific negative experiences while using the aids. Technical difficulties were a common issue, as evidenced by participant comments such as, "Sometimes [the aids] didn't work well enough to make them worth using" (P19) and "I found a lot of errors" (P14). The interpretation aid was particularly noted to have technical challenges: "The interpretation aid was glitchy. I think it could be easier if it was working. Ideally, it could be really great" (P8). Some participants questioned the usefulness of certain aids, with one stating, "Some of the aid[s] I was not able to really understand how it would be beneficial for someone with TBI" (P14). Technological difficulties with the equipment were also mentioned:

> *The aids...I don't know if it was the Chromebook that was making [sic], or the debugging of the aid, but the Facebook responses would come out slower or slow. It would be a long time waiting for something to happen while using the aid. The waiting was frustrating. Nowadays, everyone wants things to be done very quick. Waiting just for a Facebook post or feed, sometimes it's not worth the wait. A lot of times, I would just close the window because I thought it was crashing, and would have to close and restart.* [P1]

Issues with accuracy were highlighted, with one participant noting, "The writing tool was not as accurate, and I found it frustrating when there were so many technology glitches" (P2). Lastly, some participants raised concerns about the potential harm of using AI for functions such as sentiment analysis:

> *Everything else has the potential to be harmful for users, especially for those who want to engage in self-expression and just want help with navigating online interactions.* [P5]

Favorite Aids: Focus, Filter, and Facebook Customization

Overview

Participants were asked to name their favorite overall aid from the study. The focus, filter, and Facebook customization aids emerged as their favorites, with some participants ranking more than 1 aid as their favorite.

Focus Aid

A total of 49% (19/39) of participants appreciated the focus aid's straightforward and easy-to-use interface, noting that it significantly reduced distractions and kept the user interface clutter-free, thereby allowing for a more focused Facebook experience. For instance, participant 3 shared:

> *I liked everything! Like OMG, yesterday I was watching some cooking stuff, and the fact there is no distraction, nothing on the left that is taking my attention. Just to focus on one thing, it brought some*

XSL•FO
RenderX

> *peace of mind, less anxious. Yes, I love the focus mode.*

Similarly, participant 6 said:

> *I loved this one because when you're on Facebook, and all the apps disappear, then it's less distraction. And you're more focused on what you're doing.*

The focus aid also helped reduce feelings of being overwhelmed, as highlighted by participant 10, who said:

> *Focus Mode was my favorite. I felt less overwhelmed using Facebook and could pay more attention to what I was looking at, it felt easier to try to and write something without so much to pay attention to.*

Participant 7 echoed this sentiment, stating, "I was able to focus on what I was doing, and ignore the 'visual noise'."

Filter Aid

A total of 41% (16/39) of participants reported various features they enjoyed about the filter aid. They appreciated the ability to control what they see, such as filtering by positive posts: "I really enjoyed the ability to block negative posts" (P37) and to only show positive posts (P32 and P28). Others valued filtering by the most recent posts: "I like having the ability to see posts in chronological order!" (P11). Participants also noted the aid's ability to prioritize important posts over advertisements and irrelevant content. For example, participant 19 remarked:

> *I really liked the one that filtered my posts to where the pertinent ones were the ones that would show up—I would use this all the time. I get too easily sucked into ads and distracted by them, and it seems most of my feed is ads—it's not worth wading through all of them to find the more important posts. I don't like re-reading the same posts over and over either, so to have them in chronological order keeps them from repeating and saves my energy.*

Facebook Customization Aid

A total of 36% (14/39) of participants chose the Facebook customization aid as a favorite. One participant noted:

> *I liked the Facebook Customization aid the best in that it allowed me to turn off the various panels of FB [sic] which increased my desire to interact with FB [sic].* [P36]

Others noted that Facebook can be cluttered, and the aid helped with this problem:

> *Facebook can feel so cluttered with all the options of things to click on, that I rarely even click the options I like. To have the few options I would want to click on made Facebook look so much cleaner, not cluttered, and tailored to exactly what I would use.* [P15]

Participants appreciated the flexibility and simplicity of the aid and that it made navigating the Facebook page less busy (P29 and P22). Others noted that decluttering the page, similar to the Focus aid, helped minimize distractions, allowing them to "be able to focus on the content people posted rather than getting distracted" (P26). Participants also appreciated that the aid minimized unwanted content that could be potentially emotionally triggering:

> *The Facebook Customization was a game changer. It helped me a lot on my bad days, when I was feeling really emotional. I could just display exactly what I was able to view on that day.* [P2]

During the final poststudy survey, participants reported which of the aids they would use in daily life if given the opportunity. Of the 39 participants, 21 (54%) chose the filter and focus aids, 19 (49%) chose the customization aid, 11 (28%) chose the writing aid, and 9 (23%) chose the interpretation aid. These results largely comport with the other metrics we have reviewed; however, the filter aid was endorsed by more participants than expected. This misalignment with our other collected measures might be due to the fact that the aid endorsement questions asked which aids participants would like to use rather than which they thought worked the best. Participants may have believed the filter aid would be highly useful after further development, but that its current form did not quite meet that potential. A visualization of per-aid endorsement counts is provided in Multimedia Appendix 4.

Impact on Participants

Next, we attempted to understand how participants may have been impacted by each of our aids. Toward this effort, we conducted a pre-post study analysis to understand whether participants reported changes in feelings of emotional support, social connection, self-esteem, and life satisfaction (Figure 5). Further, 1-tailed paired-samples *t* tests with Bonferroni correction showed a statistically significant increase in participant ratings of satisfaction with life (P=.02) and nonsignificant increases across the remaining 3 metrics following the use of our aids. A full listing of the relevant statistics from these tests can be seen in Table 2.

XSL•FO
RenderX

Figure 5. Pre-post study metrics. Participants reported their perception of emotional support, social connection, self-esteem, and life satisfaction prior to and following their engagement in this study. A statistically significant increase was found between participants' life satisfaction before and after participation.

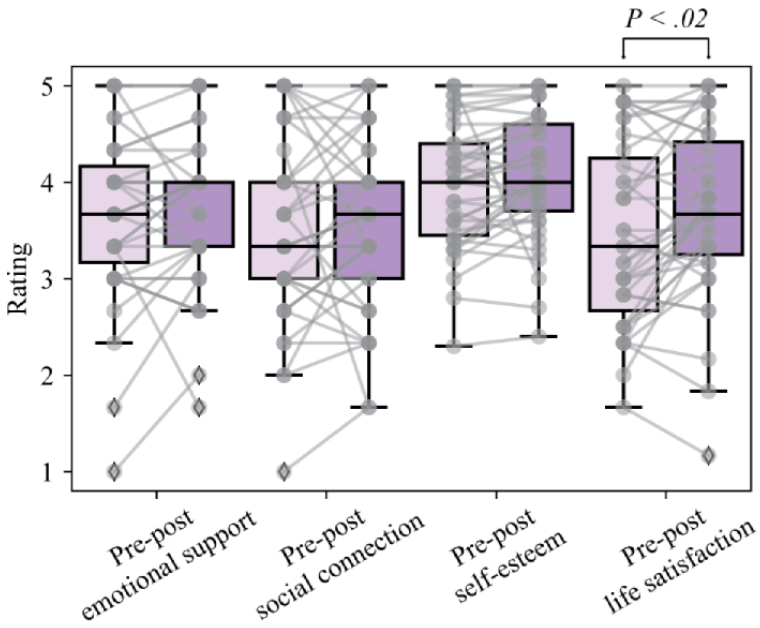


Table 2. Paired-samples *t* test statistics. The study used 1-tailed paired-samples *t* tests to assess statistical significance in pre-post differences between participants' reported perceptions of emotional support, social connection, self-esteem, and life satisfaction. A statistically significant increase was only found in perceptions of life satisfaction.

Outcome	Pretest, mean (SD)	Posttest, mean (SD)	*t* test (*df*)	Corrected *P* value	95% CI	Cohen *d*
Emotional support	3.684 (0.88)	3.761 (0.80)	−0.851 (38)	.80	−∞ to 0.075	−0.091
Social connection	3.496 (0.95)	3.547 (0.88)	−0.406 (38)	>.99	−∞ to 0.162	−0.055
Self-esteem	3.972 (0.66)	4.072 (0.64)	−1.441 (38)	.32	−∞ to 0.017	−0.153
Life satisfaction	3.449 (0.94)	3.705 (0.88)	−2.666 (38)	.02	−∞ to −0.094	−0.278

Discussion

Principal Findings

Participants with moderate to severe TBI have cognitive, sensorimotor, and communication challenges that can make social media engagement difficult or unmanageable. Our study illustrates that many of these challenges can be addressed through proper technological supports. Through this work, we have (1) demonstrated the feasibility of a longitudinal study design to examine the social media use of individuals with TBI, (2) gained novel insights into the social media experience of users with TBI and related design implications, and (3) identified new directions for researchers and developers working to promote online social connection among users with TBI.

SMART-TBI Perceptions

Through our results, we have shown that, on average, all of our aids were regarded positively by participants across all metrics. The filter, focus, and customization aids were rated by participants as their favorite aids and the aids they would have most liked to use beyond the study. These results are consistent with participants' reported sensory and cognitive challenges, as all 3 aids allowed users to configure what was displayed onscreen.

The writing and interpretation aids were regarded less positively overall. This result was unsurprising given that social challenges can be more complex and multidimensional than sensory limitations and, hence, more difficult to overcome with a technical solution. The sentiment analyses used in these aids also yielded inconsistent results, which meant they were regarded by some as untrustworthy. Participant perception may then be more reflective of our specific implementation than the core ideas the aids represent. Across daily ratings and all USE metrics, the writing and interpretation aids were consistently rated the lowest. Future implementations may be able to provide the aids' intended utility and be perceived as highly useful.

It is noteworthy that the findings did not apply to all participants, as some found the writing and interpretation aids very helpful in their current form. This variability in findings is common in TBI due to the heterogeneity across this clinical population in strengths and limitations, previous experience, and goals. It is expected that some users will benefit from certain aids, while others will not. If implemented in a commercially available product, the problems associated with these aids would likely be addressed, and users would be able to use them fully. Even with such an implementation, however, it is important to consider the impact that bias, subtle misclassifications, and overreliance may have on users. While our study did not capture

XSL•FO
RenderX

the nuance of these problems, they could introduce new challenges to social media users with TBI. Through proper research and development, these challenges may also be mitigated, but further evaluation will be needed.

Accessibility Design Insights

Beyond the aids themselves, we also identified the following three major insights from our study results: (1) participants preferred aids that assisted with sensory and cognitive challenges over social ones, (2) participants would like to tailor their social media experience to their specific needs, and (3) simple solutions to TBI challenges were preferred over complex ones.

Participants preferred aids that assist with TBI-related sensory and cognitive challenges over social ones. These findings are consistent with Zhao et al [48], who proposed that social deficits are difficult to recognize in oneself and therefore make an individual less likely to believe they may need related assistance. While the focus, filter, and customization aids all allowed users to make their Facebook experience more manageable through selection of interface elements and newsfeed content, the writing and interpretation aids attempted to compensate for social challenges by interpreting content for the user. While most interface and content changes are objective and clear, interpretations are subjective and more difficult to assess in terms of accuracy. When participants assess that some interpretations are not accurate, a challenging judgment in its own right, they may lose a sense of trust in all interpretations. As a result, these types of aids may be seen as fraught compared with those that address cognitive and sensory challenges. Additional validation will therefore be needed to improve these aids and understand the implications of their use prior to widespread implementation on social media platforms.

Consistent with the variability among people with TBI, participants appreciated the ability to tailor their social media interface to fit their needs. The ability to customize aids is essential in TBI to allow users the freedom to activate features as needed or select a baseline set of features that fit their needs. This point was well illustrated by participants' positive ratings of the filter and customization aids, which allow users to explicitly select which interface elements appear on their screen and what content appears in their newsfeed. Allowing users to choose specific accessibility features ensures that benefits are fully realized without making the resulting experience needlessly cumbersome.

While user choice allows specific needs to be met, it can also generate greater complexity to the detriment of a user's experience. If we consider, for example, the focus and writing aids, they each require different levels of effort from users. In the case of the focus aid, users simply activate the aid to blur the left and right panels of the Facebook interface. With the writing aid, however, participants activate the aid and then follow several steps while writing a post. While both of these aids have unique advantages and disadvantages, the writing aid adds much greater complexity to the baseline use of Facebook than does the focus aid. While we cannot disentangle the utility of a given aid from its cognitive demand, our results do suggest that participants prefer simpler aids (ie, the focus, filter, and customization aids) to more complex ones (ie, the interpretation and writing aids).

Limitations and Future Work

While this work shows great promise for the use of social media aids, some challenges have remained unaddressed. To begin, we had intended for participants to use our aids in their daily Facebook use as would occur naturally. However, it is clear from participants' daily ratings that participants would experiment with the aids to understand their limitations. For example, some participants wrote draft posts that included highly positive, negative, or subjective sentiments to evaluate the accuracy of the writing aid's sentiment analysis. While these participants' curiosity is understandable, these interactions illustrate the potential limitations inherent to an in-the-wild study. Additionally, we found that some participants had difficulty remembering whether they had used Facebook on a given day, leading to missed or duplicated participation. This difficulty is understandable and to be expected among participants who experience memory challenges. To address this challenge, experimenters provided friendly reminders to participants about daily participation, but challenges persisted. In the future, we believe that a usage indicator would be helpful for users to determine whether they had already participated on a given day. Such an indicator could take the form of a small overlay dashboard that contains an icon to signal whether the participant had completed their use for the day.

Furthermore, we saw that not all challenges participants reported were addressed by our aids. In particular, we expect that the writing and interpretation aids can be refined for a better overall user experience by improving their sentiment analysis features. Additionally, while the filter aid was positively regarded, we believe there are other filter options we can provide to users so they can fully tailor their display to their specific preferences. Beyond our existing aids, we also believe there are opportunities for new supports that can assist users on other social media platforms. While the current aids were developed specifically for Facebook, there may also be opportunities to apply these concepts to other platforms. Some supports, like the focus aid, may need to be tailored to the specific interface elements of a given platform, but others, like the filter aid, could easily be translated to platforms that use a feed. As social media evolves over time, similar adaptations may be needed, but, provided the core features of social media remain (eg, feed, posting, comments, and advertisements), the benefits these aids provide should continue to be relevant to individuals with TBI. Examining how these aids can be integrated into other platforms and exploring their potential impact on other user populations would substantially widen their impact.

Beyond the development and use of the aids, it is worth noting that the compensation participants received (ie, monetary compensation for participation and the gifted Chromebook) could have skewed their perceptions. While many participants did provide critical feedback about the aids, daily use and life satisfaction ratings could have been skewed by monetary gains and the novelty of using a new device. Additionally, while our results show a statistically significant increase in life satisfaction between the beginning and end of our study, we do not see a

XSL•FO
RenderX

significant increase in emotional support, social connection, or self-esteem. Given that changes of this nature may require greater exposure to our aids, further evaluation is needed to understand whether the use of such aids can achieve these outcomes.

Finally, it is important to consider the generalizability of our results. To be considered for our study, participants needed to be active users of Facebook who were willing to partake in a technology-evaluation study. Our results may therefore be limited to users with higher digital literacy and more social media experience than the average individual with TBI. Future work may be able to bridge this gap by evaluating such aids with a broader population of users with TBI, including those with more severe cognitive impairments or anosognosia. Additionally, our study does not use a comparison group or randomized controlled design. This step could be taken in similar future studies to clearly contextualize the perceptions of the developed aids and the broader impacts these aids have on participant well-being.

Conclusion

Users with TBI experience challenges related to sensory perception, cognition, communication, and social interaction. While social media platforms like Facebook can provide an outlet for users to maintain connections post injury, these platforms must provide TBI-specific accessibility features so that users may enjoy the full benefits of their social media experience. To that end, we created 5 digital aids that allowed users to modify their Facebook user interface and collected feedback on use of the aids in a longitudinal study with 39 Facebook users with TBI. While participants had varying needs and preferences for the aid extensions, overall, they had positive ratings for the aids' accessibility features. These findings suggest that aids like these have the potential to improve the social media experience of users with TBI.

Acknowledgments

We would like to thank Kim Walsh, Natalia Rivera, and Amy Koike for their contributions to our longitudinal study. This research was supported by the Eunice Kennedy Shriver National Institute of Child Health and Human Development of the National Institutes of Health (award number R01HD071089). Open-access publication was supported by the Sheldon B and Marianne S Lubar Professorship awarded to BM.

Conflicts of Interest

YH, LK, HLJ, LT, MD, CLT, and BM were involved in the development of the digital aids evaluated in this study (reported in Hu et al [8]. The authors have no financial or other competing interests to declare.

Multimedia Appendix 1
Demographic and injury characteristics of the 39 participants included in the longitudinal study. The "other" cause of traumatic brain injury includes highly specific circumstances that may otherwise identify participants. Although motorcycle collisions (MCCs) are encompassed within motor vehicle accidents (MVAs), they are categorized separately due to the unique risks and injury patterns associated with motorcycle-related injuries.

Abstract

Background: In Indonesia, people with communication disorders predominantly communicate using Bahasa Isyarat Indonesia (BISINDO). Nevertheless, all current systems for BISINDO recognition generate fragmented, word-by-word output and lack natural language generation (NLG) capabilities, thereby fundamentally constraining their communicative utility.

Objective: The aim of this study is to develop, validate, and field-evaluate SmartGlove BISINDO, an AI-assisted wearable sign language–to-speech system that embeds large language model (LLM)–powered NLG into a BISINDO translation pipeline for the first time.

Methods: This study followed the design science research (DSR) framework, covering phases 1 through 5 (problem identification, solution objectives, prototype design and development, demonstration, and evaluation). Data were collected from 12 purposively selected informants (6 domain experts and 6 deaf education companions/teachers) across 3 Indonesian cities (Malang, Surabaya, and Makassar), using a needs-analysis questionnaire and an expert validation sheet, and analyzed through statistical triangulation of agreement percentage, content validity ratio (CVR), and Aiken V. The validated prototype was field-tested in Makassar and Malang with 15 participants with communication disorders and 4 observers or companions; it was evaluated by a disability expert in Surabaya.

Results: The needs analysis yielded a grand mean of 4.77 (SD 0.51) across 4 clusters, with 89% mean agreement, indicating very high priority for all identified needs. The prototype's 5-layer architecture integrates wearable sensors, on-device gesture classification, and LLM-based NLG. Expert validation showed an overall Aiken V of 0.94, with all 14 items exceeding the 0.75 validity cutoff and with 11/14 items (79%) rated highly valid (V>0.90). The grand mean CVR was 0.76 (SD 0.16), exceeding the Lawshe minimum threshold of 0.56 (P<.05), with 3 items—gesture differentiation, AI contextual relevance, and settings configuration ease—falling below the threshold and indicating areas for refinement. During the testing phase, the system received a lower practicality score (mean 3.35, SD 0.16; 67%), particularly for clarity of speech output. However, observers and companions gave a significantly higher score of 88%, with a mean of 4.40 (SD 0.08). A disability expert also gave a score of 81% (with a mean value calculated across the 20 questionnaire items of 4.05, SD 0.60). Regarding language, the AI-generated output underwent three transformation processes: addition, deletion, and substitution. Of the 3, substitution is the most likely to alter the intended meaning.

Conclusions: SmartGlove BISINDO is a wearable sign language–to-speech system that introduces the BISINDO research landscape to LLM-based NLG connect-and-translate approaches and demonstrates strong content validity. This study presents preliminary evidence toward a replicable model for interdisciplinary DSR-based prototype development that combines augmentative and alternative communication (AAC) theory, systemic functional linguistics, and design science methodology, intended as a reference for other underrepresented sign language contexts in Southeast Asia and beyond. Field evaluation further indicated favorable practicality overall, alongside a gap between expert-perceived feasibility and user-rated experience that will guide subsequent design refinement.

KEYWORDS

assistive communication technology; sign language recognition; natural language generation; large language model; wearable sensing system; BISINDO; communication disorders; augmentative and alternative communication; inclusive technology; process innovation; Bahasa Isyarat Indonesia

Introduction

Background

Communication is a fundamental human capacity that enables individuals to express thoughts and needs while building the social relationships necessary for daily life. Around 1.3 billion people worldwide have some form of disability [1]; despite being described as a "global crisis," communication disorders remain underrepresented in global health policy, even though their negative impacts on education, employment, and social participation, as well as their associated psychosocial effects such as stigma, low self-confidence, and reduced quality of life, are well documented [2-4]. Effective assistive systems for this population must therefore be natural, meaningful, and socially appropriate [2,3]. In Indonesia, approximately 1.02% of the population experiences severe communication difficulties [5], resulting in systematic marginalization for hundreds of thousands of people.

Most deaf people in Indonesia communicate using Indonesian Sign Language (Bahasa Isyarat Indonesia [BISINDO]), which emerged naturally within the Indonesian deaf community and has its own grammar and vocabulary distinct from spoken Indonesian [6]. Because very few people outside the deaf community understand BISINDO, individuals who are deaf face limited opportunities for social interaction [7]. This study responds to the growing need for pragmatic assistive technology (AT) research addressing unmet rehabilitation needs [8], building on recent evidence confirming the feasibility and value of novel AT solutions for this population [9].

Current Trends and Challenges in Sign Language Recognition Technology

Several previous studies on BISINDO recognition have shown a consistent relationship between accuracy, sentence processing capability, and practical application. For example, a convolutional neural network–long short-term memory (CNN-LSTM) architecture achieved individual gesture classification accuracy of up to 96%, but only for isolated word-level gestures, not for continuous sentences [10]. A mobile CNN-MobileNetV2-based app enabled real-time BISINDO-to-speech conversion via camera, but its classification accuracy was only 55% across 30 gesture categories. This significant decrease limits its reliability in the real world [11]. More recent research has attempted to extend recognition to the sentence level using 3D CNN-LSTM and 3D CNN–bidirectional LSTM (CNN-BiLSTM) models with connectionist temporal classification. These studies successfully overcome the limitations of isolated gestures, but these approaches remain camera-based and only go as far as mapping gestures to text, without natural language generation (NLG) capabilities [12].

Related research developments also come from the 2026 SIBI (Indonesian Sign System) recognition system, which integrates LSTM-based gesture recognition with Indo Bidirectional Encoder Representations from Transformers (BERT) contextual modeling. Word prediction accuracy reached 89%, but that was only for word-level correction, not full sentence generation. The system also did not specifically address BISINDO [13]. On the other hand, a 2025 transformer-based benchmark using the Sign Pose-based Transformer (SPOTER), Siformer, and Multiscale Vision Transformer version 2 (MViTv2) architectures achieved up to 97% accuracy in isolated gesture classification. Meanwhile, a 2026 comparison between MobileNetV3 and EfficientNetV2B0 successfully improved the device's efficiency. However, both were still limited to gesture classification, without addressing sentence-level meaning [14,15]. Across these studies, 3 limitations recurred: reliance on camera input (rather than wearable sensing), focus on isolated word or gesture recognition, and lack of generative NLG capabilities.

For resource-intensive sign languages, sign language recognition has advanced beyond sentence processing. Transformer-based approaches, for example, are capable of performing end-to-end recognition and translation simultaneously [16]. Sequential parallelism across continuous signage has also been modeled by CNN–hidden Markov model systems that use deep learning on sequential data [17,18]. However, these advances were made in American Sign Language and Deutsche Gebärdensprache, which have largely focused on annotated corpora. BISINDO lacks such resources. Therefore, existing architectures and training methods cannot be readily adapted to sign languages with lower resources and different structures like BISINDO.

Beyond BISINDO-specific work, the broader sign language translation literature has moved decisively toward large language model (LLM)–based, gloss-to-text pipelines conceptually similar to the present system. One approach couples a lightweight Sign Pose-based Transformer (SPOTER) with an off-the-shelf LLM prompted to convert sequences of spotted glosses into fluent spoken-language sentences, requiring no additional translation-specific training or paired corpora [19]. Others have extended this idea to explicitly low-resource sign languages through in-context prompting rather than fine-tuning, to compensate for scarce parallel data [20]. However, a 2025 systematic review of LLM- and multimodal-LLM–based sign language recognition and translation work covering 2020 - 2025 cautions that most reported gains remain concentrated in a small number of well-resourced sign languages, chiefly American Sign Language, and that evaluation continues to rely heavily on machine-translation metrics such as Bilingual Evaluation Understudy (BLEU), which are known to be weak proxies for communicative adequacy and are rarely validated with deaf or hard-of-hearing end users [21]. This pattern reinforces the gap

XSL•FO
RenderX

motivating the present study: existing gloss/SPOTER-to-LLM pipelines have so far been designed and evaluated for camera-based, high-resource sign languages, and none have been extended to a wearable-sensor pipeline or evaluated directly with the target BISINDO user population.

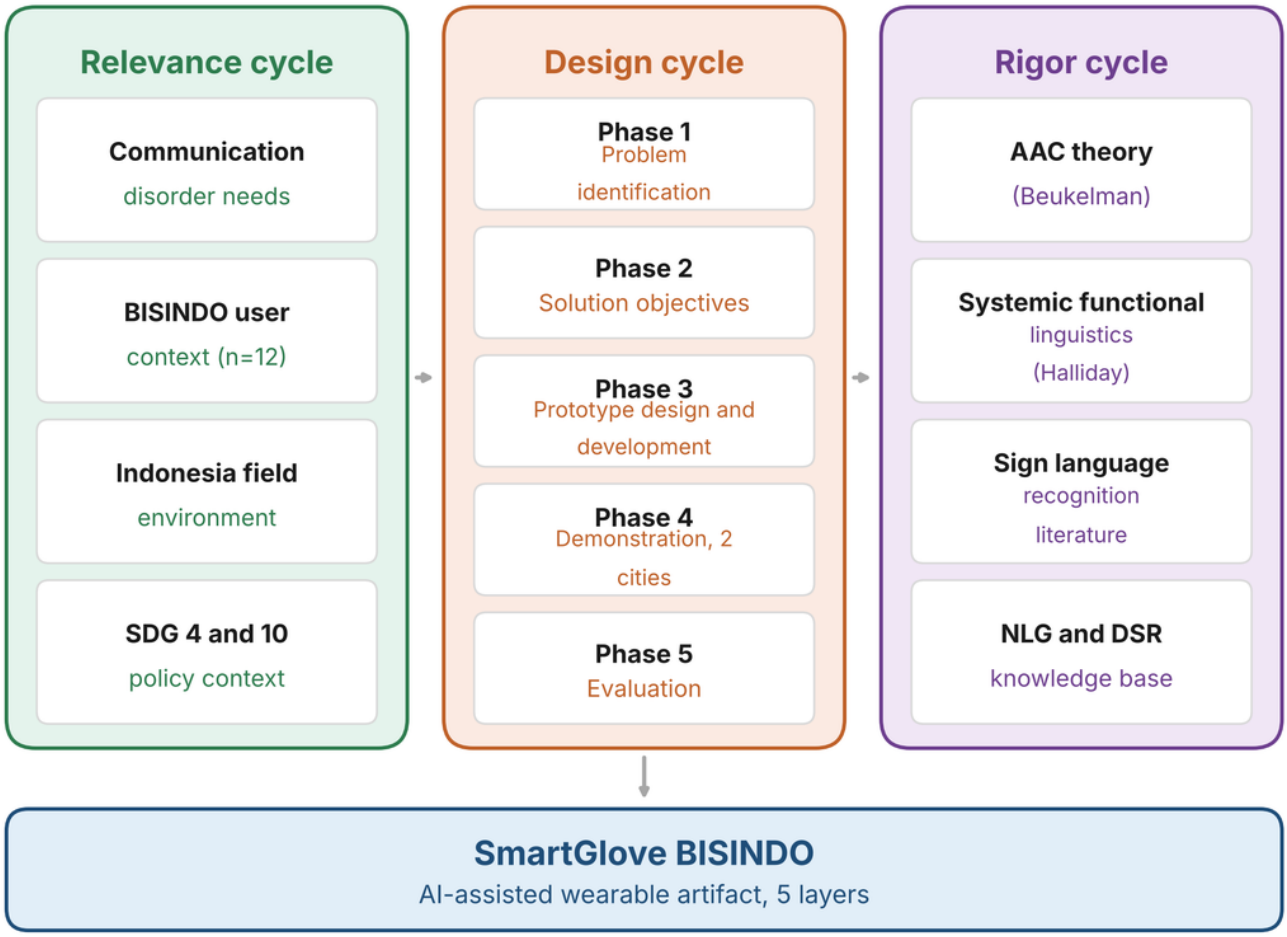
The current BISINDO system does not incorporate automatic NLG to transform detected gesture sequences into semantically coherent complete sentences. This is a critical gap. Sign languages convey meaning at the level of complete sentences, not just isolated gestures but also using gestures in context. In other words, systems not designed for AAC (augmentative and alternative communication) do not allow users to share the same language as their interlocutors [2,3]. Other researchers have overlooked some of the real potential of AAC from LLMs. For example, an LLM-based interface achieved a 29% text input rate in AAC users with amyotrophic lateral sclerosis [22]. In 2025, another study incorporated an LLM into a social support robot intended to interact with humans in real-time as part of geriatric care. The results showed a significant increase in interaction success and user engagement compared to a non-LLM dialogue system [23]. This demonstrates that LLMs as part of assistive devices for real-time interaction are not only capable but also beneficial in many areas. However, at the level of BISINDO translation, this potential is substantially underused.

Theoretical Framework

Three theoretical perspectives converge in this research, together informing the design science research (DSR) process's rigor cycle, each addressing a different layer of the same design problem. AAC theory sets the functional goal: assistive technology (AT) output must be natural and socially acceptable [2,3], a standard that isolated words, carrying no social or contextual meaning, cannot meet. Systemic functional linguistics (SFL) translates this goal into concrete linguistic properties that sign languages, like all languages, express through 3 simultaneous metafunctions [24]: the ideational metafunction conveys experiential content, the interpersonal metafunction encodes the social relationship between speaker and listener, and the textual metafunction structures the message as a coherent whole. Lexical translation alone cannot meet these functional criteria; LLM-based NLG, built on transformer architectures [25], provides the computational mechanism to derive grammatical, coherent, context- and intent-appropriate text from a queue of detected gestures [22,23]. In this chain, AAC theory defines the target, SFL specifies the linguistic properties required to reach it, and LLM-based NLG provides the technical means of fulfilling that demand. This chain directly informed the expert validation instrument, whose items evaluate grammaticality, naturalness, and contextual relevance, operationalizing the SFL metafunctions as validity metrics for the prototype.

Study Objectives

Within this framework, this study aims to design and evaluate the BISINDO SmartGlove, which will be recognized as a wearable device in the context of AI and the implementation of a sign language–to-speech system based on DSR [26,27]. In this study, DSR phases 1 to 5 were carried out: problem identification and motivation; definition of solution objectives; design and development of artifacts carried out through demonstration and evaluation [28]. This study focuses on indexing the theories of AAC, SFL, and DSR under one interdisciplinary lens. The study hopes that the DSR-based prototype development model can serve to develop inclusive AI AT. This can provide a template for other researchers that can be used in underrepresented sign language environments. Practically, this research meets the communication needs of Indonesian users with severe speech disorders. This is directly related to SDG (Sustainable Development Goal) 4 on quality education and SDG 10 on reducing inequalities. The way to do this is to allow people with hearing impairments and speech disorders to communicate independently in schools and social spaces. SmartGlove BISINDO supports SDG 4, which promotes equal access to education for persons with disabilities, and SDG 10, which calls for full social, economic, and political inclusion regardless of disability.



Methods

Research Design and Framework

This study follows 2 complementary DSR frameworks: Hevner [29] 3-cycle model and Peffers et al [27] 6-phase DSR, which covers problem identification, solution objectives, design and development, demonstration, evaluation, and communication. The DSR is one of the most widely adopted procedural frameworks in DSR [28]. DSR was chosen because it is specifically tailored to research that results in innovative technological artifacts as solutions to real-world problems. This iterative, user-centered approach reflects established AT design practices that incorporate stakeholder input throughout development [26-30]. The relevance cycle is operationalized via an analysis of needs with 12 participants, the design cycle through iterative design of a 5-layer prototype, and the rigor cycle through AAC theory and SFL as the guiding knowledge bases, as summarized in Figure 1.

XSL•FO
RenderX

Figure 1. Design science research (DSR) framework of SmartGlove Bahasa Isyarat Indonesia (BISINDO) study [26]. AAC: augmentative and alternative communication; NLG: natural language generation; SDG: Sustainable Development Goal.

Instrument Development

Both instruments were developed specifically for this study rather than adapted from preexisting validated scales, reflecting the absence of standardized measurement tools for BISINDO-specific, LLM-integrated AT. Item development followed a theory-driven operationalization process: constructs were first derived from the 3 theoretical perspectives described above (AAC theory, SFL, and DSR), then translated into observable, measurable indicators. For example, the SFL textual and interpersonal metafunctions were operationalized into needs-analysis items on sentence completeness and context-appropriate register and into validation items on grammaticality, naturalness, and contextual relevance. Both instruments operationalize the theoretical constructs associated with the DSR relevance and rigor cycles [27]. Beyond this theory-driven design process, construct validity was assessed through content validity review by 2 independent experts prior to field use and further evidenced empirically through the content validity ratio (CVR) and Aiken V results reported for each item.

Patient and Public Involvement

This study involved 6 deaf education companions and teachers from 3 Indonesian cities (Malang, Surabaya, and Makassar) as respondents in the needs analysis and as expert validators. Dataset curation was performed by a certified BISINDO dataset specialist. This informed the key design decisions. After validation, the prototype directly involves users with communication disorders, aligning with JMIR rehab AT's interest in research that includes relevant knowledge users [8].

Twelve participants were purposively sampled for their expertise and direct experience in communication contexts involving users with communication disorders in Indonesia. Although a sample of 12 is not statistically significant when using the proper computation of CVR, it is sufficient for CVR analysis, as per Warner's recommendations, since 12 participants meet the minimum required ceiling threshold (CVRthres) of 0.56 at $P<.05$. The participants were divided into 2 groups, namely, 6 domain experts (consisting of 2 sign language specialists, 2 AI technology experts, and 2 linguists) and 6 deaf education companions and teachers drawn from 3 Indonesian cities: Malang (n=2), Surabaya (n=2), and Makassar (n=2). All participants acted as both respondents for needs analysis and validators of prototype quality assessment.

Needs Analysis

The needs analysis instrument was a questionnaire covering 4 clusters and 10 items, rated on a 5-point Likert scale (full item list in Multimedia Appendix 1), developed to operationalize the theoretical requirements of AAC and SFL within the DSR relevance cycle. Content validity of the questionnaire was reviewed by 2 independent experts, who were not part of the 12-member study sample, before field use. After a brief introduction to the system concept, 12 participants completed

XSL•FO
RenderX

a requirements analysis questionnaire. Responses were then analyzed using descriptive statistics, including percentages, means, and SDs. Priority levels were divided into 2 categories: very high (mean ≥4.60) or high (mean 4.00 - 4.59).

Prototype Design

The prototype development was based on the DSR design cycle. Based on requirement analysis and literature review on existing hardware and software, the initial version was further refined based on observations from wearable use in practice and developments in NLG systems. The design resulted in an architecture specification with technical descriptive analysis and system architecture diagrams, which are 5-layered.

BISINDO Dataset

The BISINDO dataset has been constructed with the help of a real-life handwritten BISINDO gesture specialist. The expert acted as a demonstrator and authenticity validator during curation. Expert reviews were performed to refine all input gestures derived from the BISINDO standard vocabulary reference. To decrease the ambiguity of classification, some gestures were infrequently used or simply too similar to others (like most coordinate conjunctions, certain particular prepositions like “from” and “for,” or some physical verbs like “input” and “extract”). Additionally, the expert enriched the vocabulary with local references. This dataset comprises terms from the social and religious life in Indonesia such as greetings, emergency phrases, and words for extended families. An expert guiding such a process fits in well with user-centered AAC design methods [2,3] and aligns directly with the cultural and linguistic relevance criteria uncovered in needs analysis.

Expert Validation

The expert validation instrument was designed in a spreadsheet format. It consisted of 3 components and 14 items (full item list in Multimedia Appendix 2), all rated on a 5-point Likert-type scale, designed to operationalize the theoretical constructs underlying the DSR rigor cycle. Prior to the application of the instrument, 2 independent experts evaluated its content validity. Note that these experts are not part of the 12-person sample, who were followed by the research. The 12 participants undertook the role of validators after a complete demonstration of the system architecture. The team used statistical triangulation to validate the data. They examined 3 indices in parallel: percentage agreement, CVR, and Aiken V (where CVR is calculated using the Lawshe formula [31], representing a minimal threshold of 0.56, for n=12 at $P<.05$). In Aiken V [32], items are considered valid if V is greater than or equal to 0.75 and highly valid if V is greater than 0.90. The triangulation of multiple indices is more trustworthy than relying on a single index [30]. This method helps to solve the well-known limitation of using a single outcome between-participants evaluation framework in previous studies reviewing rehabilitation technologies [32]. A sample of 12 participants was purposively selected. The sample consisted of 2 sign language specialists, 2 AI technology experts, 2 linguists, and 6 deaf education companions and teachers drawn from 3 Indonesian cities: Malang, Surabaya, and Makassar. This composition was intended to be interdisciplinary, consistent with the relevance and rigor cycle of the DSR framework. Use of percentage agreement, CVR, and Aiken V concurrently was a check on interrater consistency across this heterogeneous panel. For the sample size, formal interrater reliability coefficients were not calculated.

Field Demonstration and Evaluation

Following expert validation, the validated prototype was field-tested with user participants and observers/companions in 2 Indonesian cities, Makassar and Malang, with an independent disability-expert assessment conducted in Surabaya, corresponding to DSR phases 4 and 5 (demonstration and evaluation). The field evaluation was measured using 3 instruments from different perspectives, consistent with recommended approaches for evaluating the usability of rehabilitation technologies across multiple stakeholder groups [33]. First, a practicality questionnaire was completed by users with communication impairments. Second, a parallel questionnaire was administered to an observer or companion present during use. Third, a validation instrument was administered by a disability expert. Because each instrument measures something different and results are expected to vary, analyses of these 3 sets were conducted separately. Furthermore, the study analyzed linguistic performance by taking each interaction and comparing the raw word sequences of gestures (system input) with the final sentences generated by the AI (system output). This was done qualitatively. The observed changes were linguistic shifts generated through the AI-assisted process.

Ethical Considerations

The study was carried out in accordance with the Declaration of Helsinki and applicable national guidelines for research involving human participants. All participants provided written informed consent, including details on the study objective, procedures, voluntary participation, data confidentiality, and withdrawal rights. Twelve participants signed informed consent before data collection. Field demonstration and evaluation participants, comprising 15 user participants with communication disorders, 4 observers or companions, and 1 disability expert, separately provided informed consent directly, obtained with the assistance of a sign language interpreter for user participants with communication disorders. There was no collection of personal health information; data from the 12 expert and stakeholder participants related to their professional knowledge and attitudes toward system design and validation, while data from field demonstration and evaluation participants related solely to their experience using the prototype and their perceptions of its practicality. Data collection for all stages of the research (needs analysis, expert validation, and field demonstration) was conducted in accordance with research ethics. Ethical approval was formally granted as an Ethical Exemption (reference number 183/UN38.16/KEP/EC/2026) by the Research Ethics Committee of the Lembaga Penelitian dan Pengabdian kepada Masyarakat (Institute for Research and Community Service) at Universitas Negeri Surabaya, confirming that the study met the 7 World Health Organization ethical standards of 2011, based on the 2016 Council for International Organizations of Medical Sciences guidelines.

RenderX

Results

Needs Analysis

The needs analysis used a 5-point Likert-scale questionnaire completed by 12 participants, covering 4 clusters and 10 indicators as presented in Table 1.

Table . SmartGlove Bahasa Isyarat Indonesia (BISINDO) user needs analysis results.

Cluster and indicator	Mean agreement, %	Mean (SD)
Response speed and accuracy		
Speech output <1 second after gesture completion	100	4.92 (0.29)
Real-time gesture recognition without delay	100	4.83 (0.39)
Minimization of unintended gesture detection errors	83	4.67 (0.65)
Naturalness of language output		
Output as complete grammatical sentences	92	4.83 (0.39)
Sentences comprehensible to lay conversation partners	83	4.75 (0.62)
Context adjustment for formal/informal situations	75	4.58 (0.79)
Portability and ease of use		
Lightweight portable device across contexts	75	4.67 (0.78)
Independent operation without assistance	92	4.75 (0.45)
Cultural and linguistic relevance		
Based on authentic BISINDO vocabulary	100	4.92 (0.29)
Coverage of at least 150 daily-life gestures	92	4.75 (0.45)
Total mean score	89	4.77 (0.51)

Across all 4 clusters, the needs analysis showed very high and homogeneous agreement (grand mean 4.77, SD 0.51; mean agreement 89%). Cultural and linguistic relevance had the highest cluster mean (4.84, SD 0.37; mean agreement 96%) and lowest SD, indicating strong consensus among experts; its top items, response speed and accuracy (item 1.1) and authentic vocabulary basis (item 4.1), each achieved unanimous agreement (mean 4.92, SD 0.29; 12/12, 100%). The response speed and accuracy cluster averaged 4.81 (SD 0.44; mean agreement 94%), naturalness of language output averaged 4.72 (SD 0.60; mean agreement 83%) with one item (context adjustment for formal/informal situations) falling into the High rather than very high category (mean 4.58, SD 0.79), and portability and ease of use averaged 4.71 (SD 0.62; mean agreement 83%).

Each cluster translated directly into a design principle for the prototype. The response speed and accuracy requirement set a sub-1-second end-to-end latency budget across the architecture. The naturalness of language output requirement made the NLG module a required rather than optional architectural element, driving the layer 4 design. Portability and independent-operation requirements pushed the hardware toward wearable, microcontroller-based systems with wireless communication that do not depend on external infrastructure. Finally, the requirement for authentic BISINDO vocabulary coverage of at least 150 gestures set the minimum dataset size.

Prototype Design

Informed by the 4 need clusters, SmartGlove BISINDO was designed as a 5-layer integrated system connecting sensor data acquisition to speech output. The prototype design was based on the DSR design cycle.

The workflow is illustrated in Figure 2. Once set up, both gloves (left as slave and right as master) sample sensor data at 100 Hz at matching times. The left glove itself acquires 5 flex values and 6 inertial measurement unit (IMU) values, which are transmitted to the right glove through ESP-NOW. The right glove uses a data aggregator to aggregate the data with sync timestamping, sending an array of 22 Float32 features per frame over BLE 5.0 to the Android app. The data then goes through a 3-step preprocessing pipeline before being classified by the TFLite (Google LLC) model. Gestures with confidence levels above the determined threshold of 85% or higher were piped into the AI language wrapper to convert NLG-generated text from the LLM into normal sentences in Bahasa Indonesia, and then vocalized using the Google text-to-speech (TTS) Engine detailed in Table 2.

XSL•FO
RenderX

Figure 2. Flowchart of SmartGlove Bahasa Isyarat Indonesia (BISINDO) integrated system architecture. BLE: Bluetooth Low Energy; LLM: large language model.

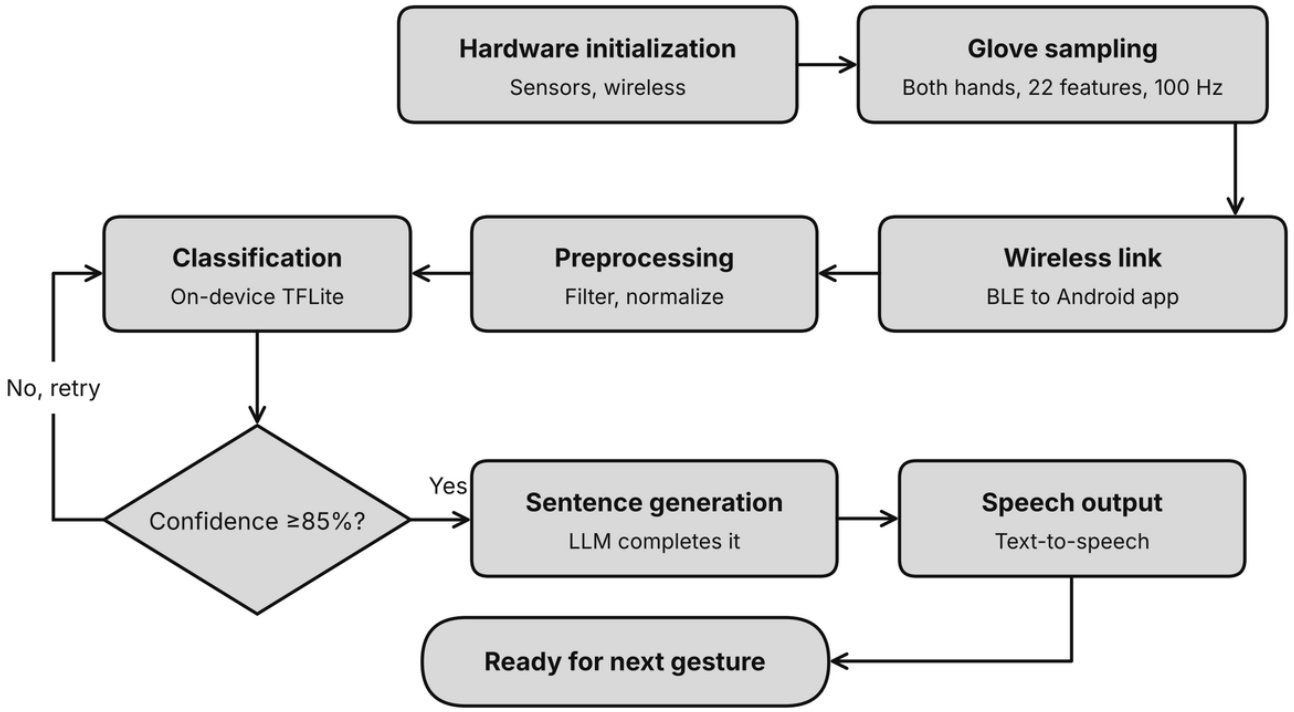

Table . Technical specifications: 5-layer SmartGlove Bahasa Isyarat Indonesia (BISINDO) architecture.

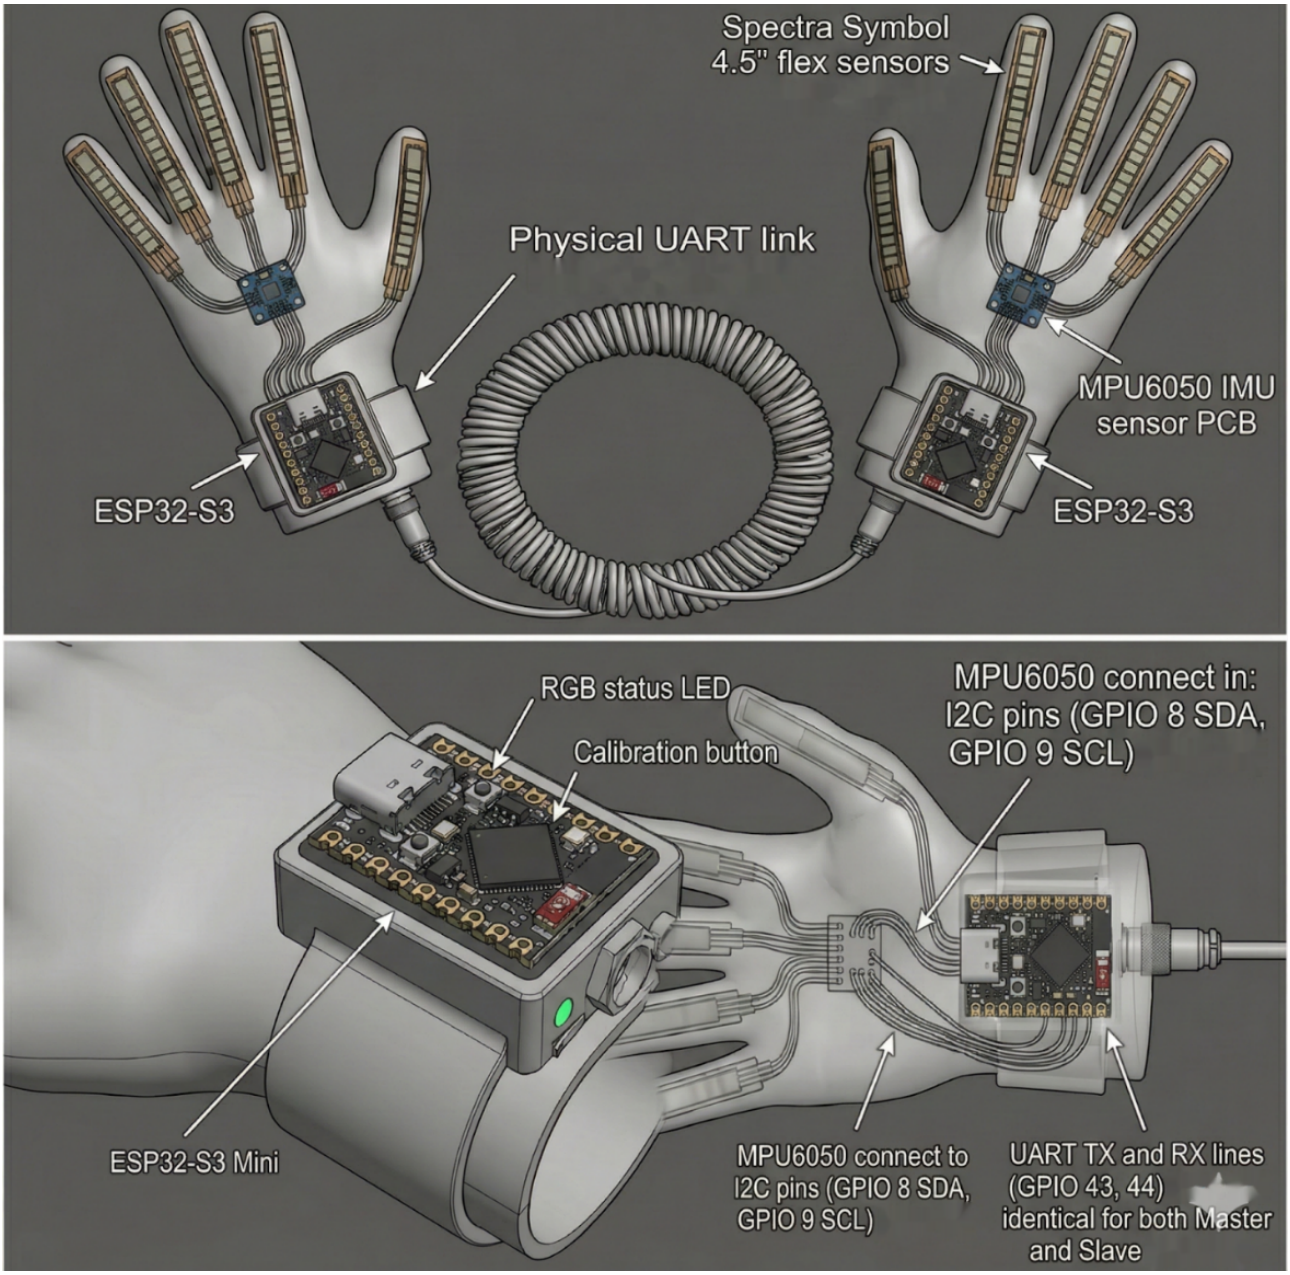
Layer	Key components	Key specifications	Primary function
Layer 1: sensor acquisition	ESP32-S3 ZERO (×2), Flex Sensor Spectra 4.5” (×10), MPU[a]-6050 IMU[b] (×2), and Custom PCB[c]	Dual-core 240 MHz; 12-bit ADC[d]; 100 Hz sampling; 22 features/frame (Float32)	Raw data acquisition from both hands simultaneously
Layer 2: wireless communication	ESP-NOW, BLE[e] 5.0, and data aggregator	ESP-NOW latency <5 ms; BLE MTU[f] 512 bytes; throughput 2 Mbps	Sensor data transmission to Android
Layer 3: processing and inference	Preprocessing pipeline, TFLite LSTM[g]+dense, and confidence threshold	Tensor (1,30,22); 150 classes; target accuracy ≥85%; latency <50 ms	On-device BISINDO gesture classification
Layer 4: AI language wrapper	Sentence buffer, LLM[h] REST[i] API, and postprocessing UI[j]	Pause-based segmentation; API response max 500 ms; RecyclerView history	LLM-based NLG[k] for natural Bahasa Indonesia sentence generation
Layer 5: Speech output	Google TTS[l] engine, Android speaker	Locale id-ID; speed 0.9; real-time playback	Conversion of sentences to Bahasa Indonesia speech

[a]MPU: motion processing unit.
[b]IMU: inertial measurement unit.
[c]PCB: printed circuit board.
[d]ADC: analog-to-digital converter.
[e]BLE: Bluetooth Low Energy.
[f]MTU: maximum transmission unit.
[g]LSTM: long short-term memory.
[h]LLM: large language model.
[i]REST: Representational State Transfer.
[j]UI: user interface.
[k]NLG: natural language generation.
[l]TTS: text-to-speech.



Layer 1 is the physical layer. Five Spectra Symbol 4.5 flex sensors (Spectra Symbol) in each glove measure finger bending, while a single MPU-6050 6-axis IMU (InvenSense/TDK InvenSense) tracks hand orientation, acceleration, and rotation.

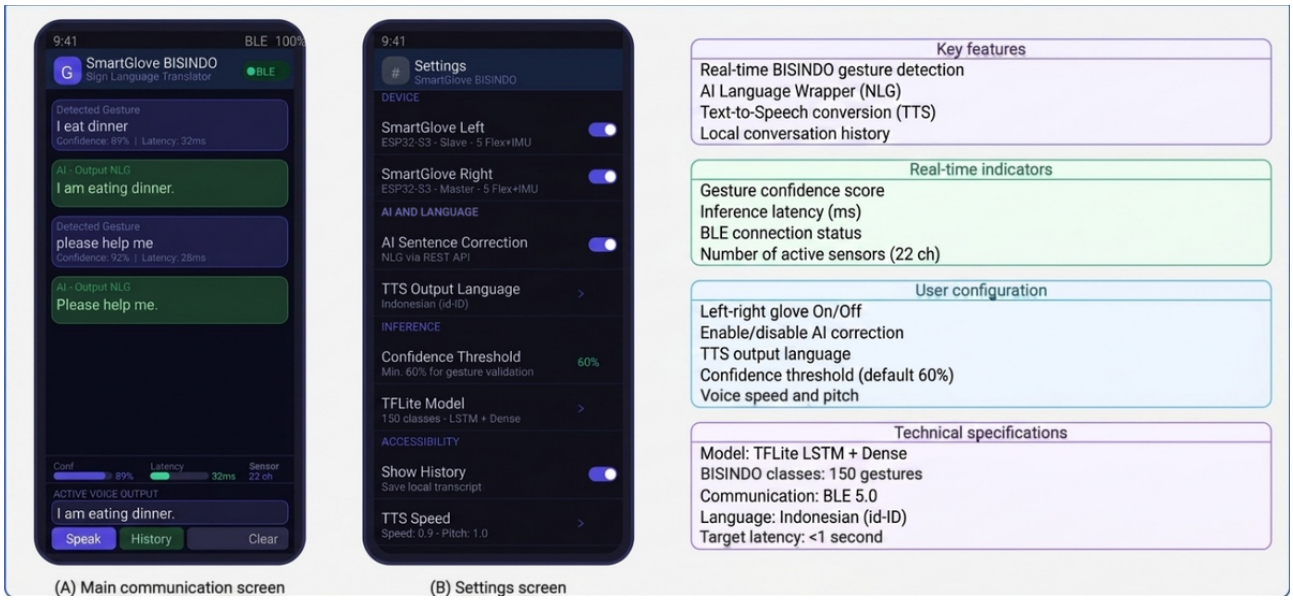
XSL•FO
RenderX

Combining 2 sensor types yields 22 features per frame. This provides a richer representation than camera-based systems and performance comparable to the validated multi-IMU glove [34]. Dual-core 240-MHz ESP32-S3 (Espressif Systems) ZERO microcontrollers control both gloves at a sampling rate of 100 Hz.

Wireless protocols perform 2 distinct functions at layer 2. The ESP-NOW communicates between the gloves via an inter-ping in less than 5 milliseconds, using peer-to-peer communication, and transmits a Float32 array via BLE 5.0 to the Android application (Google LLC) using a data aggregator, where timestamping is performed as shown in Figure 3.

Figure 3. Glove design and specifications. GPIO: general-purpose input/output; I2C: interintegrated circuit; IMU: inertial measurement unit; PCB: printed circuit board; RGB: red-green-blue; RX: receive; SCL: serial clock line; SDA: serial data line; TX: transmit; UART: universal asynchronous receiver-transmitter.

Layer 3 is performed with an input tensor (1, 30, and 22), where the data is passed through a Kalman filter to min-max normalization in a sliding window (30 frames with a stride of 5). The TFLite LSTM+Dense model classifies movements into 150 gestures; only those with 85% or higher accuracy are declared valid. At the same time, on-device inference does not hinder time performance and eliminates cloud reliance, adhering to the portable AT design principles [35].



Layer 4 is the key differentiating component of the BISINDO SmartGlove, integrating LLM-based NLG, which is not present in any previous BISINDO system [36]. Valid gesture labels are collected by the sentence buffer through temporal lag detection. The raw word sequence is sent to the language model via the Representational State Transfer (REST) API (maximum 500 ms) for grammatical and contextual correction, generating sentences like (1) "*Saya sedang makan malam*" from the inputs

XSL•FO
RenderX

"*saya*" + "*makan*" + "*malam*"; and (2) "I am having dinner" from the inputs "I" + "eat" + "night."

The LLM-AAC framework is directly applied to sign language translation. Android's RecyclerView displays the final sentence in real time and draws data from the local conversation history. At layer 5, the final sentence is converted into Indonesian. The Google TTS Engine is used via locale id-ID with a rate of 0.9. Voice is replayed in real time, and end-to-end latency remains below 1 second throughout the process as shown in Figure 4.

Figure 4. SmartGlove Bahasa Isyarat Indonesia (BISINDO) app interface. BLE: Bluetooth Low Energy; CH: channel; NLG: natural language; LSTM: long short-term memory.

The app interface (Figure 4) is based on 2 primary screens. The communication screen displays the translation step. The raw gestures that are detected, and below them, the sentence corrected by the AI. Quick access to confidence scores, system latency, and BLE connection status indicators, too! Second, there's a settings screen. You may set up device connections that connect to the inference threshold and voice output update. Accessibility and ease of use (without any specific training) are the whole design around it. This is exactly what the needs analysis showed.

BISINDO Dataset

The BISINDO gesture dataset comprised 150 classes across 6 categories: 26 letters, 42 numbers, 21 greetings and social expressions, 18 family terms, 2 core essential words, and 41 additional vocabulary items, with 80% (120/150) classes completeness at the time of the field demonstration (full breakdown in Multimedia Appendix 3). This directly addresses the cultural and linguistic relevance criteria identified in the needs analysis and reflects the participatory curation process described in the Methods section.

Expert Validation

Performance and validity of the prototype were checked using an expert validation sheet. It has 3 areas of interest: greeting the data to calculate how well BISINDO gestures were displayed, accuracy and naturalness should be calculated by NLG-generated sentences, and an app should have a user-friendly interface. Twelve validators completed the sheet. Responses were analyzed using CVR, Aiken V, and triangulated percentage agreement. The summary findings of the study are shown in Table 3.

XSL•FO
RenderX

Table . Expert validation results: SmartGlove Bahasa Isyarat Indonesia (BISINDO) prototype (N=12).

Code	Assessment item	Values, n (%)	Values, mean (SD)	CVR[a]	Aiken V	Category
K1	BISINDO gesture vocabulary is authentic and meets standards	12 (100)	4.92 (0.29)	1.00	0.98	Highly valid
K2	Coverage of 150 classes represents daily communication needs	11 (92)	4.75 (0.45)	0.83	0.94	Highly valid
K3	The system can differentiate gestures with similar finger configurations	10 (83)	4.67 (0.65)	0.67	0.83	Valid
K4	A flex and IMU[b] sensor combination is appropriate for capturing BISINDO gesture characteristics	11 (92)	4.83 (0.39)	0.83	0.96	Highly valid
N1	AI-generated sentences are grammatical and conform to Bahasa Indonesia rules	11 (92)	4.83 (0.39)	0.83	0.96	Highly valid
N2	Sentence output sounds natural and communicative to lay conversation partners	10 (83)	4.75 (0.62)	0.67	0.94	Highly valid
N3	AI can correct gesture translation word order into complete sentences	11 (92)	4.83 (0.39)	0.83	0.96	Highly valid
N4	Sentence output is contextually relevant to user gesture intent	9 (75)	4.58 (0.79)	0.50	0.90	Valid
N5	AI response time does not disrupt communication fluency	10 (83)	4.67 (0.65)	0.67	0.92	Highly valid
U1	The interface is easy to understand and operate without specialized training	11 (92)	4.75 (0.45)	0.83	0.94	Highly valid
U2	BLE[c] connection status and confidence score indicators are clearly presented	10 (83)	4.67 (0.65)	0.67	0.92	Highly valid
U3	Conversation history display helps users monitor communication flow	11 (92)	4.83 (0.39)	0.83	0.96	Highly valid
U4	Settings features (threshold, TTS[d] speed, language) can be configured easily	9 (75)	4.58 (0.79)	0.50	0.90	Valid

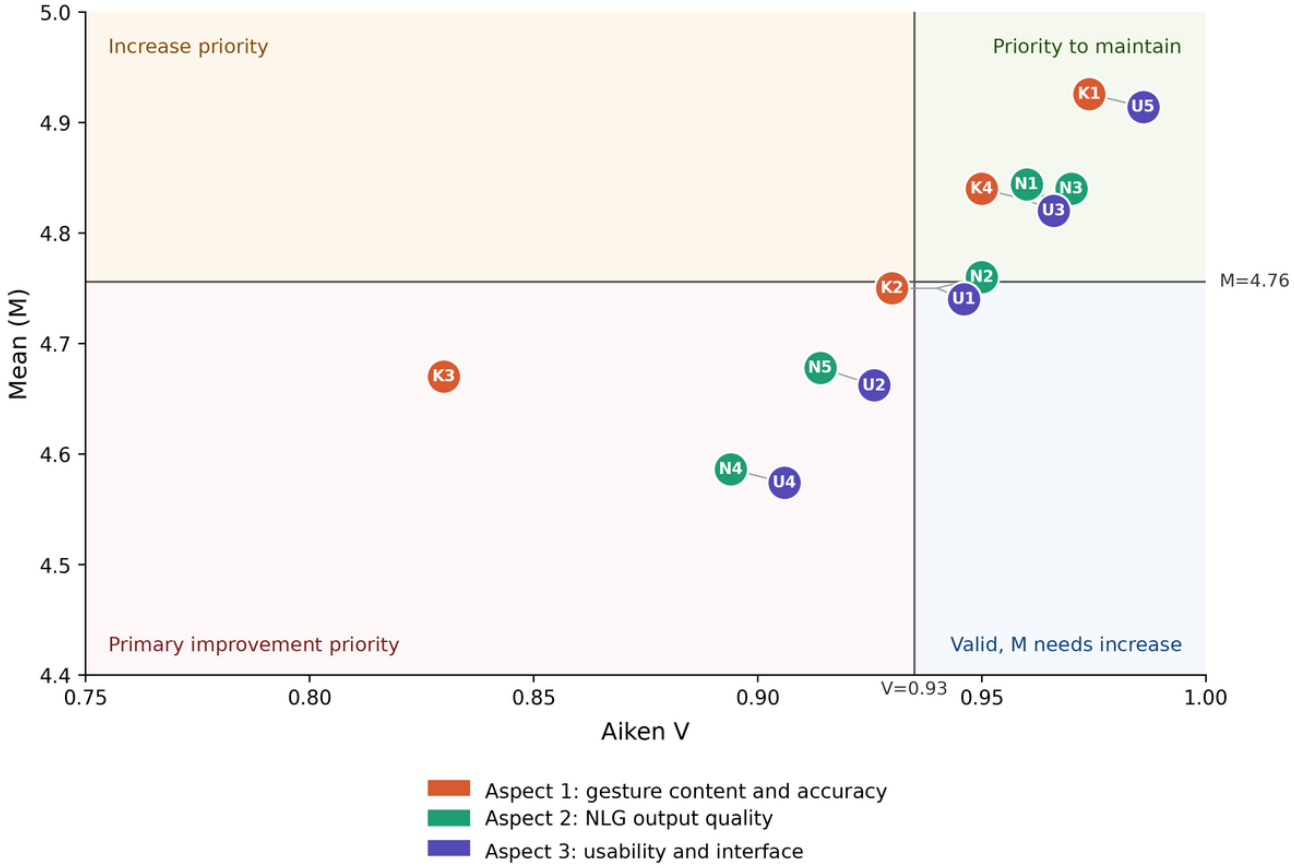
XSL•FO
RenderX

Code	Assessment item	Values, n (%)	Values, mean (SD)	CVR[a]	Aiken V	Category
U5	Interface design is inclusive and meets the needs of users with communication disorders	12 (100)	4.92 (0.29)	1.00	0.98	Highly valid
_[e]	Overall mean across all items, n/N (%)	148/168 (88%)	4.76 (0.51)	0.76	0.94	Highly valid

[a]CVR: content validity ratio.

[b]IMU: inertial measurement unit.

[c]BLE: Bluetooth Low Energy.



[d]TTS: text-to-speech.

[e]Not applicable.

It performed relatively well on content validity. The average Aiken V was 0.94 (SD 0.04), the mean Likert scale was 4.76 (SD 0.51), and the agreement rate ranged from 88% (148/168) to 100% (12/12) among all technical items tested. No item fell below the threshold of 0.75 for Aiken V, and in fact, 11 out of 14 (79%) items were classified as highly valid (V≥0.90). With an average CVR of 0.76 (SD 0.16) across 12 participants, you can see that this value was well above the Lawshe cutoff number of 0.56. For the separated aspects, aspect 1 received an Aiken V of 0.93, and aspects 2 and 3 had a value of 0.94 each.

However, K3 (overlapping movement), N4 (app context of AI in question), and U4 (low-configurable by hand) were only partly CVRs. The next iteration of the DSR design cycle should have improvements on all three. Figure 5: The Cartesian diagram will clarify this even more. The X-axis is Aiken V; the Y-axis is the mean Likert score.

Figure 5. Cartesian diagram of expert validation results. NLG: natural language generation.

The Cartesian diagram of Figure 5 shows the 2 indices plotted simultaneously against the 14 validation items. The line is drawn at this average Aiken V of 0.94 (SD 0.04) with the average of 4.76 (SD 0.11). In the first quadrant in the top right (priority to maintain) are K1, K4, N1, N3, U3, and U5. The base strengths of the prototype are indicated by a V value greater than 0.94 and a mean value greater than 4.76 (SD 0.11). K3, N4, and U4 are located in the lower left quadrant. The 3 are interrelated systematically, and these 3 items would constitute the targeted area of improvement in the next round.

XSL•FO
RenderX

Field Demonstration and Evaluation

Field testing was conducted using 3 complementary instruments across 2 Indonesian cities (Table 4).

Table . Field evaluation results (Makassar and Malang)[a].

Respondent	Makassar, mean (SD); n/N (%)	Malang, mean (SD); n/N (%)	Combined, mean (SD); n/N (%)
User participants	3.34 (0.16); 8/15 (53)	3.36 (0.17); 7/15 (47)	3.35 (0.16); 15/15 (100)
Observers/companions	4.35 (0.07); 2/4 (50)	4.45 (0.07); 2/4 (50)	4.40 (0.08); 4/4 (100)

[a]Mean scores are on a 5-point Likert scale. SD is the sample SD (n−1) of respondent-level mean scores. Mean score as a percentage of the maximum score (5): user participants, 67% (Makassar), 67% (Malang), 67% (combined); observers/companions, 87% (Makassar), 89% (Malang), 88% (combined).

In both Makassar and Malang, ratings from observers and companions were consistently higher than ratings from user participants. The reported practicality percentages represent mean Likert-scale ratings converted to percentages of the maximum possible score, rather than proportions of participants. For overall practicality, user participants with communication disorders gave an average score of 3.35 (SD 0.16) out of 5, or 67% (n=15). Conversely, observers and companions gave an average score of 4.40 (SD 0.08), or 88% (n=4). The gap in scores was as high as about 24 percentage points in Makassar and 18 percentage points in Malang. In Surabaya, an independent disability specialist rated the utility of the prototype at 81% (with a mean value calculated across the 20 questionnaire items of 4.05, SD 0.60; n=1), which backs up the higher scores from observers and companions. The Makassar (only user) responses revealed the lowest-scoring aspects of voice output suitability and clarity. Both sites repeatedly mentioned the gloves' sensitivity, that they are easy to use but not intuitive, the regional variation in BISINDO terminology, and that user guides would need to be produced.

Our comparison involves linguistic analysis of the unprocessed raw input created by gestures (the system input) and the sentence generated by AI (the system output) for each interactive simulation. Three transformation processes were identified. Addition was used to combine elements for a fuller answer, that is, "I" + "eat" became "I am eating." The process of elision removed redundant elements, for example, "I" + "already" + "drink" became "I drink water." Finally, "air" was introduced and "already" omitted, which shows how an output can go through multiple operations at the same time. Substitution occurred when the elements were replaced, causing the meaning to change, for example, "mother" + "running" became mother walking, not mother running. Among the 3 processes, substitution was the worst, because it not only introduced grammar changes but also changed what the user intended to say. Thus, this is consistent with the relatively lower user ratings of the speech output with respect to appropriateness and clarity. Any replacement effectively changes the meaning of the original sentence, causing it to become no longer what the speaker intended. Regional differences in BISINDO vocabulary were also found across sites, indicating that additional training data of the same target words from different regions is necessary.

Discussion

Principal Results

Four principal findings emerged from this study. First, cross-disciplinary stakeholder consensus, assessed quantitatively through the needs analysis, confirmed a very high and consistent priority for BISINDO-based assistive communication technology capable of generating natural, real-time speech (grand mean 4.77, SD 0.51; mean agreement 89%). Second, the SmartGlove BISINDO prototype directly addresses this need through a 5-layer architecture that, to our knowledge, is the first BISINDO system to integrate LLM-based NLG into the translation pipeline. Third, expert validation indicated strong content validity (grand mean Aiken V 0.94, SD 0.04; CVR 0.76, SD 0.16; 11 of 14 items highly valid), providing preliminary evidence that the prototype design is ready to proceed to the next DSR cycle. Fourth, field demonstration with actual users with communication disorders showed favorable practicality ratings from observers, companions, and a disability expert (81% - 88%), but lower ratings from user participants themselves (67%), revealing a gap between expert-perceived feasibility and lived user experience that motivates further design refinement.

From a linguistic perspective, items assessing the grammaticality and naturalness of AI-generated sentences (N1, V=0.96) received highly valid ratings, suggesting that the AI Language Wrapper output meets the ideational and textual metafunctions defined by SFL. Perfect agreement on interface inclusivity (U5, V=0.98) similarly supports the AAC principle of independent operability. Field-based linguistic analysis supports the expert's validity ratings. This analysis identified substitution, rather than addition or deletion, as the transformation process most likely to disrupt ideational metafunctions. This is because substitution alters the intended meaning (field demonstration and evaluation, and results).

In this study, the design of the BISINDO dataset was conducted in collaboration with certified BISINDO experts. This meant prioritizing vocabulary that people actually use in conversation while eliminating classes that are rarely encountered or difficult to visually distinguish. This stakeholder-driven refinement aligns with user-centered design principles, which are crucial for achieving adoption of rehabilitation technology in real-world practice settings [37]. Co-design with experts is a key implementation driver that requires ongoing effort.

These findings carry implications at 3 levels. At the practice level, SmartGlove BISINDO has the potential to reduce communication barriers for individuals with speech-impairment in Indonesian inclusive education classrooms, public service interactions, and daily social contexts, settings in which no deployable BISINDO-to-speech solution currently exists. Given that an estimated 1.02% of Indonesia's population experiences severe communication difficulties [4], even modest adoption

XSL•FO
RenderX

of this prototype could yield meaningful benefits for public health and educational equity, supporting SDG 4 and SDG 10. At the methodological level, the DSR-grounded, co-design-intensive development process demonstrated here offers a preliminary, potentially transferable model for AT research in other underrepresented sign language communities, particularly those facing similar constraints in dataset availability and NLG integration; this transferability remains to be empirically tested rather than assumed. At the policy level, the strong stakeholder consensus on authentic BISINDO vocabulary and independent operability provides preliminary evidence to inform advocacy for context-sensitive, locally grounded assistive communication solutions, consistent with calls to address structural barriers to technology adoption in low- and middle-income countries [38].

Comparison With Prior Work

Table 5 situates SmartGlove BISINDO against previous BISINDO recognition systems, and the most recently published related work is shown in Table 5.

Table . Comparison of SmartGlove Bahasa Isyarat Indonesia (BISINDO) with prior BISINDO recognition systems.

Study	Input modality	Recognition level	NLG[a]/sentence generation	Reported accuracy, %
Aljabar and Suharjito [10], 2020	Camera (CNN-LSTM)[b]	Isolated gesture	No	96
Candra et al [11], 2024	Camera (CNN-MobileNetV2, mobile)	Isolated gesture (30 classes)	No	55
Wiguna and Rojali [12], 2025	Camera (3D CNN-LSTM/BiLSTM[c]+CTC[d])	Sentence-level (gesture-to-text only)	No	Not directly comparable
Kindy et al [14], 2024	Camera (Transformer: SPOTER[e], Siformer, MViTv2[f])	Isolated sign, word-level	No	97
Fadzli and Rahardi [15], 2026	Camera (MobileNetV3, EfficientNetV2-B0)	Isolated hand sign	No	90 - 96
Maharjan et al [39], 2025	Wearable glove (hybrid CNN-Transformer)	Isolated gesture	No	98
SmartGlove BISINDO (this study)	Wearable dual-glove (flex+IMU[g] sensors)	Isolated gesture, LLM[h]-corrected to full sentence	Yes (LLM-based NLG)	Target ≥85%; empirical validation pending

[a]NLG: natural language generation.

[b]CNN-LSTM: convolutional neural network–long short-term memory.

[c]CNN-BiLSTM: convolutional neural network–bidirectional long short-term memory.

[d]CTC: connectionist temporal classification.

[e]SPOTER: Sign Pose-based Transformer.

[f]MViTv2: Multiscale Vision Transformer, version 2.

[g]IMU: inertial measurement unit.

[h]LLM: large language model.

A closely related system for Indonesian Sign Language, though developed for SIBI rather than BISINDO, integrated an LSTM gesture classifier with an IndoBERT language model and reported 89% gesture accuracy alongside a 3-fold improvement in word-prediction accuracy when the language model was applied [13]. This confirms that combining gesture recognition with language modeling improves output quality even in closely related Indonesian sign systems, though this approach remained limited to word-level correction rather than full sentence generation. Among wearable glove-based systems, a category of approaches reviewed extensively in the broader wearable sensor-based sign language recognition literature [40], Maharjan et al [39] reported 98% gesture classification accuracy using a hybrid CNN-Transformer model, though this system, like other prior work, does not incorporate NLG for sentence-level output.

Of all systems compared, only SmartGlove BISINDO stands apart. It's the only one that combines wearable sensors with LLM-based NLG to produce full sentences based not on words/gesture-to-text, but on other gestures. Remember, this comparison used a narrative synthesis of previous results rather than a direct head-to-head trial. This is not a fair apples-to-apples comparison since the systems are different in data sets, hardware, and evaluation protocols. This limitation is expanded upon in the Limitations section below. Additionally, it was not used to measure the gesture-recognition accuracy of SmartGlove BISINDO itself in this study. Instead, evaluation looked at content validity through an expert panel and field practicality with users, observers, and a disability expert. Technical classification performance wasn't the focus, and that's discussed under Future Directions.

Limitations

Consistent with common methodological challenges in evaluating rehabilitation technologies [30], field evaluation was limited to practicality ratings from a small sample (15 user participants, 4 observers/companions, 1 disability expert) across 2 to 3 cities, rather than a controlled effectiveness trial with a

XSL•FO
RenderX

comparison condition or pre-post outcome measures; results should therefore be interpreted as an early-stage field demonstration (DSR phases 4‐5) rather than a definitive effectiveness evaluation. Similarly, the 12-participant expert panel, while meeting the minimum threshold for CVR and Aiken V analyses [31,32], limits the generalizability of the needs-analysis and validation findings, and a formal interrater reliability coefficient was not computed given the sample size. Because both instruments were developed specifically for this study, empirical construct validation beyond expert content review, such as confirmatory factor analysis with a larger sample, was not conducted.

Several sources of uncertainty in real-time gesture recognition were not directly quantified, including sensor noise, classification ambiguity near the 85% or higher confidence threshold, and intersigner variability in gesture speed and amplitude; because the AI Language Wrapper generates sentences from already-classified gestures, such uncertainty can propagate into the output, for example, a misclassified gesture with falsely high confidence could yield a sentence that is grammatically fluent but semantically incorrect. Quantifying this uncertainty, for example through confidence-aware generation or user-facing indicators, is an important direction. Additional hardware limitations include the need for more ergonomic glove materials and sensor straps to support longer sessions, and the fact that the target TFLite model accuracy of ≥85% across diverse user cohorts and all 150 gesture classes has not yet been empirically validated.

Future Directions

Building on the preliminary evidence for content validity established here, 4 directions define the research agenda going forward. First, the gap between favorable observer/expert ratings and lower user-participant ratings, particularly for speech-output clarity, warrants deeper investigation; we recommend incorporating the technology acceptance model [41] alongside AAC and SFL as an interpretive framework, since the technology acceptance model's core constructs of perceived usefulness and ease of use are well suited to explaining why expert-perceived feasibility diverges from lived user experience. Second, empirical performance testing is needed to verify the TFLite gesture-classification model's accuracy across diverse user cohorts and hand morphologies and to quantify the classification and language-generation uncertainties identified in the Limitations section under real-world conditions. Third, the priority-improvement areas identified through expert validation point to specific refinements for the next DSR design cycle: similar-gesture differentiation (K3) toward sensor augmentation or finer feature engineering, contextual relevance of AI-generated output (N4) toward more sophisticated, BISINDO-specific prompt engineering, and settings configuration ease (U4) toward interface simplification. Fourth, scalability testing to other underrepresented sign language systems in Southeast Asia is planned, building on the language-agnostic design of Layers 1 to 3; given that over 50% of individuals in some low- and middle-income countries lack access to needed rehabilitation services [42], portable, low-infrastructure solutions such as SmartGlove BISINDO carry urgency beyond Indonesia, though this broader applicability remains to be empirically demonstrated rather than assumed.

Conclusions

This study developed and validated SmartGlove BISINDO, which is, to our knowledge, the first BISINDO sign language–to-speech system to integrate LLM-based NLG, addressing a systemic gap in prior BISINDO recognition research. A needs analysis of 12 cross-disciplinary participants confirmed a very high and consistent priority (grand mean 4.77, SD 0.51, mean agreement 89%) across all 4 need clusters: response speed and accuracy, naturalness of language output, portability and ease of use, and cultural and linguistic relevance.

The resulting prototype comprises a 5-layer architecture spanning dual-sensor glove hardware, wireless communication, on-device gesture classification, LLM-based sentence generation, and speech output. Expert validation by the same 12 participants indicated strong content validity (grand mean Aiken V 0.94 (SD 0.04), CVR 0.76 (SD 0.16), both exceeding their respective thresholds), with 11 of 14 items rated highly valid. Three items, concerning similar-gesture differentiation, contextual relevance of generated output, and settings configuration ease, were identified as priorities for refinement in the next DSR design cycle iteration. Field demonstration with actual users, observers, and a disability expert further indicated favorable practicality overall, alongside a gap between expert-perceived feasibility and user-rated experience that will guide the next design iteration.

Acknowledgments

During the preparation of this manuscript, the authors used the generative AI tools Gemini (Google) to generate initial drafts of figures and Claude (Anthropic) to edit figures and to assist in drafting responses to editorial queries during revision. The authors reviewed and verified all AI-assisted output and take full responsibility for the accuracy, originality, and integrity of the content, including all references and citations.

Abstract

Background: Despite considerable advancements in prosthetic technology, a substantial proportion of lower limb amputees reduce or discontinue prosthesis use, with reported nonuse rates ranging from 12% to 53%. This reflects the multifactorial challenges associated with long-term prosthetic use, among which comfort and skin health are consistently identified as key determinants. More specifically, studies point toward nonbreathable silicone liners trapping heat and sweat, leading to skin and hygiene problems. These persistent limitations underscore the need for alternative interface materials that offer improved breathability, moisture management, and tunable mechanical properties.

Objective: This study aimed to introduce Flexoknit, a transtibial prosthetic liner that integrates user-specific digital skin strain analysis with computer numerical control multimaterial knitting to create a mechanically tuned, breathable, and anatomically customized interface. Using digital biomechanical data as the primary design driver—rather than clinician heuristics alone—Flexoknit aims to determine the feasibility and performance of a skin strain–guided, computer numerical control–knitted prosthetic interface in terms of material function, clinical performance, and user experience.

Methods: Flexoknit uses programmable multimaterial knitting, incorporating thermal-reactive yarns that stiffen when heated to create structural support zones, alongside spandex yarns that provide elastic compression and breathable zones. Uniaxial tensile tests showed that yarn and stitch combinations can generate distinct stiffness grades, with nearly order-of-magnitude differences. The spatial layout of these graded zones aligns high-stiffness regions with the lines of nonextension, and low-stiffness regions with areas of greater skin strain. With the new prosthetic interface, a series of controlled tests was conducted to compare performance against the participant's existing prosthesis with a conventional silicone liner. User testing was organized into 3 domains (ie, mobility, suspension, and comfort) using standardized quantitative assessments and structured qualitative data collection.

Results: User testing demonstrated a 22.5% improvement in total range of motion, a 37.5% reduction in interface mass, and improved thermal regulation in hot, humid environments compared to that of a conventional silicone liner. The user walked unaided and performed sit-to-stand movements, reporting positive comfort and usability feedback.

Conclusions: This work establishes Flexoknit as a promising direction for future prosthetic development—one that integrates principles of biomechanics, textile engineering, and digital fabrication to create user-centered interface solutions. The findings suggest that digitally engineered knitted interfaces can provide a highly customizable, breathable, and compliant alternative to conventional silicone liners, particularly for lower-activity amputees or individuals prioritizing comfort and ease of use.

Introduction

Despite considerable advancements in prosthetic technology, a substantial proportion of lower limb amputees reduce or discontinue prosthesis use, with reported nonuse rates ranging from 12% to 53% [1-3]. This reflects the multifactorial challenges associated with long-term prosthetic use, among which comfort and skin health are consistently identified as key determinants. Prosthetic comfort is central to user satisfaction and long-term adherence and strongly influences mobility and quality of life [4-8]. Interface-related discomfort—particularly heat, perspiration, and skin complications—has been repeatedly identified as a major contributor to reduced wear time and

XSL•FO
RenderX

dissatisfaction among prosthesis users. Comfort is shaped by several factors, including socket design, interface materials, and suspension approaches [9], and each prosthetic socket is typically crafted through a manual, iterative process that aims to optimize fit [10]. For individuals with transtibial amputation, this precision is especially important because soft tissues must accommodate substantial loads and shear forces during everyday movement [11].

As the primary point of contact between the residual limb and the prosthetic socket, the interface plays a decisive role in user comfort. Dissatisfaction rates with this interface remain high: in a study of 78 lower limb amputees, only 43% reported being satisfied with prosthetic comfort [12]. Excessive sweating is one of the most frequently reported complaints among prosthesis users, affecting up to 70% of individuals with lower limb amputation and significantly impacting daily activities. Approximately half of users report discomfort related to heat and perspiration, highlighting the clinical significance of thermal burden within the socket-limb interface [13,14].

Silicone liners, while widely used to enhance suspension and load distribution, are inherently nonbreathable and act as thermal insulators, trapping sweat against the skin and exacerbating these issues. Among 83 amputees using silicone liners, 31% to 60% reported hygiene-related problems, including itching, perspiration, odors, and scarring [15]. Silicone's insulating properties contribute to dermatological issues, such as heat rash, folliculitis, soreness, and odor [16], and users wearing liners have been shown to experience increased residual limb temperatures during exercise, whereas those without liners did not [17]. These issues are further intensified in hot and humid climates, where thermal load and moisture accumulation exacerbate discomfort [18]. Traditional strategies such as wearing socks under or over liners may improve fit but further increase insulation, adding to the thermal burden or reducing friction, which leads to a decreased coupling grip. These findings suggest that limitations in existing liner materials, particularly their inability to effectively regulate heat and moisture, represent a key modifiable contributor to prosthetic discomfort and reduced use.

These persistent limitations underscore the need for alternative interface materials that offer improved breathability, moisture management, and tunable mechanical properties. Textile-based solutions, particularly knitted structures, present a promising approach due to their inherent porosity, efficient moisture transport, and capacity for precise mechanical tuning. The intermeshing loop architecture of knitted fabrics can produce wide-ranging stiffness, stretch, and ventilation characteristics. Recent advances in textile engineering demonstrate that multimaterial knits can achieve spatially graded mechanical behavior through stitch topology [19], thermal-reactive yarns that form rigid 3D structures [20], and hybrid yarn systems that regulate functional responses [21]. However, existing prosthetic liners primarily rely on homogeneous elastomeric materials and do not exploit these textile capabilities. Early attempts to incorporate textile and knitted interfaces into prosthetic design have demonstrated several functional advantages but remain limited in scope. For example, fabric-covered or differentiated-stretch liner concepts—such as knitted tubes layered with silicone—have aimed to reduce pistoning by restricting distal elongation while preserving proximal compliance or modifying longitudinal elongation over pressure-sensitive areas, thereby improving suspension using the textile architecture [22]. Similarly, breathable textile liner designs using spacer fabrics and partial silicone coatings have shown improved ventilation, moisture transport, and cushioning, although these were largely reported in upper-limb applications and were individualized through manual trimming rather than digitally generated geometry [23]. In parallel, knitted compression systems for amputated limbs have demonstrated that stitch density, loop structure, and yarn selection can be used to tune compression and mechanical response; however, these designs were primarily intended for compression therapy or limb shaping rather than as load-bearing prosthetic interfaces [24,25]. More recently, digital workflows linking 3D scanning to knitting have demonstrated the feasibility of producing geometrically customized liners, but these approaches remain focused on geometric shape conformity and automated manufacturing [26].

Taken together, these studies establish that textile-based interfaces can improve breathability, cushioning, compression control, and even geometric customization. However, they do not yet demonstrate a prosthetic interface in which the regional mechanical properties of the material are prescribed based on subject-specific biomechanical data. In particular, prior work has not integrated digital skin strain mapping with multimaterial textile design to spatially align stiffness, compliance, and reinforcement with the mechanical demands of the residual limb.

A critical missing link in the pursuit of personalized prosthetic interface design is the integration of digital skin strain analysis into material architecture. Skin strain reflects the deformation of superficial tissues during movement, offering direct insight into where support, compliance, or protection is most needed. The concept of lines of nonextension (LoNEs)—regions of the skin that undergo minimal stretch during motion—first described by Iberall [27], has become increasingly adopted in the design of wearable devices. Aligning stiff materials with LoNEs and compliant materials in regions of high strain can minimize shear, reduce friction-related injuries, and enhance comfort.

Our previous work introduced a clinically accessible, low-cost digital workflow for mapping the surface strain field and identifying LoNEs on transtibial residual limbs using marker-based photogrammetry and open-source 3D reconstruction software [28]. This method quantifies maximum, minimum, and directional skin strains and reveals consistent patterns across individuals, including peak tensile strain over the patella, compression in the popliteal region, and anatomical yet individualized LoNE trajectories. These results extend prior studies using more complex imaging approaches [29], demonstrating that skin strain mapping provides actionable biomechanical data for prosthetic interface design.

The convergence of digital biomechanics and computer numerical control (CNC) multimaterial knitting presents an opportunity for medical device development. CNC knitting machines can precisely position yarns of different elasticity,

XSL•FO
RenderX

stiffness, and thermal and moisture management properties, enabling the creation of functionally graded textiles that respond to the unique strain environment of each user. By integrating skin strain data with the knitting design process, stiff knitted structures can be strategically aligned along LoNE pathways to enhance suspension and reduce pistoning, while compliant, breathable knit zones can be placed in areas of high deformation to reduce friction, pressure, and heat accumulation.

Building on these innovations, this study introduces *Flexoknit*, a transtibial prosthetic liner that integrates user-specific digital skin strain analysis with CNC multimaterial knitting to create a mechanically tuned, breathable, and anatomically customized interface. Using digital biomechanical data as the primary design driver—rather than clinician heuristics alone—Flexoknit aims to determine the feasibility and performance of a skin strain–guided, CNC-knitted prosthetic interface in terms of material function, clinical performance, and user experience.

Methods

Study Design

This study used an experimental, mixed methods design to develop, characterize, and evaluate Flexoknit, a transtibial prosthetic interface created through CNC multimaterial knitting and informed by residual limb skin strain patterns. The study comprised three major phases: (1) *digital design and fabrication* of multimaterial knitted structures, including yarn selection, stitch programming, and interface construction; (2) *material and fabric characterization* involving thermal analysis, mechanical testing, and moisture management assessment of the knitted samples; and (3) *user testing* to evaluate mobility, suspension, thermal and moisture comfort, and overall user satisfaction compared with a conventional silicone liner.

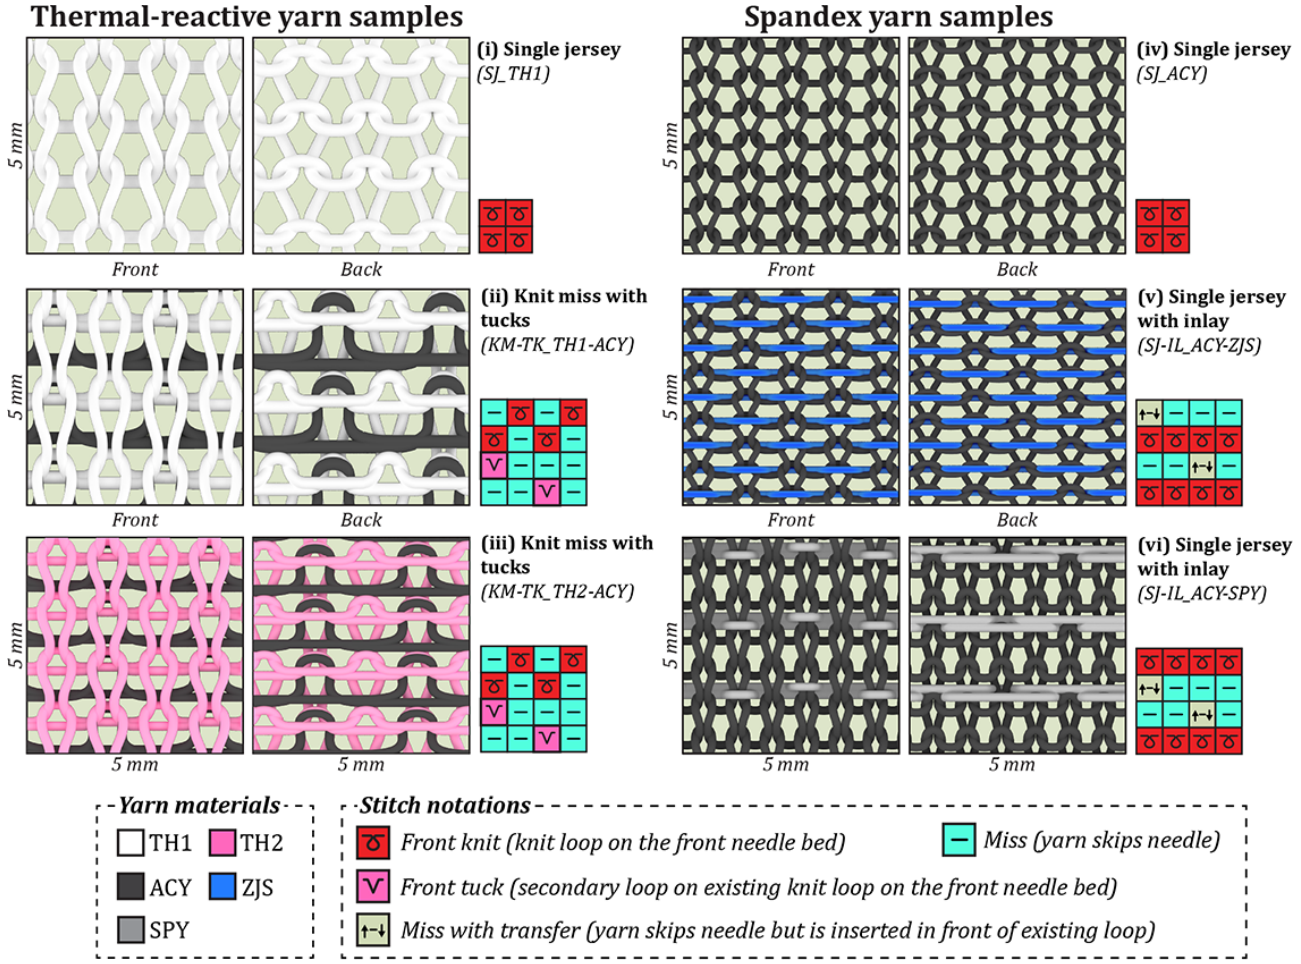
This design enabled a comprehensive evaluation of both the engineered textile properties and the user-level functional response to a digitally informed prosthetic interface.

Recruitment

Participants were recruited from a prosthetics clinic in Singapore using convenience sampling. Inclusion criteria included participants aged ≥21 years, unilateral transtibial amputation, regular prosthesis users, and the ability to ambulate independently with or without assistive devices. Exclusion criteria included active dermatological issues on the residual limb, acute musculoskeletal conditions, or medical conditions affecting ambulation.

One long-term transtibial prosthesis user (76-y-old man) completed the full user testing protocol, including mobility, suspension, thermal, moisture, and satisfaction assessments. An additional healthy participant (35-y-old man) performed the outdoor thermal test in hot and humid conditions to simulate typical Singapore climate exposure. The difference in participants between the indoor and outdoor tests was due to the age of the amputee participant. As the intention of the outdoor sweat and thermal test was to generate adequate sweat within a relatively short duration (15 min) by having a user who could exert themselves under the hot sun, the team opted for a healthy younger participant to perform this outdoor test instead.

Materials and Fabrication



For the main body of the Flexoknit interface, 2 types of thermal-reactive yarns were used. TH1 consists of a 10/1 bicomponent polyester binder spun yarn supplied by Unitika, branded under the model ESPORAN. This yarn is constructed with a polyester core that has a melting point of 256 °C and a co-polyester sheath with a melting point of 110 °C. TH2 is made from a blend of polyester, polyurethane, and nylon, featuring a fusing point of 100 °C, supplied by Asahi Kasei. Three types of spandex yarns were used: ACY (300 D polyester DTY (96 F) and 100 D spandex); ZJS (210 D spandex and 2 ends of 75 D polyester, under the model number 2107575) from Zhejiang Kangjiesi New Material Technology Co., Ltd; and SPY, a low-stiffness elastic yarn from Shima Seiki called Shima Set Up Yarn.

The yarns were knitted into fabric on a Shima Seiki MACH2XS153-15L WHOLEGARMENT 15-gauge flat-bed weft knitting machine programmed using the SDS-ONE KnitPaint software. Three stitch patterns were used in the knitted prosthetic interface (see Figure 1 for diagrams of the stitch patterns). Single jersey (SJ), also known as plain jersey or stockinette stitch, is formed with only front knit stitches. SJ with inlay (SJ-IL) consists of 1 yarn to knit a SJ fabric, while a second yarn is woven in and out of the knitted loops of the first yarn. The second yarn forms approximately straight floats of yarn along the course of the fabric. Knit-miss (cross-miss) 1×1 with tucks (KM-TK) uses 1 yarn to knit the knit-miss 1×1 stitch pattern, where alternate needles knit and miss stitches, with the order of the knit and miss stitches reversing in every course. A second yarn tucks on the knit-miss 1×1 fabric at regular intervals.

More information on the fabrication of the prosthesis can be found in Multimedia Appendix 1.

XSL•FO
RenderX

Figure 1. Stitch patterns and yarn combinations used in the knitted prosthetic interface. For each stitch pattern, a diagram of the front and back of a 5 mm square of fabric is shown, with a knit notation of the stitch pattern at the bottom right. There are three combinations that contain thermal-reactive yarn: (i) single jersey (yarn: TH1), (ii) knit-miss (TH1) with tucks (ACY), and (iii) knit-miss (TH2) with tucks (ACY). There are 3 combinations that do not contain thermal-reactive yarn: (iv) single jersey (ACY), (v) single jersey (ACY) with inlay (ZJS), and (vi) single jersey (ACY) with inlay (SPY).

Material and Fabric Characterization

Yarn Materials

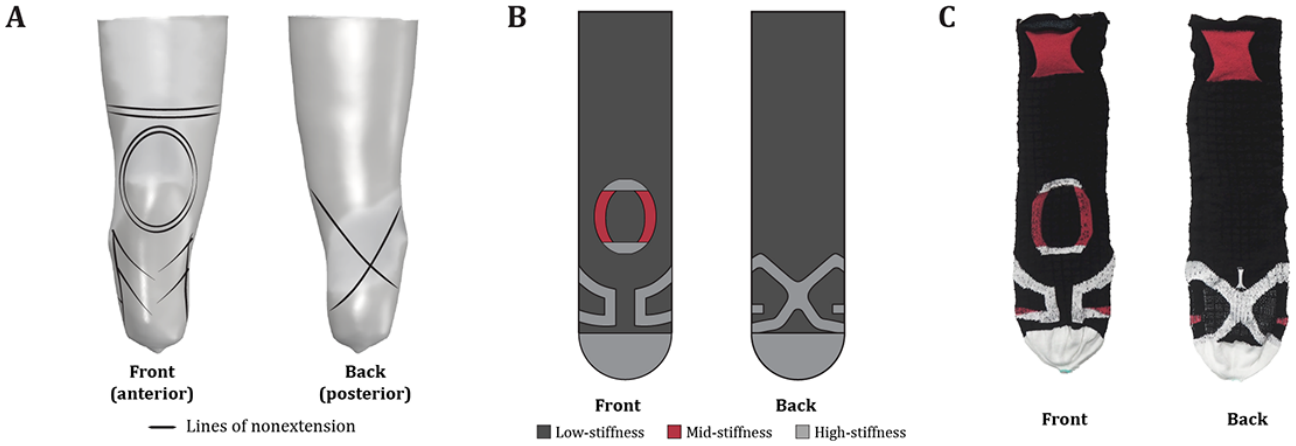
The 3 yarn materials that were used most extensively in the knitted prosthetic interface were characterized using a PerkinElmer DSC 6000 differential scanning calorimetry (DSC) machine. A sample of yarn weighing 7.5 to 8.6 mg was placed in a 50 µL aluminum pan and heated and cooled from 15 °C to 200 °C to 15 °C for 2 cycles at a rate of 10.00 °C per minute in a nitrogen atmosphere (20 mL per minute; see Table S1 in Multimedia Appendix 1 for more details).

Knitted Fabric

The uniaxial tensile properties of the knitted fabrics were characterized according to a modified standard referencing ISO (International Organization for Standardization) 13934 - 1: 2014 (strip test) using an Instron 5943 with a 1.0 kN load cell (see Uniaxial tensile test sample preparation in Multimedia Appendix 1 for more details). The samples were first prepared by heating tubes of fabric on plywood blocks. As the knitted prosthetic interface is stretched in the course-wise (CW) direction when the interface is worn on the residual limb, the samples were made in 2 sizes: *regular* (tube circumference: 390 mm) and *narrow* (tube circumference: 286 mm or 26.7% narrower than regular tubes). The narrow tubes had to stretch to fit onto the plywood blocks. After heating, flat samples were cut out from the tubes to fit onto the tensile testing machine. Each sample size was 50 mm in width and 50 mm in gauge length, and each knit configuration was tested separately in 2 orientations: *wale wise (WW)* or 0° and *CW* or 90°. The strain rate used was 50 mm per minute across all samples. For each knit configuration, the force-strain curves were plotted, and the average breaking force, tensile strain at break, and elastic modulus were calculated.

For thermal and moisture characterization, 8 stitch patterns were tested using ACY yarn: interlock, mesh, pique lacoste (cross-tuck 1×1), purl (garter stitch), rib 1×1, SJ (plain jersey), single pique (cross-tuck interlock), and tuck 1×1. For each test, 3 samples were tested for each stitch pattern. Thermal resistance (K/W) and relative water vapor permeability (%) were measured using a fast skin model Permetest instrument (Sensora Instruments) in a manner similar to ISO 11092 [30]. Wicking rate was measured using a vertical wicking rate test [31,32], with the WW axis of the fabric aligned to the vertical axis. More information on the vertical wicking rate test can be found in Multimedia Appendix 1.

Prosthetic Interface Fabrication



LoNEs are regions of the body that undergo negligible skin strain during movement [27]. Prior studies have suggested using

XSL•FO
RenderX

LoNEs to guide material placement in wearable systems—including prosthetic sockets [33] and mechanical counterpressure suits [34]—by positioning stiff materials along low-strain areas and reserving compliant materials for regions of higher deformation. This strategy allows structural reinforcement without restricting natural skin mobility. Similar approaches have been applied in orthotic design using selectively reinforced 3D-printed elements [35].

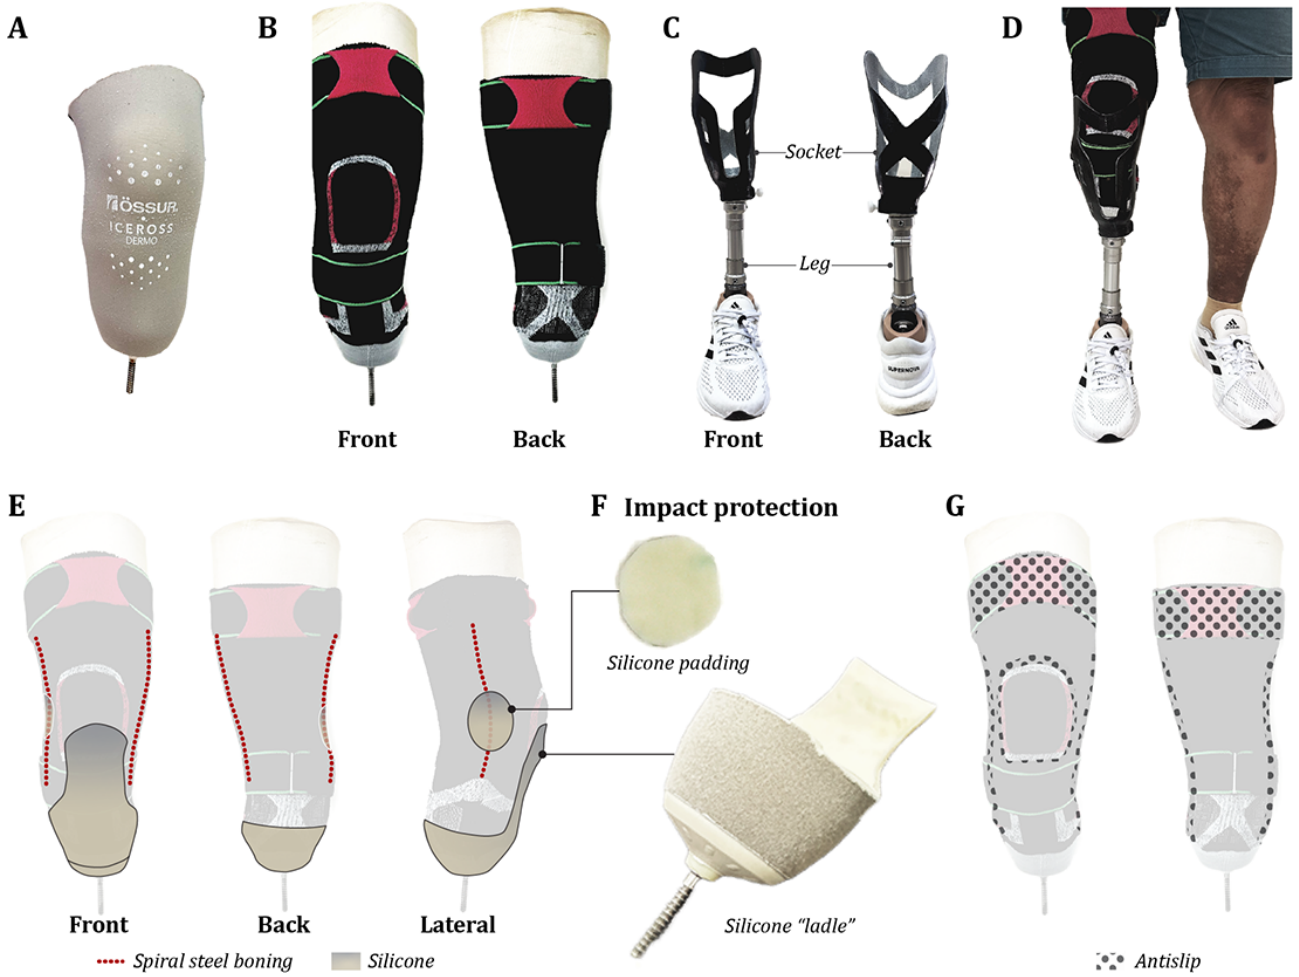
In this study, LoNEs informed the spatial layout of stiffness zones within the knitted prosthetic interface. The user's residual limb was photographed in multiple poses, reconstructed as a 3D model, and analyzed to generate directional strain fields (Figure 2A; see [28] for full methodology). High-, medium-, and low-stiffness zones were then mapped based on these strain patterns (Figure 2B), forming the structural template for the knitted design. In this study, mapping was conducted under controlled, non–weight-bearing conditions, with the participant supported and not loading the residual limb. Skin deformation was captured between 2 standardized knee positions: full extension (0°) and flexion at approximately 60°, measured using a goniometer to ensure consistency.

Figure 2. Design of the graded stiffness knitted prosthetic interface. (A) Diagram of lines of nonextension based on directional strain field from photographs of the user's residual limb. (B) Diagram of high-, medium-, and low-stiffness zones on the prosthetic interface. (C) Photograph of the knitted prosthetic interface.

For each posture, a circumferential video of the residual limb was recorded over approximately 90 seconds, from which a sequence of images (~300 frames) was extracted for 3D reconstruction. The strain field was computed by comparing the reconstructed limb geometry between the extended and flexed states, and the resulting directional strain data were used to identify LoNEs for interface design. A single mapping sequence was performed for the participant, and the derived strain field was used directly for design implementation.

This mapping approach captures kinematic skin strain behavior under controlled conditions and does not account for additional deformation under load-bearing scenarios. Accordingly, LoNEs are interpreted as functionally low-strain design pathways rather than fixed anatomical lines under dynamic loading.

High-stiffness zones were positioned directly over LoNE pathways, providing mechanical reinforcement without restricting mobility. These areas resist elongation under load, supporting suspension, minimizing pistoning, and redistributing pressure toward more tolerant regions of the residuum, such as the medial and lateral tibial surfaces and calf musculature [36]. A stiffened distal zone was added to improve load transfer at the socket-interface junction while reducing overall weight by confining rigid materials only to targeted regions.



Medium-stiffness zones were placed adjacent to the patella, where controlled flexibility is required to accommodate knee movement. This configuration provided directional stiffness in the vertical axis to prevent interface deformation and limit migration while preserving transverse flexibility for knee flexion.

Low-stiffness zones corresponded to regions experiencing high skin strain and were designed to stretch freely, supporting soft tissue deformation during movement. As these zones form most of the interface surface, using breathable, compliant yarns in these areas substantially improved comfort and thermal and moisture management. Integrated compression structures in both layers further improved mechanical coupling between limb and interface and helped manage shear.

The final Flexoknit interface was constructed as a double-layered knitted tube (Figure 3). The outer layer incorporated spatially graded stiffness elements through specific yarn and stitch combinations. High-stiffness zones were primarily knitted using the KM-TK_TH1-ACY configuration, while SJ_TH1 was used at the distal end to allow 3D shaping without compromising rigidity. Medium-stiffness zones used KM-TK_TH2-ACY, and lateral and medial regions included integrally knitted channels containing spiral steel boning. The boning provided vertical stiffness to reduce pistoning while preserving transverse flexibility for knee movement.

XSL•FO
RenderX

Figure 3. Prosthetic interface components. (A) Photograph of current Iceross silicone liner used by the user. (B) Photograph of experimental Flexoknit prosthetic interface. (C) Photograph of hard socket with artificial leg. (D) Photograph of complete Flexoknit prosthetic system. (E) Diagram showing locations of spiral steel boning and silicone padding for impact protection. (F) Photographs of silicone padding for impact protection. (G) Diagram showing the location of antislip.

Low-stiffness regions were knitted with compliant spandex yarns (eg, SJ_ACY) to enable close limb conformity and accommodate local strain. Compression was strategically integrated: SJ-IL_ACY-SPY provided CW compression in the outer layer, while SJ-IL_ACY-ZJS applied surface-level compression in the inner layer, enhancing mechanical coupling and reducing shear.

Additional design features addressed impact protection, suspension, and adjustability. Cushioning pads were placed over vulnerable anatomical areas, including the fibular head, tibial crest, and distal stump. Suspension was facilitated by the thermoformed fit of the knitted tube, augmented by hook-and-loop straps, a patellar silicone ring, and antislip regions aligned with LoNEs. These elements improved security during ambulation without compromising donning ease or adaptability to limb volume fluctuations.

The knitted prosthetic interface was fabricated on a Shima Seiki MACH2XS153-15L WHOLEGARMENT 15-gauge flat-bed weft knitting machine, with all stitch programming executed in SDS-ONE APEX/KnitPaint. Thermal-reactive yarns (TH1 and TH2) were used to enable structural fixation after heat setting. During the user tests, the knitted prosthetic interface was inserted into a rigid laminated transtibial socket and aligned to ensure correct placement of stiffness zones.

User Testing

Following fabrication of the Flexoknit prosthetic interface, a series of controlled tests was conducted to compare performance against the participant's existing prosthesis with a conventional silicone liner. User testing was organized into 3 domains (ie, mobility, suspension, and comfort) using standardized quantitative assessments and structured qualitative data collection. A summary of the test protocol is provided in Table S2 in Multimedia Appendix 1.

Mobility Testing

Range of Motion

Range of motion (ROM) measurements were obtained using a standard goniometer. Joint angles were recorded for the hip, knee, and ankle with and without the prosthesis in place. ROM measurements followed the procedures described in Range of Motion in Multimedia Appendix 1.

Ten-Minute Walk Test

The participant was instructed to walk continuously for 10 minutes at a self-selected pace within a designated indoor gym

XSL•FO
RenderX

space. Distance covered was recorded. Temperature readings were collected concurrently as described in Skin temperature measurements in Multimedia Appendix 1.

Ten-Meter Walk Test

Walking speed was assessed on a straight 10 meter walkway. To reduce participant burden, timings were obtained during the first 3 laps of the 10-Minute Walk test (10MinWT). The test was performed at a comfortable and safe pace.

Timed Up and Go

The Timed Up and Go (TUG) test followed a standardized procedure: starting from a seated position, the participant stood on cue, walked 3 meters, turned, returned to the chair, and sat down. Total completion time was recorded.

Suspension Testing

A static elongation test was carried out. Two reference marks were applied along the proximal brim of the rigid socket—one at the highest lateral point and the other aligned with the patella. With the participant standing, the prosthetic limb was lifted while maintaining full knee extension. Vertical displacement between the original and displaced marks was measured to determine socket migration relative to the knitted interface. Displacement was measured manually using a ruler aligned to the reference markings, with a measurement resolution of 1 mm, and measurements were repeated across 3 trials for each prosthetic condition, with the mean value reported. The measurement error for vertical displacement using manual reference markings was estimated to be +1 or −1 mm based on repeated pilot measurements. Any measured variability across the 3 trials would also be reported as well.

Testing was performed with the knee maintained in full extension throughout to minimize variability due to joint position. Limb loading was standardized using the participant's body weight during standing prior to limb lifting, followed by manual unloading of the prosthesis; however, no instrumented load measurement was used, and the applied force during limb lifting was not quantified.

This method represents a static assessment of suspension and does not account for dynamic loading conditions encountered during gait, including cyclic loading, shear forces, and stance-phase transitions. Given the manual measurement resolution and estimated error margin, small between-condition differences should be interpreted with caution. Supplementary feedback on suspension was collected through brief unstructured interviews.

Comfort Testing

Mass Measurement

The total mass of each prosthetic configuration was recorded using a digital scale (Model 103272; Redman). Socket mass was measured separately, and interface mass was calculated as the difference between total system mass and socket mass. The same procedure was used for both the silicone liner system and the Flexoknit system.

Thermal Comfort

Thermal measurements were collected during the indoor 10MinWT. The indoor environment was measured at 23 °C, and the participant was dressed in a T-shirt and shorts on the day of the test. A ProtoCentral MAX30205 wearable body thermometer was secured to the center of the calf muscle belly. This location was selected due to the muscle's role in generating heat during physical activity [37,38]. Continuous skin temperature data were recorded throughout the 10-minute walking period for both liner conditions.

As the 10MinWT was conducted indoors in an air-conditioned clinic, a secondary experiment was designed to evaluate thermal performance in a warm, humid outdoor environment, reflective of typical daytime conditions in Singapore (31 °C - 33 °C) [39] and reflective of a more accurate simulation of prolonged heat exposure. A healthy participant (35-y-old man), who was dressed in a T-shirt and shorts, wore customized versions of the silicone and knitted interfaces with dual openings for ease of donning. Each test included a resting period (5 - 15 min or until temperature stabilization) followed by 15 minutes of continuous walking on a partially sun-exposed track. Temperature was recorded using the same protocol as the indoor testing.

Moisture Comfort

Moisture comfort was assessed through verbal feedback and postactivity inspection of the prosthetic interface. Examinations focused on the presence of sweat accumulation and tactile dampness. Observations were documented immediately following each walking trial for both interface types.

User Experience and Satisfaction

Standardized Questionnaires

Two validated user-reported outcome measures were administered: (1) Socket Comfort Score (SCS) [40] and (2) Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST 2.0).

The participant provided independent ratings for the conventional liner and Flexoknit conditions.

Qualitative Interviews

Unstructured interviews were conducted to gather additional feedback related to perceived comfort, usability, adjustability, and overall experience with each interface. Real-time observations of interface behavior during walking and donning were also recorded.

Data Analysis

Material properties (DSC peaks, breaking force, strain at break, modulus, thermal resistance, vapor permeability, and wicking rate) were analyzed. Tensile results were plotted as force-strain curves. Mobility and suspension outcomes were compared between the Flexoknit interface and the participant's silicone liner. Temperature data were analyzed as continuous time series profiles. Moisture comfort and qualitative feedback were thematically summarized. Questionnaire scores (SCS and QUEST 2.0) were tabulated and compared across configurations.

XSL•FO
RenderX

This study comprised a material characterization phase and a single-user proof-of-concept evaluation. Owing to the single participant design of the user testing component (n=1), no inferential statistical analysis was performed for the clinical, functional, thermal, or satisfaction outcomes. Normality testing and hypothesis testing were not appropriate for single participant data. User testing results are therefore presented descriptively as raw values and percentage differences between the experimental and conventional prosthetic conditions.

For specific outcome measures, ROM, gait, mass, thermal comfort, and SCS data are reported as observed values, while QUEST 2.0 results are summarized using median scores. Suspension testing using the static elongation method is reported descriptively, with mean displacement values presented for each condition.

Material and fabric characterization data were also analyzed descriptively. Thermal and moisture management results are presented as mean values, as presented in Table 1, and mechanical behavior is presented using observed ranges and representative force-strain responses across yarn-stitch combinations. As this study was designed as a proof-of-concept investigation, no inferential comparisons were performed.

Table . Thermal and moisture comfort results.

Stitch pattern	Thermal resistance		Water vapor permeability		Vertical wicking rate

Ethical Considerations

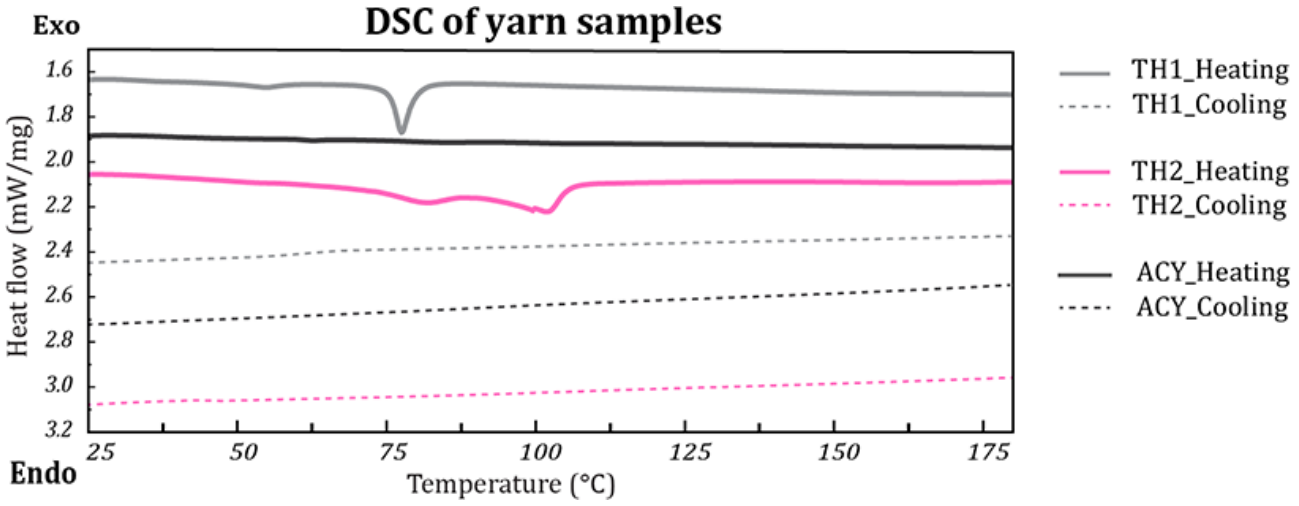
This study was approved by the Institutional Review Board of the Singapore University of Technology and Design (HBR-22 - 00507). All participants provided written informed consent prior to participation. Participants were informed of the study objectives, procedures, potential risks, and benefits, and were free to withdraw from the study at any time without penalty. All data were deidentified prior to analysis and reporting to protect participant privacy and confidentiality. Only the study investigators had access to identifiable participant information, which was stored securely in accordance with institutional data protection requirements. Participants did not receive financial compensation for participation in this study.

Results

Results are presented according to the 4 methodological domains: material and fabric characterization, user testing results (mobility, suspension, and comfort), user experience, and user satisfaction.

Participant Characteristics

One transtibial prosthesis user (76-y-old man, height 173 cm, weight 78 kg, and 15 y post amputation due to diabetes) completed the full mobility, suspension, comfort, and user experience testing. The participant's conventional prosthesis consisted of a 6 mm silicone locking liner, laminated composite socket, pylon components with a pin lock suspension system, and a 1C30 Trias foot, worn for an average of 9 hours daily.



Material and Fabric Performance

Thermal Characteristics (DSC Results)

DSC revealed distinct thermal behaviors among the yarns (Figure 4). TH1 exhibited a single melting peak at approximately 75 °C, while TH2 showed 2 broad melting transitions at approximately 75 °C and 110 °C. The ACY spandex yarn demonstrated no significant thermal transitions within the tested range.

XSL•FO
RenderX

Mechanical Behavior of Knitted Fabrics

Uniaxial tensile testing demonstrated clear differentiation in mechanical behavior across the yarn-stitch combinations (Figure 5). Fabrics incorporating thermal-reactive yarns exhibited higher breaking forces and lower tensile strains at break compared with those knitted solely from spandex-based yarns. Analysis of elastic modulus values showed that the knitted samples consistently fell into 3 stiffness categories:

- Low stiffness (38 - 288 N/m): SJ_ACY, SJ-IL_ACY-SPY, SJ-IL_ACY-ZJS
- Medium stiffness (1224 - 2978 N/m): KM-TK_TH2-ACY
- High stiffness (12,886 - 110,337 N/m): SJ_TH1, KM-TK_TH1-ACY

Figure 5. Material characterization results. (A, B) Uniaxial tensile tests for 6 stitch pattern and yarn combinations (regular-width samples only). (A) Force-strain curves for samples containing thermal-reactive yarn and (B) force-strain curves for samples that do not contain thermal-reactive yarn. (C-E) Thermal and moisture comfort results for 8 stitch patterns knitted with ACY yarn. (C) Thermal resistance, (D) relative water vapor permeability, and (E) vertical wicking rate.

The inclusion of thermal-reactive yarns resulted in substantially higher stiffness and strength at break. For example, KM-TK_TH1-ACY exhibited an elastic modulus nearly an order of magnitude greater than KM-TK_TH2-ACY, despite both samples using the same stitch architecture. KM-TK_TH1-ACY showed a more brittle stress-strain response, whereas KM-TK_TH2-ACY demonstrated greater elasticity, with pronounced anisotropy characterized by higher stiffness in the CW direction than in the WW direction.

To evaluate the effect of prestretching during heat setting, both regular and narrow samples were tested. Narrow samples, which replicated the stretch applied when forming the knitted interface

XSL•FO
RenderX

over a mold, generally exhibited increased stiffness and breaking force in the CW direction, along with reduced tensile strain at break. In the WW direction, narrow samples typically showed decreased breaking force, increased strain at break, and reduced stiffness. An exception was SJ_TH1, which demonstrated increased stiffness in both directions when tested in the narrow state. Across all combinations, narrow samples showed more homogeneous mechanical behavior between axes, indicating reduced anisotropy after prestretching. No systematic differences were observed between front and back sample orientations.

In addition, the force-strain curves in Figures 5A and 5B revealed the distinct failure modes of the different knit samples. Upon testing the samples to their breaking point, the thermal-reactive yarn samples exhibited brittle failure with a sudden force drop, possibly due to the presence of hardened thermoplastic (TH1 and TH2) in the knit. The failure mode is akin to a cleavage in the middle of the sample's testing area. On the other hand, the spandex yarn samples exhibited ductile tensile failure with significant "noise" upon breaking. The tested samples showed necking before failure, followed by several consecutive instances of columns or rows of elastic yarn loops breaking and unraveling upon failure. This behavior was reflected as several step-down peaks after the sample reached its breaking force.

Thermal and Moisture Management Performance

Eight stitch patterns were evaluated for thermal resistance, water vapor permeability, and wicking rate (Table 1). SJ demonstrated the lowest thermal resistance and highest vapor permeability, with a mid-range wicking rate, ranking highest overall for thermal and moisture management performance.

User Testing

Mobility Outcomes

Range of Motion

ROM testing showed measurable differences across prosthetic configurations. Using the knitted interface alone, maximum knee extension remained unchanged, while maximum flexion decreased by 10°. When used with the LoNE-aligned rigid socket, total knee ROM was 98°, compared with 80° when using the participant's current prosthesis (silicone liner and hard socket). In both conditions, terminal knee extension was limited to 20° of flexion (ie, a 20° extension deficit). Total ROM was calculated as the difference between peak flexion and terminal extension, and the 18° increase in ROM for the knitted interface and LoNE-aligned rigid socket is therefore attributed to increased flexion capability rather than a change in extension (Table 2).

Table . Range of motion (ROM) measurements of the various prosthetic configurations.

Prosthesis type	Extension (°)	Flexion (°)	Total ROM (°)
None (bare skin)	0	130	130
Knitted prosthetic interface	0	120	120
Current prosthesis	20	100	80
Experimental prosthesis	20	118	98

Gait Performance

During the 10MinWT, the participant covered 10.5% less distance with the experimental prosthesis compared with the conventional system. In the 10-Meter Walk Test (10mWT), walking time increased by 8.3% when using the knitted interface. The TUG test duration increased by 1.7 seconds. The participant ambulated independently during all tests.

Suspension Outcomes

Socket migration measured using the static elongation test showed a mean displacement of 4 mm (+1 or −1 mm) with the experimental system and 3 mm (+1 or −1 mm) with the conventional system. Given that the observed between-condition difference (1 mm) lies within the estimated measurement error of the manual marking method (+1 or −1 mm), this finding should be interpreted with caution. During indoor walking, the participant reported a gradual loosening sensation and sinking at the distal tibia when using the experimental prosthesis, despite the small measured difference in static displacement. These observations were recorded during the structured suspension assessments.

Comfort Outcomes

Mass

The experimental prosthesis weighed 26.1% less than the participant's current prosthesis. The knitted interface alone was 37.5% lighter than the silicone liner.

Thermal Comfort

In the indoor air-conditioned setting (23 °C), the user's resting posterior limb skin temperature increased by 0.89 °C with the knitted interface and 0.18 °C with the silicone liner. During the 10MinWT, the skin temperature increased by 0.82 °C (knitted) and 0.62 °C (silicone).

However, in the warmer outdoor setting (34 °C), the nonamputee's resting posterior limb skin temperature increased by 0.21 °C (knitted) and 0.71 °C (silicone). During the 10MWT, the skin temperatures rose by 1.95 °C with the knitted interface and 2.88 °C with the silicone liner.

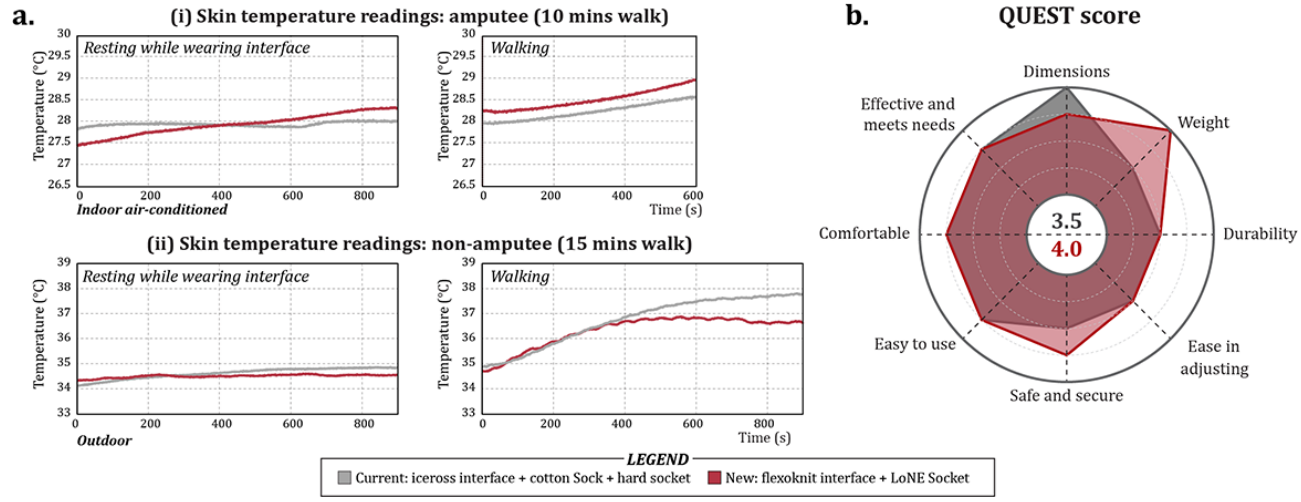
Moisture Comfort

No sweat accumulation was observed in indoor trials. In outdoor trials, visible perspiration accumulated beneath the silicone liner, and the participant reported a sweaty sensation. The knitted interface left the skin dry on doffing, although the fabric itself was damp. A sharp drop in skin temperature after removing the

XSL•FO
RenderX

silicone liner was observed; no similar drop occurred with the knitted interface.

User Experience and Satisfaction



Socket Comfort Score

The participant rated the knitted interface 7/10 and the current prosthesis 9/10.

QUEST 2.0 Satisfaction

The knitted prosthesis received a higher median satisfaction score (4.0) than the conventional prosthesis (3.5; Figure 6B). The IQR of the knitted prosthesis's score was 0.5, while the conventional prosthesis was 1.0, demonstrating that there was less variation in the participant's responses for the knitted prosthesis than the conventional one.

Figure 6. (A) Skin temperature measurements when resting while wearing the prosthetic interface and walking while wearing the prosthetic interface and socket for (i) the amputee and (ii) the nonamputee users. (B) Quebec User Evaluation of Satisfaction with Assistive Technology (QUEST) score showing the user-reported outcomes for the current and experimental prostheses. The numbers in the center of the spider diagram show the median scores for the current (black) and experimental (red) prostheses. A score of 1 represents "not satisfied at all," and a score of 5 represents "very satisfied." LoNE: line of nonextension.

Qualitative Feedback

Qualitative feedback from interviews and real-time observation provided additional insight into the participant's experience using both prosthetic systems. When using the Flexoknit interface, the participant consistently remarked on the noticeably reduced weight of the device, describing it as feeling lighter and more compliant during walking. The knitted structure was perceived as "springy," and the participant noted a softer underfoot feel compared with his usual prosthesis. In indoor trials, the participant reported that the knitted interface felt warmer around the limb, whereas in outdoor trials, the nonamputee participant described the knitted interface as feeling cooler and less sweaty than the silicone liner. The textile appearance of the knitted interface was preferred, with the participant expressing positive reactions to its aesthetic qualities.

During donning, the participant reported that the hook-and-loop suspension straps added steps to the usual routine and occasionally caught on the surface of the knitted fabric, although no structural damage was observed. While walking with the experimental prosthesis, the participant described a gradual sinking sensation at the distal tibia, corresponding to the mild static elongation observed during suspension testing. After returning to the conventional prosthesis following the experimental trials, the participant described the device as feeling comparatively "hard" during stance and walking, indicating a perceptible difference in interface compliance between the 2 systems.

Discussion

Principal Findings

This proof-of-concept study demonstrates the feasibility of a digitally informed, multimaterial knitted prosthetic interface for transtibial users while also highlighting the biomechanical trade-offs introduced by increased interface compliance. By combining residual limb skin strain analysis with CNC multimaterial knitting, we created Flexoknit—a double-layered, graded stiffness interface integrated with a LoNE-informed rigid socket. Material characterization showed that targeted yarn-stitch combinations can generate 3 distinct stiffness tiers spanning nearly an order of magnitude in elastic modulus. When implemented in a transtibial system, this graded design reduced interface mass relative to a conventional silicone liner, preserved or improved knee ROM, and showed context-dependent thermal and moisture advantages, particularly in hot outdoor conditions. However, suspension-related challenges, including the participant's reported distal "sinking" sensation, and the reduced distance walked during the 10MinWT indicate that improvements in ROM and comfort-related properties do not necessarily translate into better gait performance or interface stability. Despite the suspension-related challenges and donning complexity, user-reported satisfaction scores and qualitative feedback indicate that the concept is acceptable and potentially attractive for lower-activity community amputees. Taken together, these findings suggest that increased interface flexibility may have facilitated greater knee excursion during isolated ROM testing, while simultaneously reducing

XSL•FO
RenderX

stance-phase stability during walking through less consistent limb-socket coupling. These findings therefore support feasibility but also highlight the need for further refinement of load transfer and suspension security before broader clinical application.

Design of Multimaterial Graded Stiffness Knitted Fabric

The material characterization phase confirms that both yarn composition and stitch architecture can be systematically tuned to control mechanical behavior. Thermal-reactive yarns (TH1 and TH2) exhibited clear melting transitions and, once heat-set, produced knitted structures with substantially higher stiffness and strength than fabrics knitted solely from spandex yarns, consistent with prior work on thermal-reactive knits [20]. Uniaxial tensile testing showed that KM-TK_TH1-ACY and SJ_TH1 formed the high-stiffness group, KM-TK_TH2-ACY formed the medium-stiffness group, and SJ spandex configurations formed the low-stiffness group. The separation between these categories—38 - 288 N/m; 1224 - 2978 N/m and 12,886 - 110,337 N/m, respectively—provided a clear design palette for allocating support and compliance within the interface.

Prestretching the knitted tubes prior to heat setting, a process that mimics forming the fabric over a limb mold, further modified the mechanical response. Narrow (stretched) samples typically showed increased stiffness and breaking force in the CW direction and more homogeneous behavior between WW and CW axes, suggesting reduced anisotropy once the fabric is tensioned to its in-use configuration. This behavior is advantageous for prosthetic applications, where a predictable, direction-independent response can improve suspension and load transfer.

Thermal and moisture management testing indicated that stitch patterns can be used to optimize comfort-related properties independently of stiffness. Among the patterns assessed, SJ achieved the best overall balance of low thermal resistance, high water vapor permeability, and adequate vertical wicking, supporting its use as the dominant structure in low-stiffness, high-contact zones. Collectively, these findings show that multimaterial CNC knitting can deliver a controlled spectrum of mechanical, thermal, and moisture management properties within a single seamless interface.

LoNE-Guided Reinforcement Design

The LoNE-guided, digitally manufactured construct illustrates a shift from uniform material liners toward spatially tailored interfaces in which stiffness, compression, and breathability are all driven by patient-specific biomechanical data. LoNE-guided reinforcement may improve suspension by placing stiffer load-bearing elements along relatively low-strain pathways, where they can resist migration with less disruption to natural tissue motion. However, LoNEs are not assumed to remain perfectly fixed under load-bearing conditions and should instead be interpreted as functionally stable design zones. Nevertheless, the present findings suggest that anatomical alignment of stiffness zones alone is insufficient; effective suspension depends not only on alignment with LoNE pathways but also on the absolute magnitude and spatial distribution of interface stiffness required to maintain stable load transfer during dynamic gait.

Interpretation of User Testing and Clinical Implications

In functional testing with the participant, the Flexoknit system preserved maximum knee extension and increased overall knee flexion when compared with the conventional prosthesis, yielding a 22.5% improvement in total ROM. This suggests that aligning stiff zones with LoNEs and reserving compliant structures for high-strain regions may permit greater sagittal-plane excursion at the knee without immediately compromising basic structural support. However, the increase in ROM should not be interpreted as a direct proxy for improved functional mobility, as gait performance during the 10MinWT, 10mWT, and TUG was modestly worse with the experimental system. Despite the 26.1% reduction in prosthesis mass, the participant walked more slowly with the experimental system. This suggests that prosthetic weight alone was not the dominant determinant of performance in this case. From a biomechanical perspective, walking efficiency depends not only on limb mass but also on the quality of load transfer, proprioceptive consistency, and the user's confidence during the stance phase. It is therefore plausible that the benefits of reduced mass were offset by less stable mechanical coupling at the limb-socket interface. Importantly, the participant was able to ambulate independently and perform functional tasks such as sit-to-stand, indicating that the experimental system met minimum requirements for community mobility.

The participant's report of a gradual distal tibial "sinking" sensation is biomechanically significant, suggesting incomplete load transfer coupling between the residual limb, knitted interface, and rigid socket. In an optimally coupled system, axial and shear forces are distributed proximally and circumferentially to maintain stable limb positioning. In this case, the increased compliance of the knitted interface likely permitted localized deformation—particularly distally—reducing the efficiency of axial load transfer. This may explain the perceived distal settling despite only a 1 mm difference in static elongation, highlighting that small displacements can be clinically meaningful when repeatedly experienced at sensitive anatomical sites.

Although the study was not designed to isolate the precise structural cause, this behavior likely reflects a combination of compliant material response and insufficient longitudinal reinforcement in low-stiffness regions. While these compliant zones were intended to accommodate soft tissue and enhance comfort, they may have allowed excessive vertical deformation under load. Future iterations should therefore refine not only overall stiffness but also the spatial distribution of reinforcement to improve suspension without compromising comfort.

This phenomenon also has implications for gait stability. While compliance can enhance pressure distribution, excessive deformation may introduce micromovements that reduce proprioceptive consistency and perceived security during stance. This may contribute to a more cautious gait pattern, reduced efficiency, and slower functional performance, even in the

XSL•FO
RenderX

absence of pain. The participant's slower walking speed and longer TUG time are therefore likely influenced not only by device unfamiliarity but also by altered mechanical coupling at the interface, potentially reducing confidence during weight acceptance and forward progression.

The graded stiffness design also achieved a substantial reduction in mass, with the experimental prosthesis approximately one-quarter lighter overall and the knitted interface over one-third lighter than the silicone liner. The participant's perception of the prosthesis as "lighter" and "springy" aligns with these findings and may explain the increased knee flexion observed during ROM testing. However, this reduction in mass did not translate to faster gait. The perceived "springiness" likely reflects increased compliance, whereby some mechanical energy during stance was absorbed within the interface rather than efficiently transferred to forward progression. While this may enhance comfort, it may also reduce the stability required for confident movement. These findings suggest that reductions in prosthetic weight should be considered alongside interface stability, as improvements in one may be offset by compromises in the other.

Thermal and moisture outcomes were environment dependent. In the air-conditioned clinic, the knitted interface produced slightly greater temperature rises than the silicone liner, suggesting increased insulation when ambient temperatures are low. In contrast, in a hot outdoor setting representative of tropical climates, the knitted interface limited skin temperature rise and left the skin dry after walking, while the silicone liner trapped sweat and was perceived as hot and sticky. These findings imply that an open, wicking knitted structure may offer particular advantages in warm, humid environments, where dermatological complications and heat intolerance are common.

Despite generally adequate suspension, the static elongation test and user reports indicated minor distal "sinking" with the experimental system. This finding likely reflects the combined mechanical behavior of the compliant knitted interface, the stiffness zoning strategy, and the structural response of the LoNE-informed rigid socket under dynamic load. Rather than representing gross pistoning alone, the sensation may indicate localized compression and delayed load sharing across the limb-liner-socket complex, particularly during repeated stance loading. Clinically, this is relevant because even subtle distal displacement can alter pressure concentration, disturb the user's perception of stability, and reduce confidence during walking. This observation may also help explain the slower walking speed and longer TUG duration despite the reduced prosthetic mass. Even subtle distal settling or micromovement at the interface can alter how ground reaction forces are transmitted through the prosthesis and may reduce the user's confidence during loading response and mid-stance. In response, the user may adopt a more cautious gait strategy, with slower progression and more conservative transfer during transitional movements such as turning and sit-to-stand. This likely reflects the combined behavior of the compliant interface and the LoNE-informed rigid socket, including possible flexing of the latter under load.

The lower SCS for Flexoknit compared with the user's own device appears to be driven by this sensation of gradual loosening rather than by gross discomfort or pain. This interpretation is also consistent with the higher overall QUEST score and positive qualitative feedback regarding appearance, weight, and perceived compliance, suggesting that user acceptance of the concept remained favorable despite the mechanical shortcoming. Taken together, these findings suggest that interface compliance must be carefully balanced: sufficient to accommodate tissue motion and improve comfort, but not so great that it compromises distal support or mechanical coupling.

Future iterations should therefore investigate increasing distal and longitudinal stiffness, refining the suspension mechanism, and optimizing outer socket rigidity to reduce perceptible settling during gait. Nonetheless, the higher overall QUEST score and the participant's preference for the device's appearance and perceived security suggest that, with refinements to the outer socket stiffness and suspension strategy, user comfort could be further improved.

Conclusions

This study presents a proof-of-concept transtibial prosthetic interface—Flexoknit—engineered through a multimaterial, graded stiffness knitting approach informed by LoNEs. By combining thermal-reactive yarns, spandex-based elastic yarns, and spatially targeted stitch architectures, the knitted interface achieved distinct zones of mechanical behavior that were aligned with the user's residual limb strain patterns and functional requirements. The fabrication process demonstrated that CNC knitting can reliably integrate structural reinforcement, compliance, compression, and breathability within a single seamless textile construct tailored to an amputee's limb geometry.

Material testing confirmed that the yarn-stitch combinations produced the intended stiffness gradients, while functional testing showed that the interface supported safe ambulation and preserved or enhanced joint mobility when used with a LoNE-aligned rigid socket. Improvements in thermal and moisture regulation, particularly in warm outdoor conditions, and a substantial reduction in overall prosthesis weight further demonstrated the potential benefits of integrating knitted structures into prosthetic design. User feedback highlighted the comfort, lightness, and aesthetic appeal of the device, reinforcing the feasibility of this approach for improving user experience.

As an early prototype, some usability challenges remain, including potentially inadequate prosthesis stability under load and the need for more intuitive suspension and donning mechanisms. Nonetheless, the findings suggest that digitally engineered knitted interfaces can provide a highly customizable, breathable, and compliant alternative to conventional silicone liners, particularly for lower-activity amputees or individuals prioritizing comfort and ease of use.

Overall, this work establishes Flexoknit as a promising direction for future prosthetic development—one that integrates principles of biomechanics, textile engineering, and digital fabrication to create user-centered interface solutions. Further research is warranted to refine structural performance, evaluate long-term

XSL•FO
RenderX

durability, and validate the design across diverse user groups and real-world conditions.

Limitations and Future Work

This study has several limitations that should be considered when interpreting the findings. First, the prosthetic evaluation was conducted with a single transtibial amputee user, and thermal testing in a hot outdoor environment involved only one additional healthy participant. The results therefore reflect an in-depth case study rather than population-level evidence and may not generalize to users with different limb geometries, activity levels, or comorbidities. Second, the familiarization period with the Flexoknit system was short, so the gait and comfort outcomes likely include early adaptation effects. Longer-term use may alter both objective performance and subjective preferences. Third, the prototype system combined a novel knitted interface with a bespoke LoNE-informed rigid socket that has not yet been fully optimized. The biomechanical interpretation of distal "sinking" is based on user reports, static elongation data, and observational findings rather than instrumented assessment of in-socket motion or pressure distribution. In addition, while material and bench-top testing were extensive, real-world durability, laundering behavior, and the long-term skin response to continuous fabric–skin contact were not assessed. These aspects are critical for translation to everyday clinical practice.

Future work should therefore focus on multiparticipant studies that include a broader range of ages, activity classifications, and residual limb shapes, with follow-up over weeks to months. Such studies should incorporate more detailed biomechanical outcomes (eg, 3D gait analysis, interface pressure, and shear mapping) and dermatological assessments to evaluate skin integrity over time. On the design side, iterative optimization of the rigid socket stiffness, strap layout, and donning sequence is needed to reduce distal sinking and simplify daily use. Finally, further development of the digital workflow—from automated LoNE extraction to direct translation into knit patterns—along with systematic durability and wash-cycle testing, will be essential to move Flexoknit from proof-of-concept to a clinically deployable, manufacturable system.

Abstract

Background: Lack of functionality is one factor that contributes to prosthetic rejection rates. Electromyographic upper limb prostheses are controlled through muscle contractions in the user's residual limb. The incorporation of multigesture controls into a novel, in-house developed upper limb prosthesis requires users to differentiate between the strengths of muscle contractions to trigger programmed gestures. Little research exists on the limitations of expanding device capabilities. This expansion may lead to a decline in accuracy and perceived usability or an increase in training time and cognitive workload.

Objective: This study aimed to determine the feasibility of implementing multiple gestures when learning electromyographic controls during a single training session.

Methods: Participants with full upper extremity control were fitted with a Flex Controller, a surface electromyography device that measures muscle contraction. Contractions were visualized as peaks and calibrated through an adjustable scale on a tablet. A training app was developed in-house to test novice users on an electromyography control system. Users interacted with 1, 3, or 5 zones on the screen. Each horizontal zone represented a threshold required to trigger a distinct gesture on the prosthesis. The cohorts were labeled A1 (n=9), A2 (n=10), A3 (n=9), and B1 (n=26). Every participant completed 3 trials per arm, and each trial consisted of 15 randomized cues. Each cue was represented by a green color change, with 1 point earned after a successful peak. Collected outcomes included performance, the System Usability Scale, and the National Aeronautics and Space Administration Task Load Index.

Results: Scores decreased significantly as zones increased (Kruskal-Wallis H_3=24.9, P<.001). The mean scores were 15.0 (SD 0.0) for 1 zone, 9.1 (SD 1.1) for 3 zones, and 5.5 (SD 1.1) for 5 zones. Perceived usability, measured by System Usability Scale, showed modest omnibus difference across cohorts (Kruskal-Wallis H_3=5.22, P=.16); however, a pairwise comparison showed the 5-gesture cohort rated usability lower than the progressive cohort (2-tailed Welch t_{11}=–2.19, P=.05). The 5-gesture cohort rated the system lowest (mean 63.3, SD 16.2). Cognitive workload, assessed through the National Aeronautics and Space Administration Task Load Index, increased with the number of gestures. The performance subscale showed a significant omnibus difference across cohorts (Kruskal-Wallis H_3=21.4, P<.001). Mean performance subscale scores were 84.4 (SD 14.7) for the single-gesture condition, 30.6 (SD 21.7) for the 5-gesture condition, and 44.2 (SD 21.2) for the progressive cohort, reflecting increasing perceived difficulty with more gestures. The sample size for quantitative analysis was 54.

XSL•FO
RenderX

Conclusions: These findings support the implementation of progressive training for 3 gestures. Usability perceptions were the highest among the more complicated progressive cohort, which is likely related to perceived improvement. Progressively learning 3 gestures enables a balance between device capability, user intention, perceived usability, and cognitive workload.

Introduction

Upper limb prostheses must meet the functional demands of daily life [1,2]. Varied factors cited as contributors to prosthesis rejection demonstrate the need to further understand how to optimize training and device usage to meet these demands [3]. Electromyographic prostheses have fewer reported cases of device abandonment, attributed to increased capabilities [4]. Despite this, the lack of device functionality that contributes to prosthetic rejection rates [5] underscores the need to further expand device capabilities while maintaining user accuracy and perceived usability for novice users. The integration of advanced grips, finger configurations, and gesture recognition enables greater adaptability and reliability in a system [6]. Similarly, incorporating multiple gestures may improve prostheses' functional capabilities, but they must be feasible for users to adopt the control scheme in daily life.

Electromyographic prostheses are controlled by muscle activation, which triggers the device to perform a preprogrammed gesture. Noninvasive surface electromyography (sEMG) detects microvoltages from the skeletal muscle, which are detectable from the skin's surface [7,8]. To receive the electrical signals, sEMG can be embedded anywhere the device makes contact with the user's residual limb. Multigesture electromyographic prostheses similarly require muscle activation but can perform multiple distinct movements. There are a variety of ways to process data collected by sEMG sensors to trigger a specific motion. Control schemes can use machine learning models in conjunction with several placed sEMG sensors [9], pattern recognition sequences [10], or magnitude-based discretization using a single sensor [11]. While a single-gesture prosthesis typically performs an open-close grasp with each muscle contraction, a multigesture prosthesis offers a variety of hand motions, such as pinch-point gestures, task-specific grasps, or individualistic expressions. Multigesture prostheses can be approached from a direct, single-sensor control perspective or from a pattern recognition standpoint [10]. Pattern classifiers have been found to potentially identify a user's intention with up to 90% accuracy under ideal conditions, but present significant issues, including electrode shift, position variation, and force variation [11]. However, using a single electromyography (EMG) electrode with multigesture capabilities through force grading has been shown to be effective for pediatric populations [12].

This research aims to evaluate multigesture training with single sensor control. The research team has been developing a novel multigesture prosthesis that leverages a single sEMG sensor. Patients using the device can intentionally contract their muscles at different strength magnitudes to perform various gestures with the prosthetic limb. For example, a "light" contraction would prompt a different command than a "hard" contraction. Thresholds can be set to respond to a user's individual strength range through calibration. This EMG signal processing includes amplification, rectification, band-pass filtration, and smoothing [13]. This control scheme is thought to perform better for people with congenital limb differences, who often have limited muscle volume and discretization compared with acquired amputations later in life.

All recorded EMG voltages from the sensors are processed and reported as values from 0 to 1023, with higher values indicating greater muscle contraction intensity. The input is filtered and rectified using bandpass filtering to reduce the reference scale to a comfortable range of contraction. When reading and processing muscle contraction for multigesture control, a single "flex" is quantified as the highest recorded EMG value within a series of recorded values above a set resting baseline. Each user can adjust this resting baseline to account for natural variance in base noise sensor readings. Any values below this resting threshold are effectively ignored by the prosthesis, allowing for intentional contractions to be easily differentiated from resting noise. When the continuous EMG signal from the prosthesis reaches a value above the resting threshold, all values are recorded within the current "flex" until the signal dips below the resting threshold again. Once the EMG signal falls below the resting threshold, the highest recorded value for the previous contraction is identified as the peak. This peak value is then compared with the preset multigesture thresholds to determine which threshold was hit. Each gesture threshold has a minimum contraction value, ranging from 0 to 1024, that can be manually set by each user. A threshold's range spans from its minimum value to the next highest minimum value of the following threshold, or 1024 if there are no higher thresholds. When a discretized threshold is met, the corresponding hand gesture is triggered.

Implementation of multigesture EMG control using a single sensor is limited [11,14,15], but has leveraged pattern recognition and magnitude control. One example of this control implementation used to perform complex gestures is an assistive device that incorporates a hands-free wheelchair interface [14]. In this interface, engagement of the user's temporalis muscle controls a wheelchair's movement. Different levels of contraction correspond to wheelchair commands, including turning left, right, and moving forward similar to previous prosthesis controls [16]. This may be applicable in populations without the manual dexterity required to operate a traditional wheelchair joystick, such as those affected by a stroke or

XSL•FO
RenderX

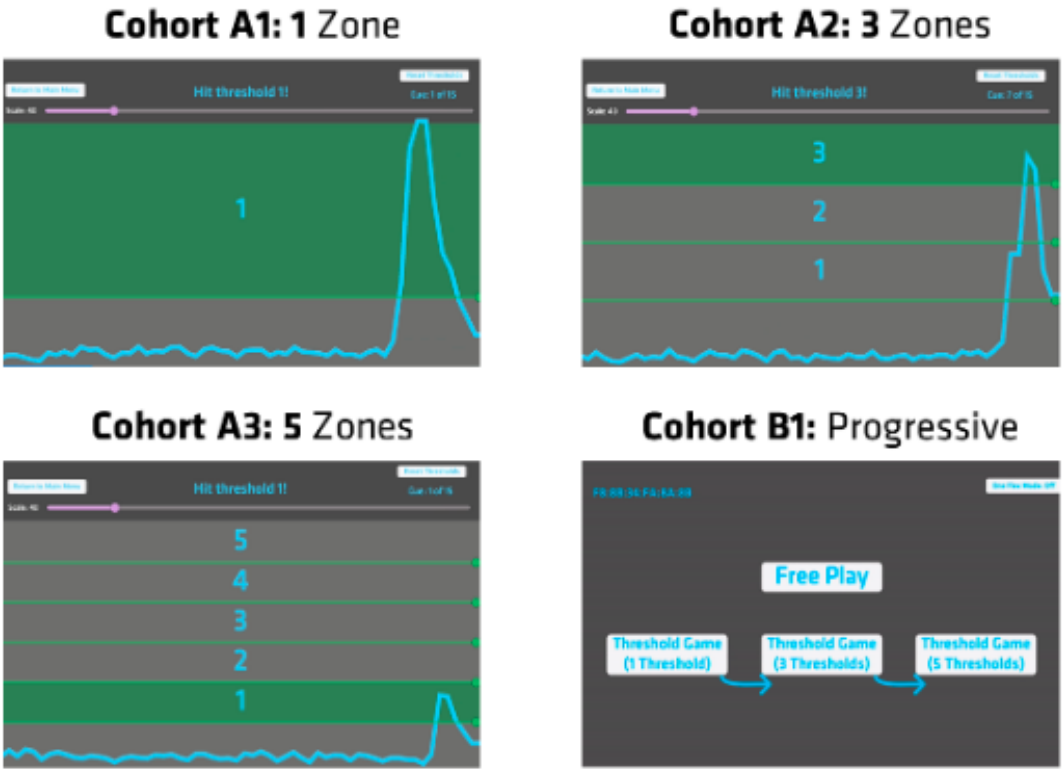
amyotrophic lateral sclerosis. This interface includes 3 levels of discretization, and research demonstrated that users could successfully gain control of the system [17], with three user control methods that allow independent use of the wheelchair and increase human-machine interaction and user autonomy. This successful schema demonstrates the potential for using a single-channel EMG system to control multiple outcomes.

Gamified training applies game design elements to nongame situations [18] and offers an engaging option to familiarize a patient with a system or motion. For electromyographic prostheses, gamified training can help teach novice users how to engage the targeted muscle and learn novel controls. There is a need to explore the impacts of serious gaming further, as discrepancies in the literature suggest that evaluating training platforms should be done on a case-by-case basis [19]. In a pediatric population, compliance with a training regimen is a multifactorial struggle that often falls on the caregiver [20]. Gamified training can encourage consistent preparation for an electromyographic prosthetic arm. The purpose of such training games is to expose and strengthen the children's residual muscles before receiving their prostheses, which is intended to lower the time they need to become proficient with the device [21]. Game-based intervention shows an overall improvement in sEMG control and fine muscle activation [22].

The gamification in this study is built upon a preexisting gamified training strategy. The intention of the system is to prepare pediatric patients before using an EMG-powered prosthetic arm, with past research demonstrating gamified training leading to positive outcomes [23]. Training that starts at the time of initial device or before receiving a prosthesis may be beneficial [24,25]. Rehabilitation protocols are often progressive, requiring the establishment of baseline skills [26]. Some muscular rehabilitation settings have observed a benefit from using progressive training over static training [27]. In other settings, such as pain rehabilitation, no significant difference was found when comparing static and progressive training [28]. Various factors affect pediatric rehabilitation compliance, including engagement, motivation, and cognitive workload [29]. The cumulation of these factors has led to the need to examine progressive training in regard to pediatric electromyographic prosthesis use.

A gap in the current literature exists regarding the usability of electromyographic prosthesis systems, specifically those using a single-sensor system as opposed to the more common practice of including multiple sensors on the residual limb to gather EMG input [30]. The magnitude of contraction is less often the activation input for EMG devices; instead, multiple sensors working in conjunction using further signal analysis are more widespread. However, the incorporation of multiple sensors can add additional complexity to the system and make it more prone to error [15]. Although there is a range of electromyographic prostheses within the field of assistive technology, it has become apparent that standardization is necessary in the evaluation of EMG controls for single-sensor device models [31]. Additionally, opting to prioritize a single sensor may increase ease of learning in the pediatric population. While these multichannel systems using a field of muscle responses may be more beneficial toward amputees, who are more likely to have numerous feasible muscle groups for targeting with sEMG, this may differ in those with congenital limb differences. Amputees have been shown to learn new motor control schemes and muscle activation patterns via sEMG training [32].

As the etiology of congenital limb difference may vary, it is important to consider that the muscular architecture of each individual may not allow for multiple muscle targets. Methods of control for multigesture vary greatly, with each potentially benefiting from its own method of quantification. The use of a single-channel EMG system is uncommon, necessitating the development of a specific evaluation process for user acclimatization to the device. Additionally, an evaluation to determine the limit of the number of possible discretization thresholds should be developed. This testing software, in conjunction with the survey instruments, is intended to effectively measure the perceived difficulty level of the varying modes (1, 3, or 5 discretization zones within a single sensor) that are analogous to the multigesture electromyographic prosthetic device.



Methods

Study Design

To observe the results of novice users attempting to target various levels of contractions, a gamified training app, the Muscular Discretization Assessment Tool (MDAT), was developed in-house for user testing. The research team designed the MDAT to resemble the calibration system used by participants in a clinical trial testing the Limbitless Solutions prosthetic arm. Ensuring the effectiveness of the gamified MDAT controls before usage by prosthesis users was intended to optimize gameplay before distribution. When designing the gamified training app, complete parity with the functionality of the multigesture prosthesis was one of the main design aims. Each participant's muscular contractions were displayed in a graph showing real-time voltage changes, as illustrated in Figure 1.

XSL•FO
RenderX

Figure 1. Representation of the progression scheme of each of the four cohorts. Cohort A1 included 1 section for participants to flex within. Cohort A2 consisted of the screen divided into three sections for participants to flex within. Cohort A3 consisted of the screen divided into five sections for participants to flex within. Cohort B1 had participants complete the first round with the screen divided into 1 section, the second round with 3 sections, and the third round with 5 sections.

The app recorded and processed EMG input through the same mechanisms as the electromyographic prosthesis; once the user's EMG signal passed the base resting threshold, all EMG values were recorded and saved until the signal fell below the resting threshold again. The EMG processing provides filtered data that directly corresponds to a muscular contraction, with a sampling rate of 1000 Hz. These steps include amplification, rectification, band-pass filtration ranging from 2 to 1000 Hz, and smoothing [13]. The highest recorded value between these 2 points was then identified and was considered the peak value of this contraction. This peak was used to determine which multigesture zone the contraction fell within. The app also allowed for the manual adjustment of each threshold, as well as a global scaling value, which amplified the measured EMG signal to allow users with weaker readings to still hit all thresholds easily. The prosthesis similarly allows for these levels to be adjusted and calibrated for a personalized experience.

The EMG Flex Controller sends data to the multigesture app approximately 60 times per second. These data are validated and processed by the app every time a new visual frame is calculated, which occurs at a capped rate of 30 times per second on the tablets available for user gameplay. This translates to a rate of processing and data reading from the controller once every 33.3 milliseconds. The app reads in muscle strength from the user directly as captured by the EMG sensors on the Flex Controller, and no additional adjustments are made to the readings by the game. The app also reflects the threshold system for triggering different gestures on the prosthetic, which provides one-to-one parity. Before app implementation in the study, internal testing was conducted. Since the software of the app was built on the framework of the calibration app used for the existing EMG-controlled prosthetic, the data are as reliable and seamless as they would be in real-world applications. The accuracy of this software has been tested before this study and has been implemented in ongoing clinical trials.

The calibration period consisted of participants completing a maximum muscular contraction. Based on where this signal ended, the sensitivity was adjusted. For example, if the participant was not able to easily reach the top of the screen via their muscular contraction, the signal sensitivity would be increased. This scale effectively "zooms in" the reading captured by the controller to bring the maximum captured value closer to the user's readings without losing the accuracy and fidelity of data. This allowed for a standardized normalization process that was based on the user's maximum contraction. The zone areas are initially segmented equally, but are customized to each participant such that they can feasibly hit all thresholds, with their baseline signal remaining below the lowest threshold. For additional support, the participant was prompted to hit each of the zones before actual gameplay.

The MDAT had a freeplay mode and various settings to replicate the multigesture thresholds analogous to the prosthesis control. The participant was fitted with an in-house developed Flex Controller around the forearm that contained surface electrodes to detect microvoltages from muscle contractions. The freeplay mode was used before data collection to calibrate the user's Flex Controller to their personal muscle capabilities. The gameplay modes provided an environment for users to contract

XSL•FO
RenderX

at various thresholds, recreating the muscle engagement required to operate the corresponding multigesture prosthetic device. In these gameplay modes, the screen was divided into 1, 3, or 5 sections, as presented in Figure 1.

The user interface (UI) for the gamified MDAT was designed to communicate the EMG signal and thresholds to the user as clearly as possible. Other elements, such as score, game instructions, and options, were placed at the top of the screen space to maximize the area available for EMG-related elements. Clarity was provided through explicit instructions for which randomized muscle strength grading thresholds are hit, delivered in a similar fashion as a game of *Simon Says* or *Bop It* (Hasbro Inc). A limited yet bright color palette was chosen for the UI to ensure that important elements stand out to users. A thick, bright blue line represented the user's EMG signal from the Flex Controller, allowing users to understand how their muscle activity was translated in-game. Horizontal green lines across the screen indicated gesture thresholds. These were the only green elements in the UI and were intentionally chosen to make thresholds easy to identify at any moment during playtime. To further enhance threshold identification, each zone was visibly labeled as a numerical range. This aided users in identifying which threshold they were being prompted to hit during gameplay, as the game presented messages in the form of "Hit threshold X!." X, in this instance, would correspond to the assigned threshold number that was cued to be hit. The cued threshold zone was highlighted in green, intuitively demonstrating to users which threshold they must hit without having to read the instruction prompt.

The participant had 1 attempt to reach within the threshold, and there was no time limit on completing an attempt. An attempt was considered successful if the participant's peak contraction was within the cued highlighted threshold. Successful attempts were scored out of 15 cues per round to record overall performance.

A total of 54 participants completed data collection, with ages ranging from 18 to 30 years old. Anyone was invited to participate if they were between the ages of 18 and 64 years, able to consent, had full control of their upper extremities, had no injuries to their hands or arms that would impact their upper extremity control during data collection, and if they had never used a Limbitless Solutions myoelectric prosthesis or Flex Controller. Participants were assigned a cohort (A1, A2, A3, or B1) based on participation order. Cohort A1 included 1 section for the users to contract within, while sections A2 and A3 corresponded to 3 and 5 threshold sections, respectively. Cohort A1 had an analytical population of n=9. Cohort A2 had an analytical sample of n=10. Cohort A3 had an analytical sample of n=9. Cohort B1 had an analytical sample of n=26. Each of these cohorts completed 3 rounds with their respective number of zones. B1 was the progressive cohort, in which participants progressed through the 1, 3, and 5 zone modes in sequence. Users were first fitted with the Flex Controller on the right forearm. The controller was calibrated in freeplay mode based on the ease of comfortably reaching each threshold. This was guided by the researcher and manipulated by changing the sensitivity of the surface electrodes. Before gameplay, each user was informed of their respective cohort and shown each of the thresholded screens. For participants in the progressive cohort, researchers further explained the thresholds as fixed increments that changed progressively after each of the 15 cues was presented. Each participant played through the 15-cue round 3 times, taking 1-minute breaks in between each round to avoid fatigue. This procedure was then repeated with the Flex Controller on the left forearm.

After the testing period concluded, postassessment surveys were delivered to participants. These surveys included the Systems Usability Scale (SUS) and the National Aeronautics and Space Administration Task Load Index (NASA-TLX) [33,34]. The SUS is a 10-item scale commonly used as an objective measure of a digital interface's usability [33]. The NASA-TLX measures cognitive workload through 6 categories [34]. The Edinburgh Handedness Inventory (EHI) was also completed to determine the participants' dominant hand [35]. Finally, the user's grip strength was measured using a handheld dynamometer. Grip strength was measured on both the right and left hands, and each was tested twice. The highest score for each hand was recorded. Participants also reported confidence with video games, confidence with exercise, confidence with visual cues, and activities they have participated in during the current week.

Ethical Considerations

These procedures were approved by the University of Central Florida Institutional Review Board on October 1, 2024 (STUDY00007067). The inclusion criteria for participation consisted of people aged 18-64 years with full control of their upper extremities. Full informed consent was presented in both a visual and an auditory manner. Participants were encouraged to ask questions throughout the informed consent process and to request extra rest periods as needed. Participant confidentiality was preserved wherever possible by assigning a randomly generated 8-digit user ID based on participation order. These IDs were generated and stored on a premade linking spreadsheet. Once an ID was used, it was marked as "claimed" on the spreadsheet to ensure each was used only once. The Qualtrics forms containing all of the study data were linked to this ID, and no identifiable participant information was retained or used for analysis. The only potential participant compensation was extra credit from an instructor, which was offered at the discretion of the instructor. Each instructor who offered extra credit from this study was required to provide an alternative assignment of equal time and effort for the same amount of credit in the case that a participant could not complete the study.

Statistical Analysis

Analysis was conducted in Python (version 3.12.9) using the libraries *pandas*, *NumPy*, and *scipy.stats*. The analytic sample was 54 participants (N=54). Tests were 2-tailed with α=.05; results were not adjusted for multiple comparisons. Normality was assessed for within-subject differences for paired comparisons using the Shapiro-Wilk test. When a paired comparison showed evidence of nonnormal differences (Shapiro P<.05), a Wilcoxon signed-rank test was run as a nonparametric sensitivity analysis and both results were reported. Nonparametric checks were used for ordinal or multilevel factors. SDs use $t_{(n-1)}$=1 for effect size testing.

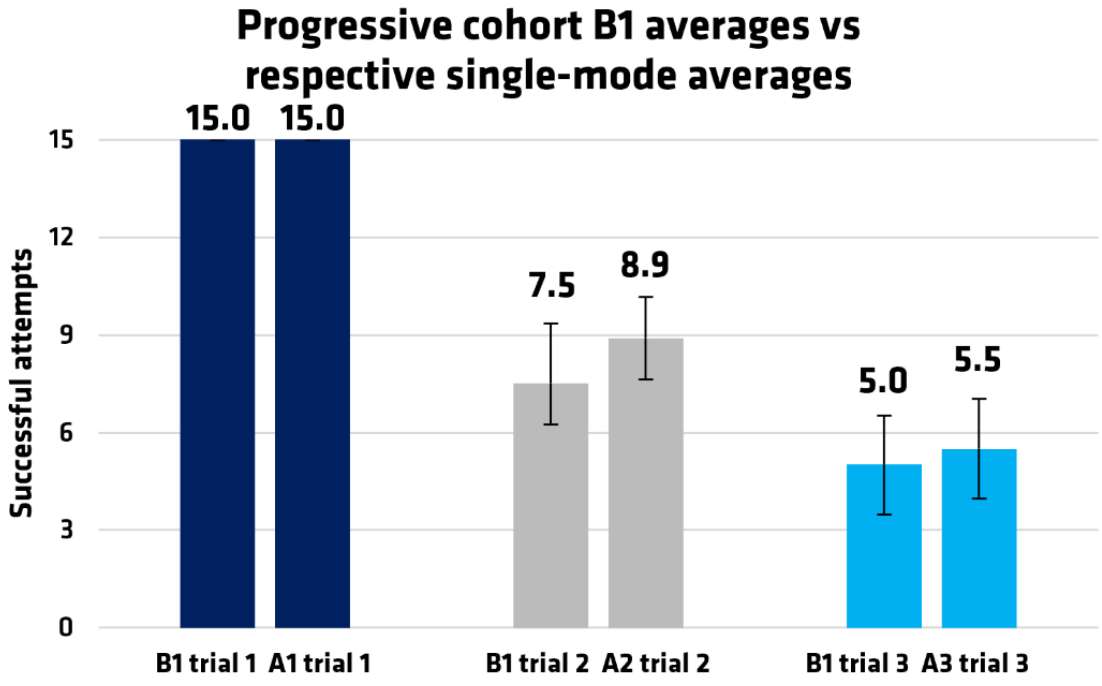
XSL•FO
RenderX

Score construction was in accordance with SUS standard guidelines (odd items: x–1; even items: 5–x; sum×2.5 to yield 0-100 scores) [33]. NASA-TLX raw inputs (1-21) were rescaled to 0-100 scores via (x–1)×5 [34]. The EHI laterality quotient was calculated via (R–L)/(R+L)×100, with R representing the responses associated with right-handedness, and L representing left-hand responses.

Within cohorts, trial scores were compared using paired, 2-sided *t* tests. The mean difference (95% CI), $t_{(df)}$, *P*, and paired effect size Cohen *d* with Hedges *g* small-sample correction were calculated.

To assess the difference between a progressive and static mode of learning, in-between cohort comparisons were made between cohort B1's trials and each of the respective A cohorts. For example, B1, B2, and B3 were compared with trial 1 of cohort A1, trial 2 of cohort A2, and trial 3 of cohort A3, respectively. This was done to make analogous comparisons based on the number of zones and trial numbers. Differing trials were isolated to account for users' exposure time to the game and control system. Comparisons between cohorts were done using Welch 2-sided *t* tests due to unequal variances. The mean difference (95% CI), Welch $t_{(df)}$ and *P*, and effect sizes (Cohen *d*, Hedges *g*, and average d_{av}), were determined using pooled Cohen *d*, Hedges *g*, and average *d* (d_{av}).

Associations between secondary variables (eg, confidence with video games, exercise, and cue use) and outcomes (trial scores, SUS, NASA-TLX, etc) were assessed using Spearman rank correlation computed within cohorts; ρ and *P* were reported. For ordinal factors with multiple levels, Kruskal-Wallis omnibus tests were conducted, with *H* and *P* reported where relevant. For multiselect variables (eg, videogame experience categories and activities), binary flags were created and compared groups via Welch *t* tests, reporting d_{av}. Odds ratios were not calculated in this study, as they were not appropriate considering the data. Gender comparisons used Mann-Whitney *U* tests with rank-biserial r as effect size, as normality could not be assumed in the smaller subsample of men (n=12).



Results

Performance Scores

Overview

Comparisons were made between cohort B1's trial 1, trial 2, and trial 3, and the Al, A2, and A3 respective cohorts. These respective trials are matched for comparison based on the number of thresholds, as well as the time spent exposed to the game, which was measured through sequential trials. The outcomes demonstrate that user accuracy decreased as the number of zones increased. When playing with 1 threshold, as illustrated in Figure 2, as B1 trial 1 and A1 trial 1, the average score was 15 (SD 0) successful attempts out of 15 possible points per round. Scores from playing with 3 thresholds are displayed in the middle column, labeled B1 trial 2 and A2 trial 2. Scores from playing with 5 thresholds are displayed on the right side of the graph, labeled as B1 trial 3 and A3 trial 3. This trend is displayed in Figure 2.

Figure 2. A comparison was made between the nonprogressive and progressive cohorts to determine performance differences. These performances are scored out of 15 potential successful attempts and visualized to include pairwise comparisons between Cohort B1's Trial 1, Trial 2, and Trial 3, and the Al, A2, and A3 respective trials. Cohort A1 averaged a score of 15, A2 averaged 9.1, and A3 averaged 5.5. The progressive B1 cohort also followed most of these averages with average scores of 15, 7.5, and 5.0, respectively. Error bars correspond to plus/minus one standard deviation. A general trend observed was that performance decreased as the number of zones increased in both cohorts; however, there were no statistically significant differences between the cohorts.

XSL•FO
RenderX

Cohort A1 averaged a score of 15 (SD 0.0), A2 averaged 9.1 (SD 1.1), and A3 averaged 5.5 (SD 1.1). The progressive B1 cohort also followed most of these averages with average scores of 15 (SD 0.1), 7.5 (SD 1.8), and 5.0 (SD 1.5) for each of the 3 trials, respectively. SD was included in parentheses, as seen in Table 1. Table 2 compares the B1 progressive gameplay mode to each of the respective A cohorts, paired by the number of zones. Cohort A1 averaged a score of 15 (SD 0.0), A2 averaged 8.9 (SD 1.5), and A3 averaged 5.5 (SD 1.1); the progressive B1 cohort also followed most of these averages. Overall, no statistically significant differences were found between the B1 cohorts and their corresponding A cohorts, indicating that the groups are comparable.

Table 1. Performance scoring by successful attempts.

Cohort	Trial 1, mean (SD)	Trial 2, mean (SD)	Trial 3, mean (SD)	Average score, mean (SD)
A1	15.0 (0.0)	15.0 (0.0)	15.0 (0.0)	15.0 (0.0)
A2	8.9 (1.5)	8.9 (1.3)	9.6 (1.8)	9.1 (1.1)
A3	5.6 (1.9)	5.3 (0.7)	5.5 (1.5)	5.5 (1.1)
B1	15 (0.1)	7.5 (1.8)	5.0 (1.5)	9.2 .9)

Table 2. Between-cohort comparisons.

Cohort and trial	Mean difference (95% CI)	Welch *t* (*df*)	Hedges *g*	Cohen $d_{(av)}$	*P* value
B1, A1, Trial 1	–0.04 (–0.09 to 0.02)	–1.44 (25.0)	–0.32	–0.40	.16
B1, A2, Trial 2	–1.38 (–2.49 to –0.27)	–2.57 (23.8)	–0.79	–0.88	.02
B1, A3, Trial 3	–0.48 (–1.75 to 0.79)	–0.81 (13.7)	–0.31	–0.32	.43

Performance Scoring by Successful Attempts

Performance was determined by the number of correct randomized cues a participant hits with a peak contraction out of 15 total cues. Performance scores were compared across cohorts and separated by trial, with SDs included (Table 1). Cohort A1 averaged a score of 15 (SD 0.0), A2 averaged 9.1 (SD 1.1), and A3 averaged 5.5 (SD 1.1). The progressive B1 cohort also followed most of these averages, with an overall average of 9.2 (SD 0.9).

Within-cohort paired comparisons across trials did not show statistically significant changes in performance. In cohort A2, trial 1 vs trial 3 differences deviated from normality (Shapiro *P*=.01); therefore, a Wilcoxon signed-rank test was conducted as a sensitivity analysis. Results were consistent with the paired *t* test (t_9=−1.07, *P*=.32; Wilcoxon W=13.5, *P*=.59).

Comparison Between Cohorts

Between-cohort comparisons were also assessed to determine statistical significance in user performance. Cohort A1 averaged a score of 15 (SD 0.0), A2 averaged 8.9 (SD 1.5), and A3 averaged 5.5 (SD 1.1). The progressive B1 cohort also followed most of these averages. There were no statistically significant differences between the B1 and the respective counterparts for A1 (*P*=.16) and A3 (*P*=.43). Cohort A2 performed significantly higher in Trial 2 than Cohort B1 (*P*=.02, ρ=0.8). A negative mean difference favored the A Cohorts. Hedges *g* was also listed in the table (Table 2). The average (SD) standardized mean difference was $d_{(av)}$.

SUS

Cohorts A1, A2, and B1 had the highest perceived usability as measured through the SUS, as seen in Table 3 [33]. The SUS is measured using a 100-point scale, with 100 portraying the best imaginable product, and 0 indicating an unusable product [33]. Cohorts A1 and A2 both had an average SUS score of 75 (cohort A1: mean 75.0, SD 18.9 and cohort A2: mean 75.0, SD 16.8). Cohort A3 had the lowest SUS score with an average of 63.3 (SD 16.2). Cohort B1 had the highest average SUS score with 76.2 (SD 11.7). The overall group SUS score was 73.6. A Welch *t* test showed a significant difference between cohorts A3 and B1 (*P*=.05).

Table 3. Overall System Usability Scale scores by cohort.

Cohort	Overall SUS[a], mean (SD)
A1	75.0 (18.9)
A2	75.0 (16.8)
A3	63.3 (16.2)
B1	76.2 (11.7)
Overall	73.6 (15.1)

[a]SUS: System Usability Scores.

XSL•FO
RenderX

SUS is a measure of perceived usability and was taken as a postassessment survey [33]. Average overall SUS scores and the respective SDs are separated by cohort. Cohorts A1, A2, A3, and B1 had overall average scores of 75.0 (SD 18.9), 75.0 (SD 16.8), 63.3 (SD 16.2), and 76.2 (SD 11.7), respectively. The overall average score between all the cohorts was 73.6 (SD 15.1), which falls in the "Good" category on the corresponding subjective scoring of the SUS [33].

NASA-TLX and Subscales

Inversely, NASA-TLX scores are on a 100-point scale, with 0 indicating the desired lowest cognitive workload, and 100 indicating the highest cognitive workload [34]. The NASA-TLX consists of 6 different subscales that are the main contributors to cognitive workload—mental demands, physical demands, temporal demands, frustrations, effort, and performance [34]. These subscales were selected due to underlying theories of workload that correspond to demands that a user perceives during a task [34]. These subscales are depicted visually per cohort in Figure 3. The performance subscale has an inverse relationship, where higher self-reported performance scores indicate a lower cognitive workload and are considered more favorable [34]. Average NASA-TLX scores were highest among cohort A3 in 5 out of 6 subcategories. From a Kruskal-Wallis test, each subscale had a *P* value. Only the performance subscale passed the significance threshold. These results are presented in Table 4. This follows the expected trend of cognitive workload increasing as the number of zones expands. Differences in perceived effort and perceived frustration were not statistically significant between cohorts. To clarify how these workload patterns varied between specific cohorts, pairwise comparisons of performance and temporal demand subscales are presented in Tables 5 and 6. The largest and most significant differences emerged in the performance subscale, where the single-gesture cohort A1 outperformed all other cohorts with large mean differences. The temporal demand subscale had significant comparisons involving cohort B1, with higher perceived time pressure than cohort A1 and cohort A3. Within the mental demand subscale, cohort A1 tested significantly lower than cohort B1 (P=.01, $d_{(av)}$ =–0.80). In the physical demand subscale, no tests achieved statistical significance, but cohort A2 had a lower score than A3 (P=.15, $d_{(av)}$=0.70).

Figure 3. The National Aeronautics and Space Administration Task Load Index (NASA-TLX) measures perceived cognitive workload [34]. It is divided into 6 subscales, each on a 100 point scale where 0 is the desired low cognitive workload [34]. Performance is on an inverse scale, where 100 would indicate a more desirable performance [34]. This subscale is depicted on the right in its own graph to account for this difference. The trends overall confirmed the hypothesis that demand would increase, while performance would decrease, due to increased zones of control. The progressive training Cohort B1 countered the expectations, having less perceived difficulty than Cohort A3. Note: *:P<.05; **:P<.01; and ***:P<.001.

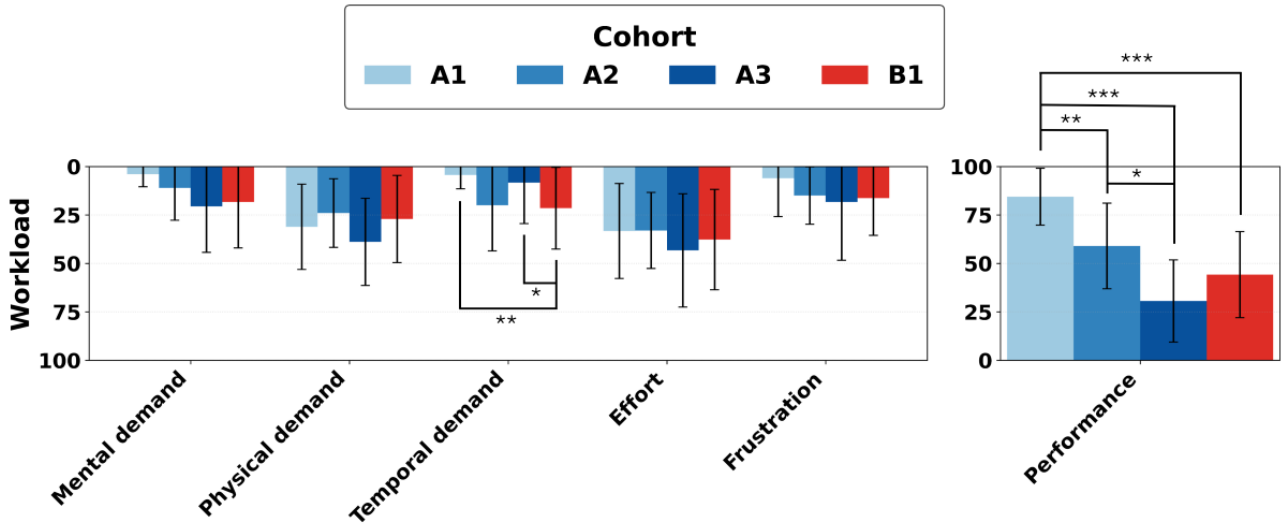


Table 4. Average NASA-Task Load Index subscores (separated by cohorts, with corresponding SDs included for each of the scores).

Cohort[a]	Mental demand	Physical demand	Temporal demand	Performance	Effort perceived	Frustration perceived	Overall
A1, mean (SD)	3.9 (6.6)	31.1 (22.0)	4.4 (7.1)	84.4 (14.7)	33.3 (24.5)	6.1 (19.7)	16.4 (10.9)
A2, mean (SD)	11.0 (16.7)	24.0 (17.7)	20.0 (23.6)	59.0 (22.1)	33.0 (19.6)	15.0 (14.8)	24.5 (14.1)
A3, mean (SD)	20.6 (29.7)	38.9 (22.5)	8.3 (8.9)	30.6 (21.2)	43.3 (29.2)	18.3 (30.1)	33.3 (19.6)
B1, mean (SD)	18.3 (23.7)	27.1 (22.5)	21.5 (21.1)	44.2 (21.2)	37.7 (25.9)	16.3 (19.2)	29.7 (14.5)
P value	.49	.38	.09	<.001	.86	.29	.12

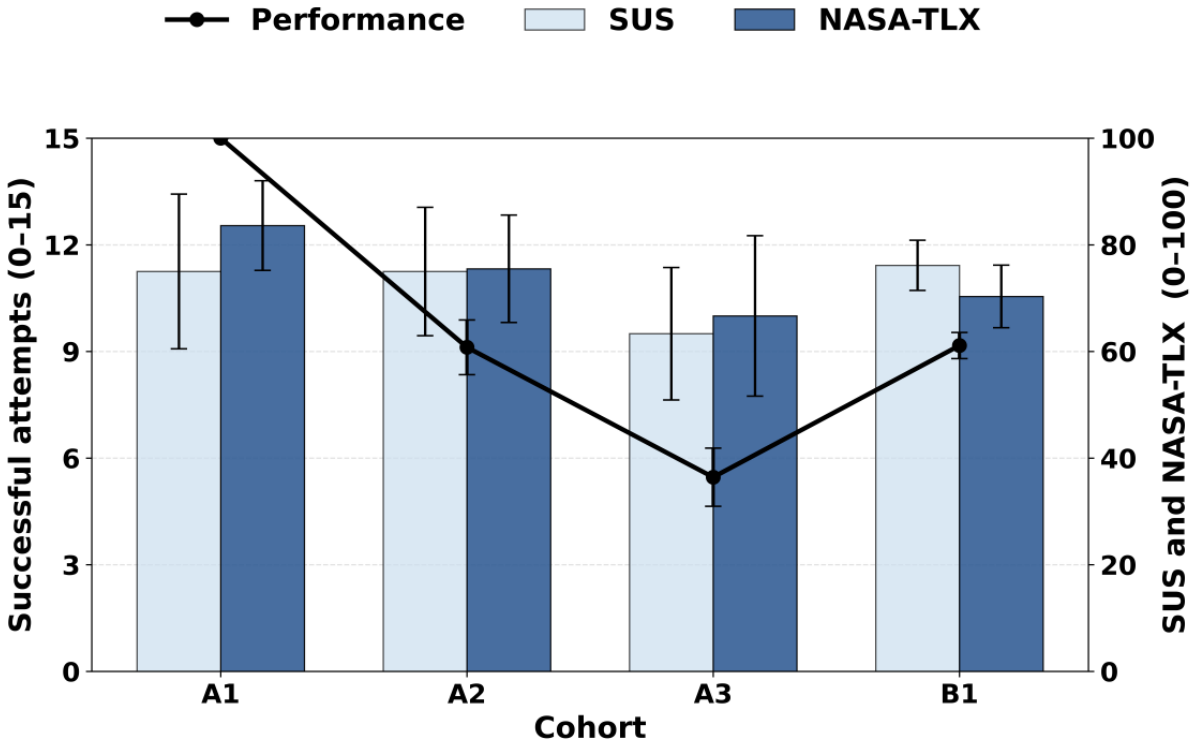
[a]Scores for each subsection are on a 100-point scale, with 0 indicating a desired low cognitive workload [34]. The performance subscale is the only exception to this, where 100 would indicate a more desirable score [34]. The NASA-Task Load Index measures perceived cognitive workload through a postassessment survey [34]. A general trend of cognitive workload increasing with a higher number of zones was observed.

XSL•FO
RenderX

Table 5. Pairwise comparisons for the NASA-TLX performance subscale. This subscale is scored inversely, with higher values indicating better perceived performance and lower cognitive workload [34]. This subscale had the largest and most consistent differences between cohorts. Cohort A1 rated its performance significantly higher than Cohorts A2, A3, and B1 with large standardized mean differences. Rows are organized with the most significant results at the top.

Comparison	Cohen $d_{(av)}$	Cohen $d_{(av)}$ (SE)	*P* value
A1, A3	2.91	0.70	<.001
A1, B1	2.20	0.47	<.001
A1, A2	1.36	0.52	.009
A2, A3	1.23	0.51	.01
A2, B1	0.68	0.38	.09
A3, B1	–0.64	0.39	.12

Table 6. Pairwise comparisons for the NASA-TLX temporal demand subscale [34]. Temporal demand showed fewer significant results than the performance subscale, but still reflected meaningful differences between cohorts. Cohort B1 reported significantly higher temporal demand than cohort A1 and cohort A3. Other pairwise contrasts within this subscale did not reach significance, although cohort A1 and cohort A2 showed a medium effect size trend. Rows are organized with the most significant results at the top.



Comparison	Cohen $d_{(av)}$	Cohen $d_{(av)}$ (SE)	*P* value
A1, B1	–1.06	0.41	.001
A3, B1	–0.79	0.40	.02
A1, A2	–0.89	0.48	.07
A2, A3	0.65	0.47	.17
A1, A3	–0.48	0.48	.32
A2, B1	–0.05	0.37	.89

Performance and Composite SUS and NASA-TLX Scores Compared Between Cohorts

Successful attempts at scoring, SUS scores, and NASA-TLX scores are compared across cohorts in Figure 4. This allows for the visualization of trends and tradeoffs between the number of zones and accuracy, usability, and cognitive workload.

XSL•FO
RenderX

Figure 4. NASA-TLX (National Aeronautics and Space Administration Task Load Index) and SUS (System Usability Scale) composite scores are displayed in a combined bar chart, and successful attempts are overlaid as a line graph for Cohorts A1, A2, A3, and B1 [33-34]. This allows for the visualization of trends and tradeoffs between number of zones and cognitive load, usability, and accuracy. The number of successful attempts decreased as the number of zones increased from Cohort A1 to A3. No meaningful conclusions could be drawn from composite NASA-TLX scores between cohorts. The SUS composite scores did not differ significantly between Cohorts A1, A2, and A3, but a significant difference was found between Cohorts A3 and B1. NASA-TLX composite scores are inverted so that a higher score is favorable for the sake of graph continuity and tradeoff visualization.

Dominant Hand Grip Strength

Grip strength was measured in kilograms using a dynamometer after the completion of the postassessment surveys. The average grip strength in kilograms is segmented by gender. The frequency of each reported gender and the SDs are included in Table 7.

Table 7. Dominant hand grip strength by self-reported gender.

Gender	Frequency, n	Grip strength (kg), mean (SD)
Men	12	44.0 (11.2)
Women	40	27.3 (4.6)
Other	2	21.3 (0.6)

Secondary Assessments

Secondary measurements included the EHI and participants' confidence with video games, exercise, and following visual cues. Participants were also asked to share activities they completed within the last 7 days that required the use of fine or gross motor skills. Based on EHI calculations, all participants tested into pure right-handedness, with a laterality total of >40. Across correlation tests per cohort, most associations were small and nonsignificant (median |ρ|=0.12, IQR 0.05-0.34). Only 2 showed significance after inspection, that is, exercise frequency vs grip strength (ρ=0.53-0.75, *P*=.03-.002) and cue-use confidence vs workload (ρ=0.45, *P*=.01).

Preassessment surveying also included demographics, video game experience, exercise, crafts, instruments, and other fine-motor tasks. Handedness inventory, self-reported dominant hand, and grip strength were assessed. There was no correlation between gender and performance (ρ=–0.11, *P*=.43), despite large grip strength differences between male and female participants (ρ=–0.57, *P*<.001).

Discussion

Principal Findings

This study aimed to evaluate potential trade-offs associated with increasing gesture capability in an electromyographic prosthetic arm actuated by a single sensor. Increased training time, increased perception of cognitive workload, decreased accuracy, and decreased usability may all be factors discouraging the implementation of multiple gestures. This study explored 1, 3, and 5 distinct gestures triggered by magnitude control and their training feasibility in a single-session rapid learning environment. In addition, differences between static and progressive learning modes were also evaluated. The progressive

XSL•FO
RenderX

training mode (cohort B1) demonstrated the feasibility of reducing demand on the user.

Extrapolating from past work and the results of this study, a long-term training regime using a gamified interface that closely corresponds to the prosthetic device's interface may allow users to improve multigesture use. Developing control of electromyographic inputs in a low-stress, low-consequence manner is critical to unlocking the prosthesis's advanced functionality without patient rejection. Devices with more features and more advanced controls may result in frustration for patients and lead to rejection. Providing a "challenge mode" to test controls that can unlock additional device functionality may be a solution to this issue. The results of this work indicate that a 3-tiered gesture control scheme is capable with a limited training timeline. However, it is important to note that able-bodied users may experience different fatigue patterns or motivation levels compared with individuals with limb differences. In the prosthesis clinical trial protocol, the training games are delivered before the prosthetic arm in an effort to train basic muscle control and discretization. Once the prosthesis is delivered, it has a single threshold control for open and close functionality. Gamified training continues until a 3-threshold differentiation is easily achievable by the user, and only then is multigesture support unlocked in the prosthetic device. The goal is to have the majority of failures occur in the training games and increase initial success with the prosthetic device. The outcomes of this work show that a tiered approach is appropriate for training 3 thresholds. Future work will help determine if long-term training can support a 5-threshold model.

Cohort Performance Scoring

To determine if including multiple gestures is feasible, it is necessary to consider performance, usability, and cognitive workload. The 3-gesture mode demonstrated similar usability scores as the single-gesture cohort, with better cognitive workload and performance scores than the 5-gesture mode. This suggests that incorporating 3 gestures may strike a functional balance between difficulty and usability for first-time interactions with the system. Additionally, a progressive mode of learning demonstrated the highest perceived usability, despite incorporating up to 5 gestures, which had the lowest scores and the highest cognitive workload in the static mode of learning. Capping initial progressive training at 3 gestures has the potential to increase perceived usability further while retaining the higher accuracy and lower cognitive workload of cohort A2.

Previous studies have shown that increased time on task is associated with higher user performance outcomes with the electromyographic controls [23,36]. Additionally, close correspondence of a training period with posttest tasks resulted in greater performance scores, demonstrating the importance of task-specific training.

SUS

The overall SUS scoring of 73.6 falls into the "ok" designation, demonstrating that this system was likely deemed usable by the participants [33]. Individual cohort scoring indicated that cohort A3 had the lowest perceived usability. Since this cohort had also reported the greatest perceived mental workload and the lowest performance among participants, this was expected to have the lowest usability scoring. Cohort B1 has the highest perceived usability, which is supported by lower NASA-TLX scores and similar performance scores to the nonprogressive cohorts [34]. The 12.9-point SUS difference between cohort A3 and cohort B1 is both statistically significant (P=.05) and meaningful with a Cohen d of −0.91. This indicates a substantial difference between cohort averages relative to within-group variability. Clinically, a significant difference with a large effect size implies that users in a progressive learning environment experience are likely related to higher levels of usability than users in a static 5-zone learning environment.

NASA-TLX

The NASA-TLX, measuring perceived cognitive workload, demonstrated that cognitive workload increased as the number of gestures increased [34]. Similar to the trend in scoring, difficulty tended to increase with the inclusion of more gestures, so it was expected that cognitive workload would follow the same pattern. NASA-TLX scores were aligned with scoring deficits instead of perceived usability as measured through SUS [33,34]. Cohort A3 demonstrated the highest cognitive workload in 5 of the 6 NASA-TLX subcategories [34].

Limitations

One limitation of this study was the unintentional inclusion of exclusively right-handed participants. Although a small proportion of participants self-reported as left-handed (n=6), the EHI score indicated right-hand bias [35]. This may not be representative of true population proportions, however, and instead may be due to the relatively small sample size of this study.

Similarly, 40 of the 54 participants in the study were female. This can be explained by smaller sample sizes and convenient population sampling of college students. Throughout the data collection process, minor collection discrepancies were accounted for. One participant withdrew from the study due to a personal situation during data collection. The participant revoked their consent to participate, and the research session was terminated immediately. Their data were removed from the dataset. During another session, one user ID was claimed by 2 distinct participants during the data collection process. Since both participants completed the study independently of each other, the datasets were differentiated with an (a) and (b) at the end of their identifier, and both datasets were used in the final analysis.

The aim of this study was to explore trends in novice users as they were exposed to different controls. This study used a proxy population of college-aged students who had full control of their upper extremities, which is not fully representative of our target population of prosthesis users. Although these findings cannot be completely generalized to prosthesis users, the intention of this initial testing is to ensure positive outcomes among users before implementation in limb-different population groups. Additionally, the target population is primarily pediatric patients, which is seen as a vulnerable population group for testing purposes. In order to limit confounding variables, such as

XSL•FO
RenderX

different levels of limb difference and the effect of differing anatomical muscle structure, a proxy, an able-bodied population, was then used. Past work in prosthesis development has shown a significant difference in muscular activation between amputees and nonamputees [32]. As such, the use of a proxy population then allows for standardization that may prove more difficult in the intended population, as well as identification of potential errors, streamlining eventual delivery. Serious games have also been tested in a proxy population of college-aged students and have been further implemented with patients with a limb difference [23,36]. The observed performance measures, including accuracy scoring, SUS, and NASA-TLX, have been used independently among studies that include different limb users [33,34]. Additionally, future work may strengthen findings through the use of a pre-post comparison. Past work in the facility has evaluated the efficacy of motor learning through serious games and evaluated participant scoring before and after intervention [23]. Future work may evaluate long-term changes in scoring using the training app. This study demonstrated the efficacy of the MDAT within a proxy population, with the intention that future work will include testing in the intended clinical population of upper limb prosthesis users.

The unequal and relatively small sample sizes in cohorts A1, A2, and A3 limit statistical power, particularly for between-cohort comparisons with the progressive cohort B1. Although effect sizes were calculated and in several cases were small to moderate, the absence of statistically significant differences between cohorts may reflect limited power rather than true equivalence. Therefore, findings comparing progressive and static modes should be interpreted cautiously and considered hypothesis-generating. Further testing with the application will be ongoing with the current proxy population and a representative limb-different population.

Another limitation of this study is the single-gesture scoring metric for cohort A1. Cohort A1 had a mean score of 15.0 (SD 0.0). This is because all contractions that are above threshold are considered a success, as there is only 1 zone. This creates a ceiling effect that may have affected variance and statistical analysis. This also highlights the functionality of single-gesture mode testing for novice users. There is a possibility of a fatigue effect due to 3 repetitive trials, which the researchers aimed to minimize by implementing mandatory 1-minute rest periods per round and offering continued rest if the participant wanted more recovery time.

Conclusions

The most clinically relevant and statistically significant results were found from the SUS scoring [33]. Specifically, the significant increase in perceived usability for the progressive cohort seen in this study may influence user adherence to training, addressing one of the primary concerns surrounding prosthetic device rejection. There were no statistically significant differences between cohorts in scoring for progressive mode and static mode, and there were only 2 statistically significant subscales of the NASA-TLX [34]. Both the SUS scores and the NASA-TLX scores displayed a trend that difficulty increases with the inclusion of more gestures as anticipated [33,34]. This is supported by the results from cohort A3, which had the lowest accuracy scoring and the highest cognitive workload.

Especially among young prosthesis users, maintaining adherence to a training regime is particularly difficult [20]. The usability of training systems is necessary to encourage motivation in pediatric training regimes [37]. Overall, these results suggest that implementing up to 3 gestures with a progressive training mode may have the potential to balance the increasing complexities required for additional gestures. This work aims to increase the functionality while not introducing an undue burden. Since reducing the complexity of a training regimen may discourage device rejection, this is an essential consideration. This may enable expanding device capabilities while maintaining accuracy, perceived usability, and a lower cognitive workload.

This control schema will be implemented in a gamified training format to teach users the musculature engagement and control required to operate an upper limb prosthesis with multiple gesture states. This progression will be introduced to the intended population through long-term clinical trials of individuals with a limb difference who are training to use a prosthetic device.

Implementing these training controls into a gamified regimen may increase time on task [23]. Prolonging the time engaged in a training measure can increase its effectiveness; this engagement may decrease the time needed to learn controls, as reinforcement learning can begin with the first introduction to controls. Reinforcement learning in gamified training may significantly improve performance scores [38-41]. Applying this principle to future training applications has the potential to encourage pediatric compliance with a training program, as time on task and reinforcement learning lead to improved performance and engagement.

Future work aims to evaluate these controls in a longer-term research trial incorporating a 2-gesture step toward training up to 3 gestures progressively. This can be implemented into the pre-existing gamified training protocol used in current pediatric clinical trials. Increasing the in-game difficulty may prepare users for the increased difficulty associated with additional gestures on the prosthetic device. One eventual aim of future work is to discern what form of gamified training would be most effective to establish device use on the first day of delivery.

Abstract

Background: Rehabilitation health care providers (HCPs) report high levels of burnout. Self-compassion interventions have shown beneficial effects on HCP burnout, but they have never been explored in specialist rehabilitation settings where challenges may differ.

Objective: This study aimed to explore the experiences of specialist rehabilitation HCPs with an online Self-Compassion for Healthcare Communities (SCHC) course aimed at providing tools to regulate emotional well-being, including burnout.

Methods: Semistructured qualitative interviews (n=20) with specialist rehabilitation HCPs were used to explore experiences with the SCHC course. A reflexive thematic analysis study design was chosen to highlight participants' insights, and inductive coding was undertaken to analyze data and organize findings into themes.

Results: Six themes that reflected HCPs' experiences with the course were constructed: (1) the nature of working in rehabilitation; (2) different perspectives on burnout in specialist rehabilitation; (3) a new perspective, less self-criticism, more self-compassion; (4) growing recognition of the importance of compassion for oneself and others; (5) challenges engaging with the SCHC course; and (6) challenges to sustaining self-compassion in specialist rehabilitation.

Conclusions: Specialist rehabilitation HCPs who participated in the SCHC course developed a new understanding of the importance of fostering self-compassion and compassion for others. This shift may have supported HCPs in navigating workplace challenges, and HCPs described experiencing changes that could help with burnout, improve their care of patients and relationships with colleagues.

Introduction

The ability to reach person-centered rehabilitation treatment goals relies on effective longitudinal communication and relational collaboration among patients, families, and health care providers (HCPs), and in this context HCP compassion is particularly important [1-3]. Compassion from HCPs enhances patient satisfaction, treatment adherence, and goal achievement [1]. Compassion describes sharing another's feelings coupled with a desire to relieve distress by taking action [2]. Compassion is often overlooked as a component of care in acute settings, but may be more prominent in rehabilitation settings due to the focus on each individual's recovery of independent function [2]. Indeed, a review of therapeutic interventions revealed that compassionate care is valued by people undergoing rehabilitation and their healing is promoted by a comforting environment [4].

Ensuring that compassion features routinely in specialist rehabilitation is challenged by HCP compassion fatigue [1], burnout [5], and secondary traumatic stress (STS) [6-11]. HCPs working in rehabilitation often endure an emotional burden throughout prolonged patient stays, especially as they manage patient and family expectations [12,13]. Compassion fatigue, a state where HCPs experience the reduced ability or motivation to care for their patients due to the sustained stressors of their duties [14,15], negatively impacts HCP quality of life and well-being [16]. Burnout is a linked construct characterized by emotional exhaustion, objectification of patients, and a reduction of effectiveness at work [17]. STS refers to a scenario where HCPs may develop symptoms typical of posttraumatic stress disorder, which mirror those of their patients, and arises when HCPs work with people who have endured traumatic events [6]. These constructs are highly correlated [18], but most research has focused on the effects of burnout, with well-developed literature on drivers and consequences [19,20]. Unfortunately, the COVID-19 pandemic and rise of digital health care in Canada have increased HCPs' risk of experiencing compassion fatigue, burnout, and STS [21,22].

To mitigate negative effects on HCPs, interventions focused on stress reduction and increasing resilience have shown effectiveness for reducing burnout and STS [23]. Mindfulness-based interventions (MBIs), which aim to systematically teach participants to "pay attention, in a particular way, on purpose and nonjudgmentally" have been widely used and shown to improve stress levels and reduce anxiety and depression among HCPs. While MBIs are helpful in mitigating the effects of burnout in-person [24] and online [25], experiences have not been assessed in rehabilitation settings. MBIs may not be feasible for busy HCPs as they are usually conducted over 8 weeks. Evidence suggests that MBIs may be the most beneficial (eg, accounting for reductions in stress) and the best attended in-person or synchronously online [3,26,27] and that brief, informal sessions (eg, less than 4 hours) improve accessibility [28]. Although the optimal MBI delivery method for HCPs is unknown, the combination of compassion cultivation training and mindfulness techniques may help mitigate the effects of burnout, compassion fatigue, and STS [29,30].

Like MBIs, compassion-based interventions effectively reduce anxiety, depression, and psychological distress, but they differ by placing greater emphasis on fostering supportive relationships and common humanity [31]. Similarly, self-compassion interventions also reduce anxiety and depression [32], and were found to do so to a greater extent than MBIs in a 2018 review [33]. In fact, an analysis of a large cross-sectional survey of nurses revealed that self-compassion was protective against burnout-related reductions in compassion [34]. Compassion-based interventions may be better than MBIs at improving HCP well-being and compassion [32], but they are complex interventions and the optimal delivery method is also unknown.

It is crucial to consider the digital landscape in which Western health care is situated with the rise of telemedicine and frequent use of digital technology since COVID-19 [35]. A mix of "asynchronous" (prerecorded online) [36] and "synchronous" (live online) components may best fit the needs of busy HCPs whose personal and professional duties require increasing levels of engagement with online platforms. An intervention which can be accessed "whenever and wherever" is likely to increase accessibility and thus improve engagement [25]. Indeed, the rise of digital health care may facilitate the success of MBIs delivered online rather than in-person [37]. A 2024 narrative review of randomized controlled trials assessing the efficacy of digital mental health interventions for HCPs revealed positive effects for targeting burnout, and acceptability was reported [38]. Factors such as flexibility, ease of use, the availability of support and feedback, and the likelihood of achieving positive outcomes were identified as facilitators of intervention effectiveness [38]. Furthermore, a 2024 scoping review on the assessment of audio-guided online MBIs suggested the need for future research to assess the diverse methods of online delivery (eg, videos and podcasts) [25].

Therefore, the purpose of this study is to explore the experiences of specialist rehabilitation HCPs with an online Self-Compassion for Healthcare Communities (SCHC) course [32].

Methods

Study Design

Overview

This study presents the qualitative process evaluation of a linked feasibility trial testing the SCHC course in specialist rehabilitation providers. No quantitative trial data are presented in this manuscript. Specialist rehabilitation providers are defined in this context as regulated health professionals working in "specially trained interprofessional teams with a focused skill set," [39]. The SCHC course on which participants were interviewed was delivered over Zoom (Zoom Video Communications, Inc), with weekly 60-minute sessions on Fridays between 12 PM and 1 PM, by a certified SCHC instructor (a specialist neuro-occupational therapist) and assistant (trainee clinical psychologist), with participants attending whole group sessions and regular smaller group break-out sessions. Participants were assigned home practice activities that varied weekly. An overview of intervention

XSL•FO
RenderX

content and week-by-week session guide is available in Multimedia Appendix 1.

Individual postcourse interviews were conducted by the study coordinator on Zoom. The Zoom platform was chosen due to widespread use across the institutional settings involved in recruitment, and to stay consistent with the course delivery. In addition, research participants generally view online interviewing methods for qualitative studies favorably, even over in-person interviews [40,41]. In-depth semistructured interviews were conducted following the final SCHC session. The interview topic guide (see Multimedia Appendix 2) explored participants' experiences with the SCHC course, its perceived effects, usage, barriers and facilitators to participation, and suggestions for improving future iterations.

Theoretical Framework

A qualitative interpretive methodology with a reflexive thematic analysis design and an inductive approach to theme generation was used without relying on preexisting theories or frameworks [42,43] to explore participants' experiences with the SCHC course. This methodology was selected to learn from qualitative data directly and to highlight participants' experiences. An inductive, rather than a theoretical analysis, relies on researchers' interpretations of the raw data, which may stray from the specific questions posed to participants [44].

As a reflexive thematic analysis, the aim was to achieve "information power" with an emphasis on data quality rather than data saturation, which prioritizes data quantity [45,46]. Whereas data saturation occurs when no new themes arise from coding new information gathered from the sample, information power refers to "the richness and relevance of data collected from a sample" [47]. Aiming to achieve a level of meaning in the data (ie, information power), and not solely redundance, is consistent with the method of a reflexive thematic analysis [45,46].

The COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist was followed to ensure ethical data collection and rigorous reporting methods (see Checklist 1) [48].

Participant Selection

Eligibility criteria for the feasibility trial in which this study's data were drawn from were being an HCP, 18 years of age or older, working substantially (ie, not agency staff) in a specialist rehabilitation setting (in-patient and out-patient) across existing specialist rehabilitation sites in a large metropolitan area (ie, the Greater Toronto Area), having the ability to communicate in spoken and written English, and not having undertaken a mindful-self-compassion course or other MBI in the past 12 months. All participants in the SCHC course (n=26) were eligible to interview. Participants were informed they would be invited for an interview following the course, but that participation would be voluntary. Following the course, all enrolled participants received up to 3 successive email invitations to schedule an interview with the study coordinator.

Data Collection and Setting

Demographic data (eg, age, gender, and professional role), available in Multimedia Appendix 3, were collected prior to course commencement via an online survey. Interviews were held and recorded on Zoom by the study coordinator (EC), who was present throughout the course only to manage administrative work and technology issues. On average, interviews lasted 50 minutes. Virtual interviews were hosted from the study coordinators' place of work. Participants joined their one-on-one interview from their workplaces or their homes. The interview audio files were transcribed verbatim by a secure third-party service and not returned to participants for review.

Research Team and Reflexivity

Personal Characteristics and Relationship With Participants

The research team situates themselves within a pragmatic paradigm, centering their beliefs and motives on the real-world significance and usefulness of research findings (ie, what is practical and achievable). In this case, this applies to the SCHC course as a tool for helping specialist rehabilitation providers address the well-documented challenges of busy and stressful frontline clinical care [49].

The lead author (EC) is a younger Canadian woman and an early career researcher. Her undergraduate and postundergraduate experience with qualitative research made her well-suited for involvement in this project while bringing a fresh lens to the analysis as a student who studied psychology in undergrad and studied aging and health in graduate school. Without firsthand experience as an HCP, previous knowledge of the SCHC course, and prior relationships with participants, she was well-placed to immerse herself in the data while maintaining a broader perspective of HCP experiences with burnout. The lead author (EC) conducted the interviews to limit influence on participants as she is not an HCP herself. The lead author (EC) was known to the participants as the study coordinator, but she did not provide any of her own personal insights throughout the course or during the interviews.

The senior author is a middle-aged Scots Canadian man who works as a physiatrist with a research background in developing and evaluating complex interventions, including those based in mindfulness and compassion. His holistic understanding of working in chronically stressful health care environments and his firsthand experience with burnout among fellow HCPs in diverse settings provided crucial insider perspectives, shaping how burnout was conceptualized and interpreted. To minimize potential influence, the senior author did not attend the sessions or conduct the interviews.

The third researcher (KMK) involved with data analysis (female) is a research associate experienced in qualitative research and thematic analysis. Her background in developing and evaluating complex interventions, including those mindfulness-based, provided a valuable lens to data interpretation. Additional authors are researchers and clinicians in rehabilitation science providing guidance and expertise in the design, conduction, and review of this project.

XSL•FO
RenderX

Reflexivity

The research team included a diverse range of perspectives and backgrounds, and this richness of experience and diversity was leveraged during the interpretive process with reflexivity practiced throughout. For example, the lead author (EC) kept a reflective set of notes of her thoughts and experiences of sitting-in on the SCHC course, during the semistructured interviews (which she conducted), when working through the development of a theme journal (ie, a flexible and evolving analytic tool used to keep track of theme development), and shared these reflections with the team during regular collaborative meetings where a rich discussion and a deeper exploration of the meaning of data was strongly encouraged. Meeting notes were made and continually updated as data were qualitatively coded and themes were developed. The primary investigator of this study is a physician and how this perspective, and associated power dynamics, might influence views were transparently acknowledged and discussed throughout the entire reflexive thematic analysis process. For example, team members (KMK, DL) with clinical expertise noted their inclination to prioritize certain health-related aspects of what participants described, while others from research-focused roles highlighted broader social and cultural contexts within the story being developed.

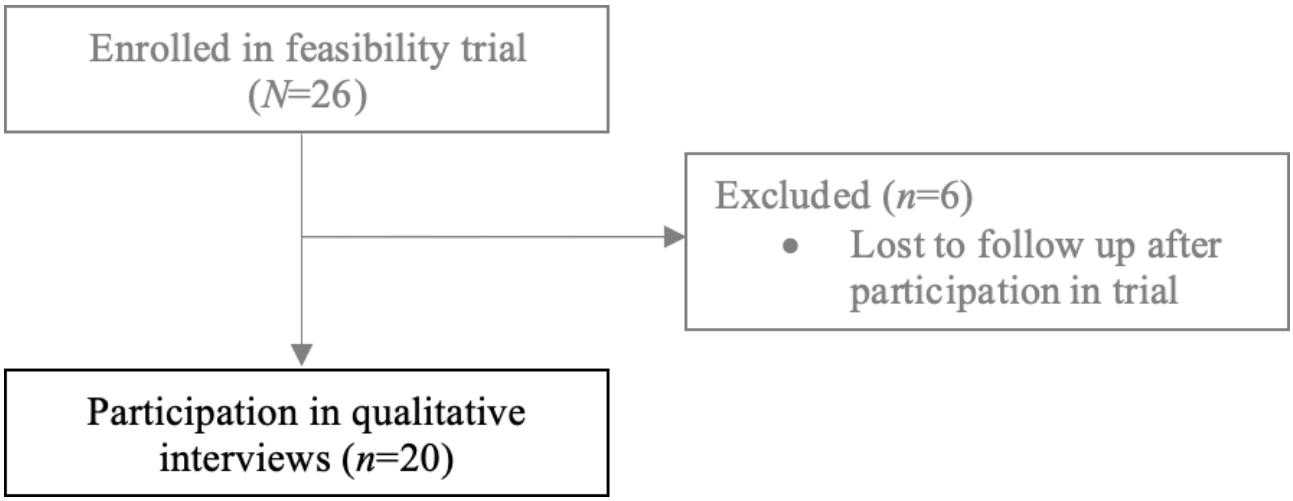
Data Analysis

Data were analyzed using a reflexive thematic analysis design with an inductive approach [44,50]. The steps followed were:

1. Familiarization: a total of 3 researchers (EC, KMK, and RobertSimpson) situated themselves with the deidentified interview data by reading transcripts several times and noting patterns or interesting points. The involvement of multiple researchers enhanced analytic depth and fostered reflexive dialogue, which was apparent throughout the entire thematic analysis process.
2. Initial code generation: initial codes were synthesized from each interview transcript in NVivo (version 12; QSR International Pty Ltd). Through an iterative coding process, 2 researchers labeled meaningful chunks of data with phrases that aligned with the research objective (eg, “course format was accessible”). A team meeting was held to facilitate collaborative discussion of initial codes, groupings, and patterns within the data. This discussion led to the re-organization of some groupings to maintain relevance to the research objective while assumptions were questioned. Initial code generation continued until all transcripts were fully labeled and organized, which itself was an iterative and recursive process.
3. Initial theme generation: subsequent team meetings facilitated theme development through discussion, during which initial themes (eg, “patterns of shared meaning” [51]) were constructed by grouping initial code labels together based on similarity and naming these groupings in NVivo. Preliminary theme definitions were also synthesized. Initial theme names and definitions were noted in a shared theme journal document to keep track of meeting progress. At this stage, mind maps were also created and continuously revised during and between meetings on an online design platform to assist with visualizing the meaning of initial groupings and the connections between them, while being able to zoom out and grasp a holistic view of the data.
4. Reviewing and developing themes: several weekly meetings were held to continue developing themes through collaborative discussion of the patterns within the data, ensuring that meaningful insights were representative of the groupings. Continuous reflexive engagement supported the development of cohesive storylines for each theme.
5. Refining, redefining, and naming themes: the research team iteratively refined the theme journal during regular conversational meetings by revisiting themes to ensure relevance to the objective. This process involved ongoing iterative refinement of themes and definitions by continuing reflexive engagement with the data. Researchers continued to question their initial assumptions and interpretations of the data and always attempted to view the data from several stances. Theme names were finalized based on theme definitions. Updated mind maps helped researchers visualize the story told by the data.
6. Producing the report: the analysis was written up to present a coherent story of the data, with continued reflexive engagement guiding development. Direct quotes from participant interviews were extracted, supplemented with researchers’ careful interpretations of each theme and how they connect to one another. Findings were situated among current knowledge in the field.

Ethical Considerations

Ethical approval was obtained from Sunnybrook Health Science Centre Research Ethics Board (SUN-5492). All study participants provided prospective written informed consent.



Results

Overview

Rehabilitation providers (n=20; see Multimedia Appendix 3 for participant demographics) who engaged in the SCHC course shared their experiences working in rehabilitation as well as their experiences with the course, thus resulting in 6 interconnected themes that portray HCPs’ intricate experiences. Only a subset of participants was interviewed, and we do not have information on the reasons why some individuals chose not to participate despite efforts to follow up after participation in the course (see Figure 1). This may have introduced self-selection bias, as those with more positive experiences may have been more likely to take part in interviews. The mean (SD) age of participants was 43.5 (10.5), the majority identified as women, almost one-third identified as White North American, and 96% worked in urban environments whereas one participant worked in both urban and rural areas. For an average of 13.6 years, HCPs worked primarily as occupational therapists and social workers, but there was indeed a vast spread of professions within specialist rehabilitation represented.

RenderX

Figure 1. Participant flow diagram. Gray represents the linked feasibility trial in which this qualitative study draws data from. Detailed trial feasibility metrics are reported separately (under review).

Participants spoke of (1) the nature of working in specialist rehabilitation, an interplay between longitudinal relationships and focus on adaptation, which heavily impacted (2) different perspectives on burnout in specialist rehabilitation and experiences with the course. Throughout the course, (3) a new perspective, less self-criticism, more self-compassion, was gained by many participants as they learned how to alter their self-deprecating attitudes. Once self-compassion was fostered using various techniques learned throughout course sessions, (4) growing recognition of the importance of compassion for oneself and others arose as participants learned how to extend their newfound sense of self-compassion to their patients, family members, and colleagues. Unfortunately, (5) challenges engaging with the SCHC course were inevitable as HCPs endured busy schedules and individuals varied in their comfortability being vulnerable in an online, group setting alongside their peers. Although it was reported by participants that the course helped cultivate self-compassion and enhanced their compassion for others, several factors limited the ability of HCPs to extend this compassion to their patients. These factors are described in the last theme: (6) challenges to sustaining self-compassion in specialist rehabilitation. Supplemental quotes categorized by theme are provided in Multimedia Appendix 4.

Theme 1: The Nature of Working in Rehabilitation

The first theme, the nature of working in rehabilitation, provides context into the aspects of working in rehabilitation that can render HCPs at risk of compassion fatigue, burnout, and STS and how these factors mirror and differ from those faced by HCPs that work in other settings. Reflecting on their experiences prior to taking the course, HCPs described how they are challenged with distinct stressors due to the nature of the specialty. Rather than curing, HCPs in this field are tasked with helping their patients adapt to new circumstances, often following life-changing illness or injury. Often, patients in rehabilitation are perceived by HCPs as initially resistant to adaptation as their expectations had not been addressed in acute care. Due to the nature of rehabilitation, HCPs build long-term relationships that can last from weeks to decades. HCPs may also connect with their patients on an emotional level, which can have positive and negative implications for well-being. Some HCPs endure long-term maltreatment from patients, and others are affected by the implications of difficult cases outside of working hours.

> *I only recognized in the last couple years … a lot of abuse and dumping … negative energy put onto you. People … or my other colleagues don't realize after four to six weeks of someone being so negative, there is an impact on you.* [Woman, aged 45 years]

> *I would be left thinking about the traumas that they had experienced…And worrying if they'd be alive tomorrow…It was harder to disconnect…I wouldn't be working, but the thoughts would still be there, or I'd have nightmares.* [Woman, aged 30 years]

Like other HCPs, rehabilitation providers experience occupational stress from a lack of agency, large caseloads, staff shortages, time constraints, and excessive administrative work. Rehabilitation HCPs described how they often experienced moral distress when discharging patients to what were perceived to be unfit home environments, simply to meet organizational pressures around bed occupancy. Stress was accentuated for specialist rehabilitation HCPs when required to perform their duties, and sometimes colleagues' duties, within an overwhelmed system.

> *Some days are stressful because I'm asked to see four patients at a time. And there's no helping around. Or…there's three patients in the gym that I have to leave unattended… the nonsense that goes on around here is frustrating beyond.* [Woman, aged 34 years]

These stressors, some of which may be unique to rehabilitation, some which are common throughout health care, made the SCHC course relevant for participants as they sought out strategies to manage burnout and build resilience.

Theme 2: Different Perspectives on Burnout in Specialist Rehabilitation

Participants from different backgrounds and professional roles described the concept of burnout in various ways, whether they had learned about the concept from the course or elsewhere.

XSL•FO
RenderX

Participants described experiences with burnout affecting numerous aspects of their lives, especially in relation to their work in rehabilitation.

Participant feedback suggested the SCHC course might help improve participants' abilities to recognize and describe burnout and compassion fatigue, phenomena that were described as common. Indeed, burnout was described by participants as poorly functioning or performing at work. Accordingly, burnout was described as affecting more than one dimension of a person's life, including emotionally and physically, which was seen to impact participants' personal lives in an "…exponential downward spiral…" (Man, age 35 years).

> *Burnout is being both emotionally, physically…spiritually, like just out of steam, and not able to get through the day without interventions. So, like there was a time when I was burned out and I needed to take naps during the day. I just was emotionally exhausted and in the afternoon I would take two hours out of work, and then I would work later, because I needed that energy to keep going.* [Woman, aged 50 years]

Participants discussed burnout and compassion fatigue as distinct but related concepts. Specifically, participants described compassion fatigue as a concept constituting a precursor to burnout, which encompasses emotional exhaustion and limits the quality of compassionate care provided to patients.

> *It starts to weigh you down, especially when you hear some of the stories. Because the patients, they open up to you … they share so much of their life experience. And you listen with compassion. But it does wear you down after a while.* [Woman, aged 34 years]

Through attending the course, participants explained gaining a clearer vocabulary to describe burnout and compassion fatigue, enhancing their self-awareness and recognition of these phenomena in their daily practice.

Theme 3: A New Perspective, Less Self-Criticism, More Self-Compassion

The third theme speaks to gaining a new perspective when it came to teaching participants how to cultivate more self-compassion and less self-criticism. Participants recognized the importance of incorporating this new perspective to shape their attitudes about themselves and others in a positive way.

Following the completion of the course, most participants shared that the concept of self-compassion had been new to them. Most described being conscious of compassion for their patients, including the circumstances which would activate this way of being, but acknowledged not recognizing ever being compassionate to themselves. A common description across interviews was that self-compassion is more difficult to inculcate than compassion for others,

> *It's easy just to blame yourself. Self-compassion I find is harder. I find it much easier to be kinder to others than to myself.* [Woman, aged 49 years]

Frequently, providers described putting patient needs and work tasks before their own. Participants often recognized a tendency to self-criticize and be hard on themselves.

> *But I do think I've had difficulties with self-compassion because I grew up in a very domineering system. You're either wrong or you're wrong. You're never right. And with that, I've internalized a lot of that.* [Man, aged 35 years]

Despite this, participants described curiosity about the concept of self-compassion, seeming to recognize a clear need for self-care and lacking a resource to do so.

> *I didn't know what to expect, because I think when I hear the word self-compassion, my mind can immediately go to, oh, get a massage, pamper myself…So, I was definitely curious as to what would come out of this. I was pleasantly surprised. I just went in with an open mind. But I think I took away something more than I thought I was going to take away.* [Woman, aged 44 years]

Participants reflected on gradually learning to recognize self-critical tendencies throughout the course and beginning to adopt new approaches over time, with deliberate attempts to incorporate compassionate responding to themselves. Recognizing the adverse effects of self-criticism, participants began to see self-compassion as humanizing how they responded to themselves.

> *Self-compassion means having compassion for yourself as an individual…This is something I really resonated with in the course and thought about it in a new way. It's like just feeling. Just remembering that you are a person too…Recognizing it's something I have to continue to work on from the course.* [Woman, aged 60 years]

Participants also noted that this had beneficial feed-forward effects in relation to others through common-humanity, with a renewed desire to alleviate the distress that all humans experience.

> *My peace can be restored when I remind myself that I'm not the only person navigating these feelings and thoughts. That common humanity piece is really important to me because it makes me feel less isolated.* [Woman, aged 49 years]

Theme 4: Growing Recognition of the Importance of Compassion for Oneself and Others

Participants described that recognizing the importance of compassion for oneself and others became more apparent throughout the course as they reflected on learning how to let go of their self-critical attitudes over time and focused on being kind to themselves, using the learned self-compassion practices, and listening to peers' similar experiences.

Participants described that a fundamental premise to fostering self-compassion is recognizing it is okay be kind to oneself, even as an HCP "it's okay sometimes to just step back and take care of yourself first, before other people," (Woman, aged 53 years). Participants reflected on using self-compassion practices

XSL•FO
RenderX

more naturalistically in their day-to-day lives as the course progressed while others described using what they had learned to incorporate in their clinical care of patients, or in their professional lives with students, or in their personal lives with family members.

> *I use the [hand on heart strategy]. I've been doing that with my family too. Like my wife when we talk, just to remind myself to be grounded. And just the practice of doing the exercises I think just made me more attuned to my patients and just helped me remember to hold space for people and have more patience. Immediately, I just felt like my practice was shifting a little bit.* [Man, aged 43 years]

Participants iterated a perceived importance of regularity of the self-compassion practice as a means of developing the skill and driving lasting change. In this regard, the course environment appeared to motivate continued engagement with the self-compassion practices, where participants described being inspired by others' reflections on personal insights and use.

> *I really did appreciate listening to others. And I found some of the other participants were so thoughtful and open and vulnerable and really shared both their struggles and how the practices were really meaningful to them. And that was inspiring in a way, to know other people are also struggling similarly.* [Woman, aged 42 years]

Indeed, the online nature allowing providers from otherwise separate rehabilitation sites reinforced a sense of camaraderie and solidarity.

> *A year or so ago, a patient died… We don't get a lot of deaths in rehab. And in rehab we're not trained for that. Being able to sit down as a group after that happened, no management, just us, and talk about how we were feeling from everybody's perspectives… was the most important thing for us to prevent burnout… and all help each other get past it.* [Woman, aged 40 years]

Setting work-life boundaries, "not taking any work home" or "not looking at emails," (Woman, aged 26 years) was also deemed a crucial element to self-compassion by participants, who described this as necessary to maintain their own well-being and ability to provide compassionate care to patients. According to HCPs, developing an understanding of cultivating inward compassion, through learning and applying specific strategies, played an integral role in fostering a grounded and clear mindset needed to extend compassion toward others.

Theme 5: Challenges Engaging With the SCHC Course

Participants described several barriers to course participation from the method of course delivery to challenges with course content, as well as individual variation in level of readiness to engage in sensitive conversations. A striking insight shared was that to make time for course engagement, participants had to give up time spent charting during their lunch-hour (ie, investing time in themselves came at a cost, causing anxiety surrounding completing work later in the day.)

> *I didn't attend all the courses. I think I only attended two and then I really had to back out because it was causing a lot more stress in terms of my workload, and I sat there more anxious than anything, so it was setting my afternoons off.* [Woman, aged 45 years]

Other challenges noted included a sense of discomfort in connecting emotionally to others online and participants worried about how exposing oneself in this way might undermine their professional identity,

> *When you're not surrounded by people, physically, you can't pick up on their body cues. It's just not a very comfortable environment to talk about your emotions or talk about your feelings.* [Woman, aged 34 years]

While some HCPs found aspects of the course to be conducive to engagement (eg, the diversity of attendees and the online format), there were many suggestions for improvement which primarily focused on timing, mode, and content. Suggestions did not follow a specific pattern and varied from implementing an asynchronous course to hosting the meetings before working hours to limiting the group to a smaller size. A persistent suggestion was tailoring content to typical challenging rehabilitation scenarios and implementing a follow-up course to reinforce new skills.

Theme 6: Challenges to Sustaining Self-Compassion in Specialist Rehabilitation

Several barriers to being compassionate in rehabilitation beyond course completion were perceived, ranging from individual (eg, changing habits) to systemic (eg, heavy workload) in nature. However, following course completion, participants explained that by necessity they learned how to implement self-compassion practices from the SCHC spontaneously in their daily lives despite obstacles, such as stepping aside for a brief period to "ground" oneself during unbidden stress.

Perceived role stipulations were cited to challenge practices from the SCHC in specialist rehabilitation, where an explicit emphasis is placed on HCPs prioritizing physical function, and less attention paid to emotional distress which often underlies impairment and impedes functioning.

> *I would say most people who are struggling physically are also struggling emotionally. I found often with [stroke patients], it was harder to get a read on really how much someone was struggling, especially if their speech was impacted. It was a little bit harder to connect with people because you couldn't quite tell all the time how much emotionally this has impacted.* [Woman, aged 40 years]

Participants also noted that implementing practices from the SCHC course could not address prevalent systemic issues directly, such as when patient and family expectations for rehabilitation were perceived as unrealistic due to not being addressed in the acute setting,

> *So that, I find, has always probably there been a consistent stress factor, dealing with families with high expectations and then managing their*

XSL•FO
RenderX

> *expectations. So, when you have those conversations and if they're very anxious or stressed and they come at you and they use you as a scapegoat sometimes.* [Woman, aged 44 years]

Systemic-level realities such as large caseloads, time constraints, and the fast pace of inpatient units were all seen as impediments to maintaining compassion, despite learnings from the course. Hinting at moral distress, there were clear depictions of the struggle to balance personal capacity (eg, energy) for delivering exceptional, compassionate care with the relentless demands of the work environment. This finding underscores the necessity of learning and implementing tools to foster self-compassion in an environment that may not inherently promote it.

> *I'm struggling with taking care of a lot of patients. I often-times feel like I don't give enough attention to them. It's more about I'm feeling guilty if I don't give enough attention to them, and I know, if I have the time, I can make a lot of difference. But I just cannot. And after all these years I do make sure I don't spend way too much time here. I know I can't sustain that.* [Woman, aged 59 years]

Discussion

Principal Findings

In this exploratory qualitative study, specialist rehabilitation providers were provided with the opportunity to engage in the SCHC course online. Reflexive thematic analysis generated six prevalent and interconnected themes: (1) the nature of working in rehabilitation, (2) different perspectives on burnout in specialist rehabilitation, (3) a new perspective, less self-criticism, more self-compassion, (4) growing recognition of the importance of compassion for oneself and others, (5) challenges engaging with the SCHC course, and (6) challenges to sustaining compassion in specialist rehabilitation.

The nature of working in rehabilitation highlights the complexities of specialist rehabilitation that can render HCPs at risk of compassion fatigue, burnout, and STS. Not only does the focus of specialist rehabilitation—adaptation—contrast with the focus of acute care—treatment or cure, but also patient and families' expectations of the goals of rehabilitation are rarely managed beforehand. Thus, managing expectations following a disabling life event becomes a daunting and burdensome task for HCPs to fulfill that extends beyond dealing with the emotional distress that may arise from completing their regular tasks. Additionally, the longitudinal nature of specialist rehabilitation affects HCPs in 2 capacities. On one hand, HCPs describe the value in getting to know their patients on a deeper level and the satisfaction of helping patients improve their functioning throughout time. On the other hand, HCPs may endure long-term maltreatment from their patients and their families if expectations are not managed properly and if functional improvements are not apparent. Further, these effects may persist outside of working hours, affecting HCPs in profound ways. Although familiar for specialist rehabilitation HCPs, these nuances may not be well understood among the general public [52,53], and effects on HCPs' well-being are not always incorporated into organizational guidelines or well-documented in the literature [54,55].

The nuances that a specialist rehabilitation setting offers may expose HCPs to highly traumatizing experiences [8] which may contribute to a significant risk of burnout [56]. Most participants in this study were unclear about how to define or differentiate between compassion fatigue, burnout, and STS. Many had heard of the concept of burnout before the course and could speculate at its meaning based on personal or colleagues' experiences. Most conveyed experiencing stress through providing patient care, some sounding personally traumatized. Participants discussed the course helping to grow their understanding of the concept of burnout and that it also provided a safe forum for discussing difficult experiences among peers who could understand, to the extent that this fed into suggestions for making the course even more relevant. Elsewhere, other self-compassion intervention studies have quantitatively reported reductions in symptoms of burnout among HCPs following participation or in comparison to a control group [57-60], and have also reported that HCPs developed an increased awareness of their own well-being [58]. In this exploratory qualitative reflexive thematic analysis, we did not assess quantitative changes in burnout pre- to postcourse, but participants did report that through participation in the SCHC course they became aware they may be experiencing burnout and also gained useful tools to combat these challenges. A better understanding among HCPs of how work in specialist rehabilitation can affect one's occupational well-being may facilitate engagement with evidence-based self-care strategies and may feed into concerted efforts to change a culture in health care that raises the risk of burnout for many HCPs [61].

HCPs have ethical duties to do no harm and to act in patients' best interests (eg, [62,63]), even if this means doing so at the expense of their own well-being, which is a prevailing and problematic cultural norm in health care [32]. Therefore, it is not surprising that participants described having an easier time being compassionate to their patients than to themselves. Most HCPs recognized that they are regularly compassionate to their patients yet had never labeled their actions as such. Even fewer participants acknowledged intentionally being self-compassionate while reflecting on their lives prior to the course. While the course attempted to emphasize the opposite, for many participants, to identify professionally as a specialist rehabilitation HCP, one cannot also show humanistic qualities. Whether this belief was perpetuated by personal factors or systemic norms and the complex association between necessitates future research. Being a "human being" (eg, being exhausted or not performing your best at work) lends well to practicing self-compassion, but for HCPs, having self-compassion was not possible without compromising professional identity. Accordingly, it appeared to take time for HCPs to gain a new perspective, less self-criticism, and more self-compassion to challenge their beliefs. In line with the findings of Neff et al [32], the SCHC course may be more beneficial for HCPs who report having low self-compassion to begin with, although in this study, changes over time were described retrospectively and not formally assessed longitudinally.

XSL•FO
RenderX

Following the new perspective participants described, many discussed the course being helpful in growing recognition for the importance of compassion for oneself and others. Participants found being intentional about one's thoughts, feelings, and actions important when seeking to cultivate compassion and debriefing about difficult situations as a health care team an important mechanism to bring compassion to bear on collective adverse experiences. Descriptions of growing compassion may align with current quantitative evidence that mindful self-compassion interventions are successful in minimizing HCPs' self-criticism [59] and improving self-compassion [32,57-60]. This study is the first study to report participant experiences of growing self- and other-focused compassion in specialist rehabilitation HCPs, despite these constructs not being assessed quantitatively.

The "new" concepts covered in the SCHC course were well-received by HCPs who were open to learning about how to improve their well-being by increasing their self-awareness and engaging with self-compassion practices. Similarly, existing literature affirms the importance of practicing the techniques from the SCHC course in a health care setting for oneself and for one's patients [58,59]. Accordingly, promoting common humanity [64] and fostering communities of support [58] continue to be useful tools to promote compassion in HCPs.

HCPs provided both positive feedback and constructive criticism based on the delivery of the SCHC course. The online format provided participants with the flexibility to join from several sites across a large metropolitan area, and the diversity of professional roles was appreciated and contributed to a sense of common humanity when peers discussed similar experiences in their duties even across sites. Additional advantages that supplement previous research [57] include saving travel time and facilitating joining from home. One of the most notable suggestions was to tailor the content to include rehab-specific examples. This suggestion was also reported in recent reviews. Emphasis on the importance of contextual adaptation underscores the need for tailoring digital interventions to the specific group of HCPs they intend to be delivered to [38] (eg, rehabilitation providers). A 2024 scoping review specific to the assessment of online MBIs primarily using audio-guided programs also suggested tailoring interventions for groups of HCPs [25]. This change is likely to enhance acceptability but would necessitate further feasibility testing.

Despite participants' acknowledgment of the benefit of self-compassion practices they learned, many noted challenges engaging with the course such as scheduling challenges, expected with busy HCPs [32]. Interestingly, not being ready to share personal struggles in a group setting was a less common challenge. It is possible that those who were unwilling to share did not participate in interviews entirely. The fact that some HCPs disclosed these feelings still emphasizes participants' curiosity about the self-compassion intervention and the importance of having trained facilitators to handle challenges that may arise. While the group format (eg, the presence of unfamiliar peers) hindered some participants' willingness to share and reduced their ability to build rapport with other course participants and facilitators, the added benefit of accessibility must be weighed with the impracticalities of in-person sessions. However, most participants appeared to value the format of the course. Also noted was the impracticability of engaging in self-compassion practices and actions at work, in line with Crandall et al [58] and in contrast to Delaney's [59] findings that most nurses found their self-compassion practices useful on the job. The lack of suitable work environments to practice self-compassion (eg, a quiet location to engage in the "hand on heart" practice) speaks to the need for leaders and organizations to understand the need to focus on employee well-being and appropriate infrastructure change (eg, staff "recovery" rooms; [4]).

To provide compassionate care to promote better patient satisfaction [1] and healing [4], both individual and systemic factors should be targeted. Participants spoke of their complex patient populations and difficulties managing patient expectations to limit the compassion they were able or willing to give. Patients undergoing specialist rehabilitation often exhibit distress in more than one area of their lives (eg, physical and emotional) as they typically experience life-altering diseases or catastrophic injuries [65,66]). HCPs should be aware that patients are frustrated with their new realities or the health care system more generally, which can be perceived as dehumanizing both by HCPs and patients alike [67]. Speculatively, increased awareness of shared distress and common humanity through participation in the SCHC course may limit HCPs' internalization of patient frustration, to instead respond with compassion, and this in turn may limit their risk of feeling burnt out, although this remains speculative and would have to be tested quantitatively to map out processes and determine proponent causality. Regardless, HCP training in compassionate care should arguably include strategies for helping identify the source of patient frustration and provide tools for HCP emotional awareness and regulation. Although not only rehab-specific [68], systemic challenges that feature in HCPs' day-to-day include being overwhelmed with case numbers and not having enough time to complete their duties. From participant accounts, the guilt that comes with wanting to be compassionate, but not being able to, may perpetuate specialist rehabilitation HCP moral distress and feelings related to burnout, and the cycle is likely to continue if changes are not made. Policy changes facilitated by leadership that foster a sense of shared humanity and a healthy workplace environment are likely to tackle barriers to compassion, such as implementing protected time with management to reflect on challenges as well as taking short breaks throughout the day [69,70].

Limitations

Although rich data were gathered to portray HCPs' diverse experiences with workplace-related stress and the SCHC course, this study comes with limitations. First, generalizability to the population of specialist rehabilitation providers is restricted. The sample all worked in the Greater Toronto Area, which limits applicability of findings to other populations across Canada or countries outside of Canada, especially those from rural areas. Fewer HCPs are employed in rural compared to urban environments, which can intensify workplace stress and increase the prevalence of role sharing among rehabilitation disciplines [71]. Such factors may intensify HCPs' experiences with burnout and thus, the course may need tailored in relation to the needs

XSL•FO
RenderX

of the population served. For instance, rural HCPs may find themselves experiencing more debilitating workplace stress that may or may not classify as burnout, as they may take on additional roles outside their scope of practice or work more hours than urban HCPs. Despite this limitation, the sample was heterogeneous, containing people of various ages and professional disciplines in rehabilitation who attended most sessions. This study recruited participants from a specific geographical area due to the nature of the research protocol. Future iterations should consider expanding the sample to increase generalizability and assess feasibility on a wider scale, something which offering an online SCHC, as opposed to in-person, can help facilitate.

Further, it is entirely possible that participants who did not interview had different experiences with the course than those who did interview, reflecting potential self-selection bias. Common barriers for participation in qualitative research include the time requirement (eg, more time intensive than survey-based research) and lack of incentives [72]. Noninterviewees could have been too busy at work to participate in an interview and thus, they may have described more severe workplace-related stresses than the group who interviewed. All participants were offered gift cards to interview. In addition to time and incentives factoring into one's decision, those who did not interview may have had poorer experiences with the course than counterparts who interviewed. Alternatively, nonrespondents may have felt as though the course was not relevant to them, which may explain the lack of desire to provide feedback. These characteristics may or may not have altered the themes that arose from this analysis if the nonrespondents provided interview data. Ultimately, it was difficult to conclude why the 6 participants did not choose to interview as they did not respond to our interview invites even after following up. Positive findings, including the perceived growth of compassion and course accessibility, should be interpreted while considering the potential reasons why a subset of participants chose not to interview. Nevertheless, the number of participants who interviewed was high and motivation for participation was captured, important pieces of the puzzle when analyzing acceptability of a program in a specific setting.

Social desirability bias, the tendency to respond in accordance with perceived socially acceptable characteristics or favorable outcomes [73], may have influenced interviewee responses. The more engagement with researchers students in a learning setting experience and the more stress in one's life (eg, being overworked or experiencing burnout), the more likely participants are to respond to questions favorably, without responses reflecting their true experiences [74,75]. Social desirability bias may explain the tendency for participants to report that the SCHC course was helpful in growing their understanding of the concept of self-compassion or limiting feelings associated with burnout or workplace stress. Additionally, HCPs may fear disclosing burnout-related feelings due to stigma surrounding mental health issues, worries about it impacting their employment [76], or privacy concerns [77]. While semistructured interviews were used to gather responses, which may increase the effects of social desirability bias, the study coordinator limited her involvement during the trial to limit potential influence, being on camera only when necessary to solve technical issues or answer logistical questions. Furthermore, the purpose of the study was communicated to participants as not to solely provide tools to improve emotional well-being, but rather to gain insights into the experiences of engagement with the course. Questions were phrased from both sides (eg, in which ways was the course helpful or unhelpful?) or as neutral as possible, and participants were assured their responses would remain anonymous. Social desirability bias has been shown to be minimized in these ways (eg, [73]) and the mix of positive and negative responses, including suggestions for course improvement, help demonstrate this. Aside from the risk of socially desirable responding, online interviewing is liked by participants, easy to use by researchers and facilitators, and conveys perceptions of empathy and rapport well when used for qualitative research [40,41,78].

Implications and Future Directions

Participation in the online SCHC course appeared to help improve HCPs' knowledge of the concept of burnout, validate common struggles with their peers, and teach them tools to foster self-compassion and compassion for others. Some participants experienced challenges feeling connected to the course and fellow participants because of the online synchronous format, course timing, and other barriers described. Accordingly, participants described program strengths and areas for improvement. Both positive feedback and constructive criticism provided by HCPs can inform the development of knowledge translation tools (eg, a website), educational sessions, organizational strategies to better support staff well-being.

This is the first study exploring HCPs' experiences with the SCHC course in a specialist rehabilitation context. Variations of the course should be tested iteratively for acceptability, accessibility, and efficacy by adjusting course timing (eg, time of day), format (eg, synchronous), and class size in line with suggestions provided by our participants. The most prominent suggestion was to make content rehabilitation specific. Future trials should include concrete examples of stressors that may arise in rehabilitation when discussing the need for self-compassion so that participants can relate. Course delivery conditions also matter; protected learning time and continuing education credits may be required.

Accordingly, to better understand potential mechanisms of action and effectiveness (eg, by measuring pre- and postburnout, compassion fatigue, and STS scores), the next phase of research will compare the SCHC course and a matched comparator, such as a Health Enhancement Program. The Health Enhancement Program is an intervention specifically designed to match MBIs in terms of group context, instructor time and attention, education on health behaviors, but not on any content on mindfulness or self-compassion [79]. This would constitute a phase 2 randomized controlled trial design [80]. Additional future studies, such as one that gathers perspectives from health leaders (eg, Division heads) can provide valuable insights into organizational structures that may facilitate participation (eg, the availability of quiet spaces) and clarify responsibility for participation.

XSL•FO
RenderX

Conclusion

An online SCHC course appears relatively acceptable and accessible to some specialist rehabilitation providers, who noted gaining a deeper understanding of the concepts of self-compassion and burnout and discussed a desire to extend more compassion to themselves, their patients, and colleagues. Barriers to participation, such as difficulties making the time to join sessions and challenges with being vulnerable online were also discussed by participants, which may limit relevance for some busy HCPs. Self-compassion interventions like this one may be a useful strategy for improving HCPs' well-being in a postpandemic context; however, optimization changes appear necessary to maximize relevance and use for all specialist rehabilitation HCPs, and this should be the focus of future research.

Acknowledgments

Thank you to the St. John's Research Team and Jillian Scandiffio for your ongoing support with this project. We are grateful for all study participants for taking time out of your busy schedules to participate in this important project.

Artificial intelligence was not used in any stages of the hypothesis, data collection, data evaluation, or manuscript preparation.

Funding

This work was funded entirely by an Associated Medical Services Fellowship in Compassion and AI.

Abstract

Background: Physician burnout is highly prevalent in Physical Medicine and Rehabilitation (PM&R), but its origins and drivers remain poorly understood.

Objective: This study aims to explore the factors contributing to burnout among Canadian physiatrists.

Methods: Using Charmaz's Constructed Grounded Theory within a qualitative interpretivist paradigm, we interviewed 30 Canadian physiatrists about their experiences with burnout. Analysis was informed by Cooley's looking-glass self theory.

Results: Burnout in PM&R in Canada stems from a medical culture prioritizing academic excellence over compassionate care. Canadian physiatrists report shame and self-criticism when unable to meet these high standards. Retrospective accounts from Canadian physiatrists suggest that burnout peaks during residency, where autonomy is low and demands are high. Participants also described feeling unprepared to handle patients' emotional needs and experiencing moral distress when necessary care cannot be delivered due to systemic barriers. Health care bureaucracy further compounds burnout.

Conclusions: Addressing burnout in PM&R in Canada requires upstream systemic and contemporary cultural change.

Introduction

Background

Burnout was originally described as an occupational stress syndrome associated with chronically stressful and emotionally intense work conditions [1]. In health care, burnout has been further classified as having 3 overlapping domains, including emotional exhaustion, diminished sense of achievement, and depersonalization, the latter of which refers to objectification of patients, or loss of compassion [2]. Of concern, burnout in physicians around the world is widespread [3], representing a crisis in health care globally. Physician burnout has significant individual, organizational, and societal costs through worse job

XSL•FO
RenderX

performance, workforce attrition, and lower patient satisfaction [4,5].

Among physician specialties in the United States, Physical Medicine and Rehabilitation (PM&R) consistently ranks among the most burned out [6] (odds ratio [OR] 1.30), with only Emergency Medicine (OR 2.53, 95% CI 2.18-2.93), Family Medicine (OR 1.46, 95% CI 1.29-1.65), and Radiology (OR 1.31, 95% CI 1.12-1.54) reporting higher odds of burnout. Burnout affects a significant proportion of PM&R specialists and trainees—ranging from 48% to 62% for specialists and up to 83.3% for trainees [7]. Putative factors contributing to burnout in PM&R physicians come mostly from US survey data, mirror those seen in physicians overall, and do not clarify the specialty-specific causes that drive or sustain burnout [6]. PM&R uniquely focuses on the longitudinal care of people with disabling conditions, aiming to treat impairments, support independence, enhance social participation, and improve quality of life [8]. These philosophical underpinnings are based on a biopsychosocial model of health [9]. This is the core work of PM&R specialists ("physiatrists") [10].

Existing literature has highlighted several potential contributors to burnout among physiatrists, including high patient load, administrative burden, limited resources [10,11], and may also include the emotional toll of managing patients with chronic conditions [6,11,12], especially those subject to trauma [13]. However, these studies have largely not explored the personal experiences of physiatrists that lead to burnout in PM&R. To our knowledge, only one qualitative study has examined burnout in PM&R, focusing on personal strategies for occupational well-being during the COVID-19 pandemic; however, it used descriptive methods and did not develop a theory explaining burnout in the specialty.

Physiatrists' work with people affected by disabling long-term conditions, coordination of multidisciplinary care, and prioritizing of functional recovery entails unique stressors not fully captured by burnout theories from other medical contexts [14,15]. This gap highlights the need for a PM&R-specific theoretical framework to clarify the unique stressors driving burnout and guide targeted interventions aimed at improving physiatrists' well-being and patient care.

Aims

By capturing the lived experiences and perspectives of Canadian physiatrists, this study aims to provide a comprehensive understanding of the origins and factors contributing to burnout in PM&R through a grounded theory approach.

Methods

Design

A qualitative exploratory approach using grounded theory was chosen for its suitability in exploring underresearched areas and generating deeper insights into attitudes, cultures, and social processes [16], specifically Charmaz's constructed grounded theory [17-19]. Grounded theory as a qualitative methodology is used when the focus is on the process and the creation of theory or a conceptual framework [17,18,20]. In this research, grounded theory was used to construct a conceptual understanding of how physiatrists comprehend and experience burnout. Charmaz's [17-19] approach to grounded theory emphasizes the coconstruction of meaning between researchers and participants, aligning well with our theoretical grounding in Cooley's [21] looking-glass self midrange theory. The looking-glass self theory posits that individuals form their self-concepts based on how they perceive others to view them. This idea was instrumental in shaping our analysis of how physiatrists internalize and respond to burnout—through both personal experiences and external reflections from colleagues, patients, health care institutions, and social systems overall [21]. Using the looking-glass self theory, this study explored how Canadian physiatrists' burnout perceptions are shaped by interactions with and perceived judgments of others. This perspective enriched our grounded theory approach by highlighting relational dynamics such as how social comparison and external validation influence feelings of adequacy or support. It also guided the creation of visual and narrative materials, which complemented narrative data by capturing the interplay between internal experiences and external perceptions central to both the sensitizing theory and our subsequent analysis [22]. Visual materials were developed to reflect scenarios where physiatrists interacted with their environments, colleagues, and patients, illustrating how external judgments and expectations contribute to the emotional and psychological responses to burnout. In this context, the visuals served as a creative tool to depict how social comparisons, external validation, and perceived judgments play a role in shaping physiatrists' experiences of burnout.

The study received approval from the Sunnybrook Research Ethics Board, ensuring voluntary participation, confidentiality, and the right to withdraw.

Data Collection

Recruitment and Sample

Between September 2023 and March 2024, 30 physiatrists from across Canada were recruited for the study. There are an estimated 501 physiatrists in Canada [23]. Eligibility required English proficiency, current employment as a physiatrist, and willingness to join an online interview. Recruitment used advertisements distributed by the Canadian Association of Physical Medicine and Rehabilitation, outreach by PM&R Division Directors, and via public licensing registries for remote areas. Potential participants received an initial email plus up to 2 reminders. The team monitored recruitment to ensure diversity in age, gender, race, geography, subspecialty, and experience with burnout, expanding outreach to PM&R leaders when needed. Participants provided consent before interviews and received a CAD $50 (US $36.05) Amazon gift card afterward.

Methods of Data Collection

Data collection occurred from September 2023 to March 2024 through in-depth qualitative interviews conducted by RS and a trained research assistant EC. Questions were designed to be open-ended, to explore participants' experiences with burnout in PM&R, with the interviewer paying particular attention to views and actions, as well as emergent areas of potential theoretical interest. Audio and video recordings were made via

XSL•FO
RenderX

Zoom (Zoom Communications). The semistructured interview guide, focused on burnout experiences among Canadian physiatrists, is available in Multimedia Appendix 1.

Data Analysis

In this study, data analysis began alongside data collection, allowing for constant comparison between new data and emerging categories. This method ensured that each round of data collection was informed by the preceding analysis, allowing the research team to refine interview questions and explore areas that required deeper understanding. We used an inductive and iterative process to derive final insights [18]. Coding was done in multiple stages—open coding to identify initial concepts, axial coding to link these concepts together, and selective coding to integrate them into a coherent framework. First, two researchers open-coded the data in NVivo (Lumivero) using descriptive codes on participant responses [24]. The reviewers then met with the principal investigator to discuss the preliminary coding and developed an inductive codebook that was applied to the transcripts. The looking-glass self theory informed our coding process by encouraging us to attend to moments in the interviews where participants referenced feedback from their work environment—whether from peers, supervisors, or patients—as central to their feelings of burnout or professional fulfillment. This theoretical approach underscored the importance of external perceptions in shaping burnout, thus enriching our analysis of the interplay between personal identity, professional role expectations, health institutions, and systemic pressures. From this, the same researchers engaged in a constant comparison analysis where meetings were held to discuss the common higher-order themes implied by clusters of open codes, leading to the development of axial codes reflecting participants' insights on the conceptualization and understanding of burnout and experiences with this phenomenon [25,26]. The looking-glass self theory served as a sensitizing concept, framing how burnout is shaped through social interactions in PM&R and guiding the interpretation of nuanced reflections on acknowledgment by self, professional peers, and institutions. Two researchers applied axial coding to transcripts, discussing the process weekly [26]. Once team discussions suggested a preliminary understanding of a theoretical framework, the researchers engaged in a final reflexive process of selective (focused) coding [27]. Selective coding involved the deliberate examination of specific aspects of the preliminary framework within the transcripts to deepen our understanding of the framework, explore relationships between the data, and extract meaningful insights [19]. Categories were identified from comparative analysis, culminating in a core category that encapsulated the study's main theme [18]. Through team discussions, the researchers were able to extrapolate prominent themes within the data to inform an overarching conceptual understanding [19]. In between the weekly meetings, the researchers went independently back to the data to further refine their ideas against the emerging conceptual framework.

We systematically searched for disconfirming cases that challenged emerging themes, documenting and analyzing them to refine our findings. Analysis and team discussions continued until a conceptual framework achieving theoretical saturation was developed [28], where themes around how physiatrists understood and experienced burnout were consistently repeating, with no new dimensions or variations emerging, and the conceptual framework appeared sufficiently dense to explain the origins and factors sustaining burnout in PM&R [27].

Positionality

Our positionality as a team influenced this process, as we were mindful of how our own experiences and professional backgrounds shaped the way we coded and interpreted the data [29]. The lead author, a middle-aged Scots Canadian physiatrist with expertise in mindfulness and compassion, contributed insider insight on burnout in high-stress health care settings, framing it through the looking-glass self theory and emphasizing emotional and relational aspects. An interdisciplinary team, including a PhD-trained rehabilitation scientist and early-career researchers, incorporated structural and institutional factors and reflected on their roles, producing a nuanced, reflexive framework capturing the complexity of burnout in PM&R.

Ethical Considerations

This study was conducted in accordance with the World Medical Association Declaration of Helsinki - Ethical Principles for Medical Research Involving Human Participants and prospectively approved by the Sunnybrook Research Ethics Board (project ID: SUN-5835). Informed consent was obtained electronically from all study participants after the nature and possible consequences of the study were explained. Respect for individual autonomy was emphasized, including that even following the granting of informed consent, participants could choose to withdraw from the study for any reason, without needing to give a reason and without adverse consequence. All participants who provided a semistructured interview received a CAD $50 (US $36.05) Amazon gift card in compensation. All reasonable efforts were made throughout to protect participant safety, dignity, privacy, and confidentiality. All personal identifying information was deidentified, and any interview quotes with potentially identifying information were not included in the study findings.

Results

Participant Characteristics

Most participants were women (19/30, 63%), with a mean age of 45.5 years. Most participants were recruited from Ontario (18/30, 60%). The most common racial identity was White European (12/30, 40%), followed by White North American (9/30, 30%), East Asian (6/30, 20%), South Asian (2/30, 7%), and Latin European (1/30, 3%). Participants worked in a wide range of PM&R settings, but most worked in an urban setting (28/30, 93%), full time (22/30, 73%), with 19 (63%) participants working 50 or more hours per week, with mixed inpatient and outpatient populations (24/30, 80%), and in most cases in neurological rehabilitation (13/30, 43%). No PM&R residents were interviewed (Table 1).

Main Findings

The study findings present a conceptually grounded theory titled "Burnout in Physical Medicine and Rehabilitation is the Hierarchical Performance Paradox." The theory comprises 3 interconnected concepts: hierarchical structure, perception of performance, and their interaction in PM&R. In this theory, which is based on retrospective accounts of the lived experience of practicing physiatrists, the origins of burnout in PM&R are sown early in the training of budding physiatrists. Specifically, the hierarchical structure of medical training and practice imposes escalating demands amidst constrained autonomy as Canadian physiatrists progress through their careers, whilst simultaneously the perceived necessity of perfection in performance—shaped by internalized appraisals by peers, patients, and regulatory authorities—foments feelings of imposter syndrome. This hidden curriculum prioritizes performance proficiency above all else, leading to a mindset of "Doctor first, human second" (Woman, aged 33 years) (the hidden curriculum here refers to the implicit lessons, values, and attitudes conveyed through the behaviors and expectations of mentors, colleagues, and the health care system, which are not formally part of the medical educational syllabus [30]). Burnout risk appears highest when autonomy is low and stress is high, fostering self-criticism and shame. Social comparison and perfectionism are reported by Canadian physiatrists to begin in medical school and intensify during PM&R residency, when autonomy and social support decline, and burnout peaks. Later, increased autonomy does not eliminate risk, as expanded responsibilities, emotional demands, health care system inadequacies, and bureaucratic pressures perpetuate moral distress and burnout throughout a Canadian physiatrist's career. Illustrative quotes from participants are woven throughout the text. Figure 1 depicts the grounded theory process from coding to theory for burnout in Canadian physiatrists. Figure 2 depicts the hierarchical performance paradox.

The Role of Hierarchy in Burnout in Physical Medicine and Rehabilitation

Retrospective accounts from practicing Canadian physiatrists indicate that burnout in PM&R originates from a hierarchical and performance-driven medical education system that inadvertently de-emphasizes compassionate care, leading to stress and emotional exhaustion:

> *Medicine is the stodgiest, most conformist profession that there is, and it has not adapted or evolved to the 20th century, and I think that creates a burnout environment.* [Man, aged 41 years]

Hierarchy in this context refers to the structured levels of authority and responsibility within medical education and practice, where individuals at lower levels, such as medical students and residents, are subject to the oversight, evaluation, and directives of those higher in the system, such as attending physicians and administrators. This hierarchical framework prioritizes academic performance, efficiency, and adherence to institutional norms over compassionate care, creating an environment where Canadian physiatrists face intense pressure,

XSL•FO
RenderX

reduced autonomy, and a heightened risk of burnout. A hidden curriculum in this context perpetuates these values, fostering emotional detachment and prioritizing efficiency and exceptional levels of academic performance. These factors, together with systemic constraints and relentless vertical oversight from within the hierarchy, and horizontal peer appraisal, contribute to burnout outcomes such as emotional exhaustion, depersonalization, and a diminished sense of achievement among many Canadian physiatrists.

Participant accounts indicated that the motivations for becoming a physiatrist are largely altruistic, reflecting core values of improving quality of life for people with disabling long-term conditions:

> *I try my hardest to be compassionate to patients because that's why I wanted to get into what I wanted to do in physiatry. I feel that you have a longer relationship with people, so you need more of a compassionate approach versus a one-off here and there if you're doing surgery or something like that.* [Woman, aged 35 years]

However, participants also stressed that, in spite of altruistic motivations, the reality is that performance stratification determines who is eligible to apply for admission to medical school, emphasizing academic performance over other qualities:

> *I think being in medicine and needing the grades you need to get into medical school, things like that require a certain degree of perfectionism, so it's something that's been valued throughout your life.* [Woman, aged 35 years]

Participants iterated that once admitted to medical school, proficiency in academic performance is strongly emphasized. Failure to meet the bar is associated with adverse social comparisons, shame, and self-criticism:

> *We're moving away from that shame-based teaching environment, but we still have a lot of that within our clinical training. Shame-based learning is by no means gone and a lot of the times it's just under the surface rather than directly somebody yelling at you for not being good enough.* [Woman, aged 33 years]

Compassion was described as not being a primary or explicit focus in this milieu; rather, the emphasis was on knowledge of disease and learning how the system really works:

> *Yes, I think part of it that I never learned that [self-compassion], it's not part of training and medicine training magnifies mistakes. We have whole rounds about how you learn from how people, quote unquote, screwed up. So, I think that that's part of it, is that the culture of medicine doesn't necessarily lend itself to that.* [Man, aged 39 years]

Participants recalled how, upon graduating from medical school, as residents in PM&R, they often faced excessive workloads fulfilling the demands stipulated by their superiors, sacrificing their autonomy and sense of self:

> *I was a resident, so I had no control over. I was just told how much call I needed to take. It was different back then, there was payroll, which is the governing body to the residents, but I don't think it was as strict as it is now. The residents were fairly powerless* [Woman, aged 48 years]

Based on participant recollections, autonomy appeared inversely related to hierarchy within the medical education and practice they experienced. In a hierarchical structure such as this, individuals at lower levels, that is, residents, have limited control over their workload, schedules, and decision-making, as these are dictated by superiors. This lack of autonomy was described as resulting in residents prioritizing institutional demands over personal needs or values, leading to a diminished sense of self.

Only upon becoming fully qualified did a sense of autonomy return, at which point physiatrists in Canada often assume a leadership role in the multidisciplinary team:

> *How I really got better was I stopped being a resident and then I became a staff, and I had more autonomy. I think that is a factor to relieving burnout, being able to control your work schedules. Being able to say yes to some things and no to other things. I think that's actually how it got helped* [Woman, aged 37 years]

However, participants recounted that the reality is that the job continues to be dictated by hierarchical health systems, regulatory body oversight, and peer appraisal of performance:

> *But I'll say that even at [rehab hospital] there have certainly been instances where I feel like the response from the organisation in response to something that happened with an error that then caused harm was not, I think the kindest and most compassionate response* [Woman, aged 37 years]

Indeed, as Canadian physiatrists advance in their careers and move up the hierarchy, although in one sense autonomy is greater, on the other hand, their responsibilities and expectations also increase, creating a persistent tension between autonomy and normative performance standards.

Regardless, Canadian physiatrists of all stages struggle to provide the care they believe is necessary for their patients due to health system constraints and fear authoritarian reprisal for failing to meet expected high performance standards:

> *I know that in Ontario, people are always like, don't mess with Ontario College of Physicians because it's a big problem.* [Woman, aged 32 years]

Where burnout is concerned, regulatory bodies were seen as threatening due to their ability to "take away your license" to practice medicine:

> *The College of Physicians was not chill about it though. Because that was PGY2, right, and then when I graduated, you had to answer some questions about did you ever get time off because of this?...the College of Quebec they were just like, have you or are you in a situation where this will be a problem? There was no differentiating it and then they were like, we need a letter from your doctor saying that you are up to practise medicine* [Woman, aged 32 years]

XSL•FO
RenderX

This highly stressful situation may partly explain the difficulties Canadian physiatrists face in providing care in this hierarchical practice climate.

> *And now they're looking at even things like being rude in your private life as being a reportable offense. I mean, really? 24/7, we have to be models of perfection, or we could be reported and lose our livelihood, which would impact whether we can pay our bills. It's from all sides. To the point where I struggle with whether or not to encourage my own children to enter the profession. Yes.* [Woman, aged 49 years]

> *But the burden of care, I think more and more what happens earlier on is your lifeline is that licence to practise, and if that gets taken away, which seems always to be this looming threat, that if I get caught doing something that's not according to the College's mandate or whatever then basically I can't earn a living because my licence is off.* [Man, aged 60 years]

Participants recalled that, as medical students, despite altruistic motivations for entering PM&R, low hierarchical status, limited autonomy, and strict academic expectations fostered vulnerability and feelings of inadequacy, contributing to early burnout experiences:

> *Again, obviously I'm a woman so I have a bit of a lens there, but imposter syndrome, which I think is more common in women, but I still feel…* [Woman, aged 35 years]

Participants described that medical schools exert authority over those who were underperforming, dictating eligibility for module completion or exclusion from training. Self-care was not explicitly emphasized and seen as antithetical to the culture of medicine:

> *And rather than being harsh towards yourself when you make mistakes or whatever, it's being non-judgmental and kind to yourself pretty much…Well that's definitely not a part of medicine.* [Man, aged 39 years]

> *Well, I'm saying that I don't think that there is a curriculum in medicine that teaches people self-compassion and work-life balance.* [Woman, aged 58 years]

Participants described how this scenario continued into their PM&R residencies, where, as trainees, they had to meet performance standards based on long working hours and antisocial working patterns. These demands prevented them from spending time with friends and family, exercising, and attending to diet and sleep. Autonomy became restricted due to strict shift patterns, and as residents, they remained dependent on guidance from their superiors. During this stage, participants described how burnout loomed large as an ever-present threat:

> *I did burn out in PGY2 and that was the reason I left, is when I had no more compassion for my patients, like I had no empathy for them. I just didn't care. I think it was more me being exhausted and other things and then when my patients started pissing me off to be honest. It was just whenever they would talk to me about things, I was like, why are you complaining about this.* [Woman, aged 32 years]

Participants described that as they transitioned from being a trainee to becoming a fully qualified physiatrist, they took on a greater responsibility and became exposed to greater distress in their patients, "Being a physician, especially for a long time, especially dealing with nasty stuff, I think, if you do let that stuff get to you, it's going to be really hard to succeed in the long run" (Man, aged 41 years), and increasingly aware of health care system limitations, which was a source of moral distress:

> *I want to be compassionate for the people in front of me, whatever role I'm having, whether it's for students and residents or whether it's for the patients and families. But I'm coming up against either structural or system or contextual issues that don't let me do the thing that I think is the right thing to do, and that causes distress* [Woman, aged 43 years]

Risk of burnout was described by participants as ever-present as they struggle to balance growing personal and professional responsibilities. Constant oversight and stringent reporting requirements were seen to create a culture prioritizing protocols and metrics over patient-centered care, participants perceiving institutions to prioritize efficiency over quality in interpersonal interactions:

> *And when you're dealing with human beings, that's extremely difficult to individualize a program for somebody in a system where you're actually a datapoint.. success is measured by the number of patients sometimes just seen, not even healed, not even heard, not even spoken to.* [Woman, aged 49 years]

The chronic lack of resources, including inadequate staffing and time constraints, was described by participants as leaving them feeling pressured to prioritize logistical demands over holistic patient needs. Heavy administrative duties and systemic constraints were seen to undermine emotional openness and sensitivity to patient distress. In this context, participants described how they may come to view compassionate care as ancillary rather than a core element:

> *I think it's like going over and beyond for patients. And also, being there for them emotionally, even though that's not really part of your job description, but sometimes they just need a Kleenex and need somebody to give them a hug.* [Woman, aged 37 years]

Consequently, as Canadian physiatrists' advance in their careers within such a framework, there may be a gradual erosion of emphasis on compassionate care in favor of meeting normative peer appraisal, health care institution, and regulatory demands. Institutional wellness initiatives were perceived as misdirected, emphasizing personal responsibility for burnout and failing to address core cultural and systemic issues:

> *We can exercise, we can mediate. We know those things. Those are not the things that we need changes on. We've all made those changes already. We need*

XSL•FO
RenderX

> *the help in the change in the system. They're the system factors that get us down* [Woman, aged 49 years]

The Hidden Curriculum and Its Damaging Effects in Physical Medicine and Rehabilitation

A hidden curriculum, rooted in medical school and reinforced through professional role modeling, was described by participants as shaping behaviors and attitudes that can drive burnout and erode well-being across a physiatrist's career. Such a hidden curriculum was seen as subtly prioritizing professional achievement over compassion, system efficiency over patient-centered care, and physical treatments over addressing emotional distress.

> *I think compassion is really a hidden curriculum kind of thing, and depending on who you're exposed to, you might or might not get any direct instruction on how it is to be compassionate to people. [Compassion] is not really emphasized a lot in medicine compared to clinical expertise. Our recruitment process and training is directed around shutting down self-compassion.* [Woman, aged 33 years]

These implicit lessons were described as conflicting with the altruistic motivations that draw many physiatrists into medicine:

> *Yes, of course. If you're a human being, you're going to be emotionally affected by other people's struggles, your patients' struggles. And that's why you end up in medicine, right, because you really want to help people.* [Man, aged 45 years]

Participants described that in the hidden curriculum, experiencing burnout is seen as a sign of weakness. To be successful in this arena, participants described how they must meet peer and professional standards at all costs:

> *And then, some of that worry about what other clinicians are going to think about my decision making and choices, and how that's going to affect long-term relationships, both with the patient, but also with the other clinicians in the workplace.* [Woman, aged 33 years]

The stakes were described as high, margins for error small, and risk of shame apparent:

> *…If we mess up, it's a big deal…the culture of we expect a lot from our students and learners in, I find it's sometimes not realistic.* [Woman, aged 32 years]

Indeed, participants recounted how to meet the demands of their work, they often had to sacrifice parts of themselves:

> *I definitely have at different times throughout my career. Having relatively recently finished residency, trying to balance work as well as studying for the [regulatory board] exam. Trying to have any semblance of social life and I mean that very loosely, seeing your parents every now and then. It's not like I see my friends or do anything really for myself all that often.* [Woman, aged 35 years]

Maintaining this level of professional performance was described as exhausting, physically and emotionally, and to deal with this, physiatrists take steps to minimize the stress they are exposed to in their work.

Participants also described that, to be a successful physiatrist in Canada, this often involved maintaining emotional distance from their patients to avoid burnout and manage the high demands of the profession:

> *I find those very challenging because I'm just trying to sling through and get through my day treating physical problems. But then when you have these mental problems that make it more challenging to treat the physical problem, I think that takes a lot of time and effort and just makes your job more difficult and it requires more empathy which is draining.* [Man, aged 32 years]

And, although participants recognized that distress is both physical and emotional, many did not feel they had been well prepared through their medical education to deal with emotional distress prevalent among their patients:

> *I was downright angry at my medical education early on.. we never even talked about stuff like this, let alone how feelings and emotions get in the way of healthcare.* [Man, aged 60 years]

> *I am generally treating physical problems and often times peoples' psychological distress or mental health problems can worsen their physical symptoms and I just, that's not a population that I do well with.* [Man, aged 32 years]

Thus, physiatrists may view emotional distress as not within their purview, leading to compartmentalization of care:

> *And I think a lot of my colleagues, especially on the outpatient side in Canada, end up seeing a lot of run-of-the mill chronic pain, which ends up being people complaining a lot. I don't have to see a lot of that and so that helps me, because I actually see real suffering. Not real suffering, psychological suffering is still real, but I'm not trained to deal with the psychological suffering of things like chronic pain.* [Man, aged 41 years]

As such, Canadian physiatrists may become desensitized to the emotional needs of themselves and their patients, focusing primarily on efficiency and protocolized medicine. However, burnout can still result from the forces of this hidden curriculum, and results can be stark. For some, there is frustration and anger towards the system, as they feel there is no time to be compassionate due to the overwhelming demands of the job,

> *So, the things that get me burnt out would be like when I have a huge amount of work in a short period of time and I don't know how I'm going to be able to get it done. A lot of work and no time, and uncertainty about how I'm going to be able to get through.* [Man, aged 48 years]

XSL•FO
RenderX

Others might become disenfranchised completely, adopting the belief that fixing the broken health care system is not their responsibility:

> *No, I have no interest in doing that. It's too much of an uphill battle.. I would have to put all of my other interests and hobbies in life aside and have to focus on mobilising myself to participate in the process of improving Canadian healthcare, which I am completely unwilling to do.* [Man, aged 41 years]

Physiatrists Lead Multidisciplinary Teams and Focus on Adaptation Rather Than Cure

Participants in this study described the work that they do in PM&R as about leading teams, with a focus on adaptation rather than cure, a source of optimism, enthusiasm, and reward for physiatrists, with many iterating that this was where they derived most joy in their work, and felt most able to help:

> *I think that's why rehab is so rewarding. I know that [short-term wins] make a big difference… It's often those little extra moments that you take.* [Woman, aged 34 years]

Participants emphasized helping patients adapt to disabling conditions and improve quality of life, rather than "fix" a diagnosis. Participants described that involving patients in their care fosters control and confidence but requires physiatrists to have a deep understanding of individual circumstances, often eliciting profound and painful empathy in the process.

> *Really severe impairments. Patients that are so injured or have terrible conditions that are very debilitating. It's very easy to find compassion and empathy for those people. When you also see people who lose a limb, or have a, are paralysed or something. It's very easy to build your compassion up and feel for that person because it's terrible. It's subjectively an awful thing.* [Man, aged 32 years]

> *I also try not to absorb the terrible situations all the time and say it's a terrible situation, but I think subconsciously, because I see it all the time and they're all terrible situations. Usually people that are coming to our services are not coming because of a good situation.* [Woman, aged 47 years]

However, using the knowledge derived from a deep understanding of patient distress, participants described how, as physiatrists, they sought to create tailored care plans that optimize functional independence in their patients. This holistic approach was seen as fundamental to the conceptualization of PM&R, but also exposes physiatrists to difficult emotions:

> *I think the patients often express frustration in different ways… It's not as glamorous or as immediately effective as they had anticipated. And so, that often comes out to us as, 'why aren't you fixing this and why is that not working?* [Woman, aged 47 years]

Participants spoke about the need to boundary themselves in relation to the emotions of others, and to see the limitations of the health care system in which they work with realism and detachment, otherwise they might be quickly overcome by cynicism and burnout. Indeed, participants perceived that forbearance was expected from them in the face of abuse and that, in the predominant culture, their emotional well-being was not a priority:

> *We take a lot of verbal, emotional, sometimes even physical abuse. The expectation is often to just keep providing care and keep being compassionate. But that's not so simple in practice. I do find that can be a real challenge.* [Woman, aged 34 years]

> *We should be, somebody, at the end of the day has said, you know what, I heard about that patient, it was rough. How are you doing? That must be a really tough thing that you had to deal with, how are you feeling? I think that everybody just presumes that they're… Everybody else is stressed out, how is that any different than yours.* [Woman, aged 47 years]

Breaking bad news was another area of PM&R, which participants described as perennially difficult in an emotional sense, especially when patient and family expectations were unrealistic, or were not met, and this experience undermined physiatrists' sense of proficiency:

> *I think sometimes [patients] want a magic pill to make all their problems go away without any side effects of any work on their part… That is that part that I find the hardest. When you strive to go above and beyond and give people ten things they can do but they have excuses… they don't ever get better.* [Woman, aged 35 years]

As physiatrists coordinate and guide multidisciplinary specialist rehabilitation teams, including deliberating over access to care, participants described how they could often be a focal point for venting from other health care providers:

> *Eventually my team pushed me to act on it, like could you do something to potentially protect her, but me knowing that there really isn't an ethical or legal way to go about making this decision on behalf of the patient, I felt very uncompassionate towards my team in that situation.* [Man, aged 35 years]

Participants also spoke about a sense of not being appreciated broadly, by patients, institutions, system leaders, and even peers. They described how feeling unappreciated by others left them feeling isolated, disconnected, and disillusioned, "Nobody, from a physiatry perspective, has said 'we appreciate what you do.' For that reason, I've tended to work more collaboratively with my colleagues in other specialties rather than my own colleagues here, which is maybe unhealthy" (Woman, aged 47 years), and disillusioned with the health care system at large. When feeling this way, participants were less inclined to listen to the nuances in patient stories and more inclined to objectify patients:

> *seeing them as their diagnosis. Like, oh that's the cervical myelopathy, and seeing it as their list, the tick list of things that you've got to do on rounds, to follow up and you're just doing it to make sure that you've done your job.* [Woman, aged 47 years]

XSL•FO
RenderX

Bureaucracy Alongside Hierarchy

Bureaucracy and hierarchy were described by participants as contributing to burnout in PM&R by shifting focus from patient care to rules, paperwork, and complex approval processes, particularly for disability income support. This pervasive administrative burden was felt to foster powerlessness, frustration, and demoralization, subtly eroding autonomy and engagement more insidiously than direct authoritarian control.

> *Stupid rules that make no sense and that take a lot of time and effort to work around. So, dealing with the bureaucracy of stupid rules... And that causes a lot of frustration and wasted energy that could be used on other things. Stupid rules... we need to have some ways to be able to say, some direct lines to be able to call somebody and say, this is why this one shouldn't follow the rules and have someone at the other end being able to say okay. I get it. Yes.* [Woman, aged 55 years]

Participants perceived rigid rule enforcement as nonsensical, adding unnecessary distress to patients and physiatrists alike. In this context, participants described feeling disconnected from their initial sense of purpose, their professional identity overshadowed by the sheer volume of administrative work, which they felt obliged to do in their derived social and professional roles:

> *Oh, I think the paperwork. So, usually, rehab forms or disability forms are at least six to ten, maybe 20 pages long.* [Woman, aged 49 years]

This chronic exposure to perceived impersonal and inflexible bureaucratic hurdles, rather than direct authoritarian mandates, appeared to truly wear down physiatrists, contributing significantly to burnout:

> *Certainly, the burden of documentation, trying to get down all the documents and organize, sometimes some people, they'll need forms filled out, and those can be very time-consuming and at times frustrating. Because you feel like you're writing down things that are already in the record but you have to write them down for the completion of a form for a referral or completion of a form for a disability tax credit, I think documentation definitely.* [Man, aged 61 years]

Discussion

Summary of Main Findings

Using a constructed grounded theory approach, based on retrospective accounts of lived experience among Canadian physiatrists, this study developed a conceptual model of burnout in PM&R, highlighting how medical hierarchy—both explicit and via the hidden curriculum—insidiously shapes professional identity from medical school throughout the practice of PM&R. Unrealistic performance standards, emphasis on academic achievement over compassion, and lack of self-care training erode well-being, foster shame, and limit Canadian physiatrists' ability to respond empathetically. Coupled to this, excessive paperwork, complex administrative processes, and strict regulatory compliance wear Canadian physiatrists down over time.

While PM&R's focus on adaptation and holistic care is fulfilling, burnout undermines Canadian physiatrists' capacity to lead multidisciplinary teams effectively, negatively impacting both colleagues and patients.

Comparison With Existing Literature

No previous studies have used grounded theory to explore burnout in PM&R. However, findings from previous studies using grounded theory to explore burnout in health care providers share similarities with ours. For example, studies in primary care and stroke medicine also suggested systemic issues such as excessive workloads, shifting job roles, and misalignment between personal and institutional values, lead to burnout [31,32]. Likewise, professional dissonance in these contexts also led to feelings of demoralization and a sense of being undervalued [31]. Among nurses, distressing relational aspects of health care also featured in conceptualizations of burnout, particularly during personal interactions, shaping care provided [33], and social support played a mitigating role, affecting emotional responses and some components of attitudinal reactions [33]. In our study, Canadian physiatrists highlighted how they felt ill-prepared for the emotional demands of the work of PM&R, and professionally isolated amid a culture of expected forbearance in the face of emotional distress, where support for their own distress was limited.

Limited literature addresses the origins and sustaining factors of burnout in PM&R. A recent US qualitative study identified similar themes to ours, including the impact of perfectionism, stigma around disclosing distress, and burdensome administrative tasks. Participants advised younger physiatrists to maintain "agency," set boundaries, and practice self-compassion to prevent burnout. These comparisons are interesting but derive from the unusual context of the COVID-19 pandemic, and are not in relation to origins or factors sustaining burnout in Canadian physiatrists [34].

With regards to the overarching concept identified in our study, of hierarchy in medicine, this is a well-recognized phenomenon [35], but has not been described previously in relation to burnout in PM&R. Hierarchy in medicine has been described as a means of imbuing power to make and enforce decisions based on knowledge and role that allows for autonomy and self-governance in the profession. Hierarchies in medicine can be conceptualized in both negative, "dysfunctional," and positive, "functional," terms. In dysfunctional medical hierarchies, those of lower status in the hierarchy are subject to lower health [36], trainees lack psychological safety and agency, and can be subject to outright abuse. In this way, hierarchies can be harmful, not just to those in low-status positions, that is, medical students, residents, but also to patients, collaboration among multiprofessional teams, which is highly relevant in PM&R.

However, it is important to note that hierarchy may also be beneficial, at the macro level, with enhanced performance and evolvability of modular systems [37], but also for the meso (institution, team), and micro (individual) levels, with role and

XSL•FO
RenderX

expectation clarity, enabling a social order that serves a greater purpose, which can support a culture of efficiency, and patient safety where the most responsible clinician is the one making critical decisions regarding patient care, particularly when risk is high, and time is pressured. However, to do this in a way that supports social justice and compassionate care likely requires openness and clarity around normative values and conscious and accountable oversight [38]. If not, hierarchy can also be the basis upon which a hidden curriculum, that is, social norms, can develop, including those around punishment, reward, and progression upwards within the hierarchy. Indeed, medical students appear to actively seek to decipher which behaviors their supervisors value most and to preferentially cultivate these [35]. The implications for the development of compassion, or less desirable behaviors [39], at the individual and organizational levels thus seem clear.

Our theoretical framework, the looking-glass self, provided a helpful lens to explore the origins and factors sustaining burnout in PM&R. Physiatrists in our study relayed how the culture of academic elitism in medicine can lead to adverse social comparisons, imposter syndrome, self-criticism, and shame. In keeping with the looking-glass self precept, Gilbert defines shame as a form of undesired self and a form of social disconnection, but differentiates self-shame from social shame perceived to arise from the judgment (and rejection) of others [40]. Unfortunately, shame is a well-described phenomenon in medical education, which can relate to mistreatment, substandard academic performance, social comparisons, and can be reinforced by hidden curricula. Bynum [41] suggests that shame within medical education can be prevented by explicitly eliminating shame-based teaching strategies, creating a culture of inclusion, and facilitating a mindset of growth in learners. Among internal medicine trainees in the US, exposure to a hidden curriculum (unprofessional conduct, including humiliation by colleagues and patients, disrespectful behavior towards patients) has been found to correlate significantly with all 3 core domains of burnout [42]. Indeed, research into hidden curricula in medical education has previously identified that assessment criteria (which drive what medical students see as being prioritized) do not emphasize compassion as a competency being assessed [43]. We found that self-compassion is seen by Canadian physiatrists as antithetical to the medical training they received. This is unfortunate, as training in self-compassion can help health care providers better self-care, improve compassion for others, and may be protective against burnout with moderate to large effect sizes [44], whilst Compassionate Mind Training may be particularly beneficial in addressing shame-based disorders associated with burnout [45].

Strengths and Limitations

This is the first qualitative study examining the origins and sustaining factors of burnout in PM&R. Strengths include a large, diverse Canadian sample, rigorous methods, and varied team perspectives. Limitations include the majority of participants being full-time urban physiatrists from Ontario, a lack of regional analysis, and a cross-sectional design, which may miss formative early-career experiences and long-term patterns in burnout development. No PM&R residents being interviewed is a notable limitation because many of participants indicated origins of burnout date back to experiences in medical school and residency. We used Canadian PM&R leaders to identify participants, consistent with purposive sampling but potentially introducing selection bias. Self-reported interviews may also be affected by recall or social desirability biases. As a preliminary grounded theory, the framework is at an early stage, may not capture all nuances of burnout, and requires further empirical validation. Findings are specific to Canadian PM&R and may not generalize elsewhere.

Future Directions

Future research should explore the views and experiences of PM&R residents and specifically seek to delve deeper into how intersectional factors influence burnout among physiatrists from marginalized backgrounds within Canada and elsewhere. Research should consider how aspects such as immigration status, ethnic minority status, religious beliefs, and sexual orientation intersect with burnout experiences. Marginalized physiatrists might face unique stressors related to their identity that impact their professional experiences differently than those of their peers. For instance, immigrants might deal with additional challenges related to cultural integration and professional validation, while members of minority ethnic or religious groups might encounter systemic biases or discrimination. It would also be very useful to explore how regional variation in normative organizational culture, health care systems, and wellness practices influences the experiences of physiatrists with respect to hierarchy, hidden curricula, bureaucracy, and burnout.

Conclusions

The origins of burnout in Canadian physiatrists relate to a hierarchical performance paradox that appears to be seeded early in their careers. Budding Canadian physiatrists cite altruistic motivations for joining the specialty, but it is difficult to maintain compassion for oneself and others amidst a hidden curriculum that prioritizes academic elitism over compassionate care. Risk of burnout among Canadian physiatrists is described as peaking in residency but is also ever-present due to the emotionally demanding nature of the work for which they feel ill-prepared, fragmented health care systems, and societal bureaucracy around disability. Burnout can be a source of shame for Canadian physiatrists and is perceived as having the potential for severe professional repercussions. Canadian physiatrists value positive peer appraisal and emotional support (ie, a supportive community); this provides a potential inroad to addressing some of the factors that are responsible for burnout in the specialty.

Abstract

Background: Evidence-based nonsurgical osteoarthritis (OA) care programs improve patient outcomes and may reduce the burden of disease. Despite their demonstrated effectiveness, their implementation into routine health care remains limited across health care systems. Understanding factors that facilitate or hinder implementation is essential to support broader adoption and long-term sustainability worldwide.

Objective: This study aimed to explore factors that facilitate or hinder the implementation of evidence-based nonsurgical OA care programs. Specifically, it examined implementation across different health care settings, implementation phases, and analog, digital, and blended care models to identify transferable insights for implementation in different national and regional contexts.

Methods: We conducted a qualitative expert interview study with 12 international experts involved in evidence-based OA care programs implemented across 6 countries. Semistructured interviews explored experiences with program development, implementation, and further development of analog, digital, and blended care models. Interview transcripts were analyzed using qualitative content analysis according to Kuckartz, using deductive and inductive category development.

Results: Key barriers included limited funding and reimbursement structures, insufficient political support, organizational complexity, and legal or regulatory requirements. Important facilitators comprised strong leadership, interdisciplinary collaboration, structured communication, adaptation to local health care contexts, and the use of existing international program structures. Participants further emphasized that implementation requirements varied across the preparation, initial implementation, and consolidation phases, highlighting the need for phase-specific implementation strategies.

Conclusions: Successful implementation of evidence-based nonsurgical OA care programs requires sustainable funding, stakeholder engagement, context-specific adaptation, and structured implementation planning across all implementation phases. Existing international program structures and collaboration may facilitate implementation across health care systems while reducing development efforts. Future implementation initiatives should consider phase-specific requirements and local contextual factors to improve long-term adoption and sustainability.

KEYWORDS

physiotherapy; blended care; implementation science; osteoarthritis; osteoarthrosis; musculoskeletal diseases; conservative treatment

Introduction

Prevention and health promotion approaches are becoming increasingly important in health care. One area in which such approaches have shown promising results is the management of knee and hip osteoarthritis (OA). This musculoskeletal disease affects up to 40% of people older than 65 years [1], leads to high costs [2], and causes a burden on patients.

XSL•FO
RenderX

For mild to moderate OA, guideline-recommended treatment is nonsurgical and combines patient education, exercises, and weight reduction [3-5]. These components are increasingly delivered through structured OA treatment programs, spanning analog, digital, and blended care models implemented at regional, national, and international levels. Such programs may be developed specifically for OA or adapted from interventions targeting other musculoskeletal conditions. Evidence suggests that these approaches are safe, effective, cost-efficient, and suitable for routine care [3].

Despite growing evidence and international interest, the integration of OA programs into routine health care remains limited [6]. Consequently, patient access outside research settings is often restricted [6,7]. The limited uptake reflects the continuing challenge of translating research findings into clinical practice [4,7].

Despite growing evidence supporting OA care programs, important knowledge gaps remain regarding how these interventions can be successfully implemented across different health care systems, delivery models, and implementation stages. To address this gap, we conducted qualitative interviews with experts involved in established OA care programs. The study addresses the following research question: What factors influence the implementation of evidence-based OA treatment programs across different health care settings, implementation stages, delivery formats (digital, analog, and blended), and stakeholder groups?

We explored barriers and facilitators to implementation across health care settings, implementation stages, delivery formats, and stakeholder groups.

By synthesizing expert perspectives across multiple international programs, this study aims to provide practice-oriented insights into implementing evidence-based OA care in routine practice and contributes to the broader implementation science literature [8].

Methods

The reporting of the study results follows the COREQ (Consolidated Criteria for Reporting Qualitative Research) framework [5].

Study Design

The qualitative approach was chosen due to its suitability for exploring contextual and implementation-related factors that cannot be fully captured through quantitative methods. We conducted semistructured interviews with experts in the field of treatment programs for knee and hip OA as well as back pain.

To identify relevant programs, we first carried out a rapid review focusing on conservative treatment programs for knee and hip OA [7]. Based on this rapid review, we assembled a list of existing approaches and consulted international experts to gain insights into national characteristics and contextual influences.

In addition to OA programs, the review identified one back pain program that had been developed through adaptation of an established OA program. We included this program because it represented a unique example of how implementation strategies and program structures can be transferred across musculoskeletal conditions. Its inclusion enabled exploration of implementation processes beyond a single diagnosis while maintaining a focus on comparable nonsurgical, exercise-based care models.

The selected interventions additionally provided insights into how treatment concepts have been adapted across countries and how care models differ between analog, digital, and blended care [9].

Program Overview

The included programs differed in their form of delivery, implementation strategies, and national contexts. Better Management of Patients with OsteoArthritis served as the foundation for the subsequent development of GLA:D (Good Life with osteoArthritis in Denmark) [10,11], while Joint Academy emerged as a digital adaptation designed to improve accessibility and overcome barriers to participation in conventional OA care [12]. Studies accompanying the GLA:D program showed a significant reduction in the risk of being unable to work due to knee or hip OA, as well as improvements in pain intensity, physical resilience, and everyday activity [6,11].

Although differing in form of delivery and organizational structure, the programs shared a common evidence-based treatment philosophy.

Recruitment and Participants

JB and TSB designed the recruitment strategy to target participants with specific expertise in implementing OA treatment programs for knee and hip. Eligible participants were professionals who had been directly involved in the development, coordination, implementation, or scientific evaluation of one of the identified programs. The interviewers (JB and TSB) had no prior professional relationship with the participants before recruitment except for one participant, with whom they had had occasional contact during a joint project in the past. This did not affect the interview situation.

The participants were informed that both researchers are currently working on the facilitating and inhibiting factors in implementation research and about the insights they had gained from the rapid review mentioned above.

In the beginning, JB and TSB compiled a list of all OA treatment programs for knee and hip that had been identified worldwide in the previously mentioned review. JB and TSB then identified and contacted the program coordinators responsible for the development and implementation of these programs. In addition, they expanded recruitment through expert recommendations provided by interview participants (snowball sampling). Recruitment continued until additional interviews were considered unlikely to provide substantially new insights regarding the implementation processes under investigation.

The research team invited all identified candidates via email to participate in the study. Candidates were asked to complete a short questionnaire regarding sociodemographic information.

XSL•FO
RenderX

In total, the research team contacted 30 experts and one additional contact email address for a specific treatment program. Twelve experts agreed to participate in the study. Recruitment and interviews were conducted between August and October 2023. The final sample was considered appropriate because it captured experts from multiple countries, health care settings, and implementation roles, providing sufficient variation to address the study aim.

Data Collection

Interviews were conducted in English or German, depending on the interviewee's language preference. Accordingly, we developed the interview guides in both languages and ensured full content equivalence across both versions.

The interview guides were reviewed by an orthopedic surgeon for technical adequacy and by a team of research assistants from the Institute of General Practice and Family Medicine at Ruhr University Bochum during a qualitative research workshop. This review process focused on content relevance, comprehensibility, and alignment with the study objectives. Revisions were made iteratively based on the feedback received and discussed within the group of authors.

The semistructured interview guides (see Multimedia Appendix 1) focused on 4 key thematic areas:

1. Background information about the treatment program and the expert's role within it;
2. Description of the implementation process;
3. Experiences in program development since implementation; and
4. Considerations, expectations, and wishes for future development of the program.

Interviews were conducted by 2 female researchers (TSB: doctoral degree in health sciences; JB: MSc in health economics), both trained in qualitative research and employed at the Institute of General Practice and Family Medicine at Ruhr University Bochum at the time of the study. In most cases, both researchers attended the interviews—one leading the interview and the other monitoring the process and taking notes. TSB and JB took turns in this role to ensure consistent quality.

Neither interviewer was involved in the development or implementation of any of the included OA treatment programs. This helped to reduce potential conflicts of interest and enabled participants to discuss implementation experiences from an external perspective. Throughout data collection, the interviewers documented contextual observations and reflected on potential influences on the interview process in field notes.

All interviews were conducted via videoconferencing (using Zoom by Zoom Communications), audio-recorded, pseudonymized, and transcribed by a professional transcription service. German interviews were transcribed verbatim in German, just as English interviews were transcribed verbatim in English. The interviews were always analyzed in the original language. German quotations selected for publication were translated into English by the research team, and the translations were checked by 2 different authors.

In one case, the formal interview was preceded by a detailed preliminary conversation, which the participant had requested before agreeing to the interview. During this conversation, the participant described his role in the program. The participant consented to audio recording only after this preliminary exchange and had limited time available. To avoid redundancy and respect these constraints, the thematic first block of the interview guide was omitted during the recording. This interview was still included in the analysis, as 3 researchers (JB, JN, and TSB) independently agreed that the data provided sufficient contextual richness. The preliminary conversation was not included as primary interview data.

Data Analysis

We analyzed the interview transcripts using qualitative content analysis following the approach described by Kuckartz [13]. Interviews were transcribed shortly after completion of data collection and prepared for analysis. The formal coding and category development were conducted between September and November 2024 using MAXQDA software by VERBI GmbH (TSB: MAXQDA 2024; JN: MAXQDA 2022). The time lapse between data collection and analysis is attributable to the authors' new professional positions and the subsequent conclusion of the project, which prevented them from working on the project earlier, and is not due to changes in the dataset. Coding was performed in English. Two researchers (TSB and JN), both holding doctoral degrees in health care science and trained in qualitative research, independently coded all interviews. Discrepancies were discussed during regular analytical meetings. Where differences in interpretation occurred, both researchers revisited the original transcript segments and agreed on a final coding decision through discussion and consensus.

We applied a structured content-analytic approach combining deductive and inductive category development. Initial main categories were derived deductively from the interview guide, while additional categories were generated inductively from the data. Throughout the analysis, the coding framework was iteratively refined and continuously compared across interviews to ensure analytical consistency.

To enhance credibility, a third researcher (JB) with experience in qualitative content analysis reviewed the final category system and code tree for plausibility, coherence, and completeness. Feedback from this review informed the final interpretation and refinement of the category system, which was finalized in March 2025.

Methodological rigor was supported through independent coding, regular consensus meetings, and review of the final category system by a third researcher. Field notes were used to contextualize interview data and support interpretation.

Ethical Considerations

The study received a favorable ethics vote from the Ethics Committee of Ruhr University Bochum (register number 21-7438) in February 2022.

Interested individuals received detailed study information outlining the study's objectives, scope, and participation

XSL•FO
RenderX

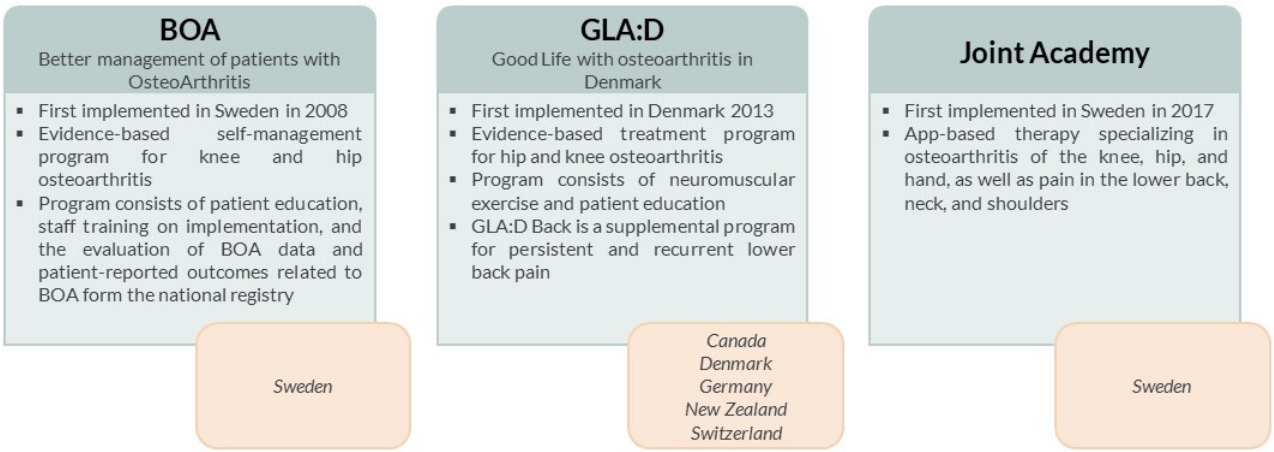
requirements. To formally participate, candidates were required to sign a declaration of consent. Participants returned the signed consent forms via email.

Participation in the interviews was voluntary. Participants could at any time—even without giving a reason—decline to participate or withdraw their consent and leave the study without suffering any adverse consequences as a result.

Participants did not receive compensation for the interviews.

Results

Participant Overview



The recruitment process resulted in 12 completed interviews with experts involved in 8 different treatment programs. The interviews ranged from 33.42 to 65.02 minutes, with an average duration of 49.5 (SD 9.42) minutes.

The majority of experts (8 of 12) were affiliated with the GLA:D network, making it the most represented program in the sample. Specifically, experts participated from GLA:D country programs in Germany (n=2), New Zealand (n=2), Switzerland (n=2), Canada (n=1), and Denmark (n=1). Another expert from the Danish GLA:D Back program (n=1) took part in an interview. In addition, experts from the Joint Academy Program (n=2) and the Better Management of Patients with OsteoArthritis program in Sweden (n=1) were interviewed.

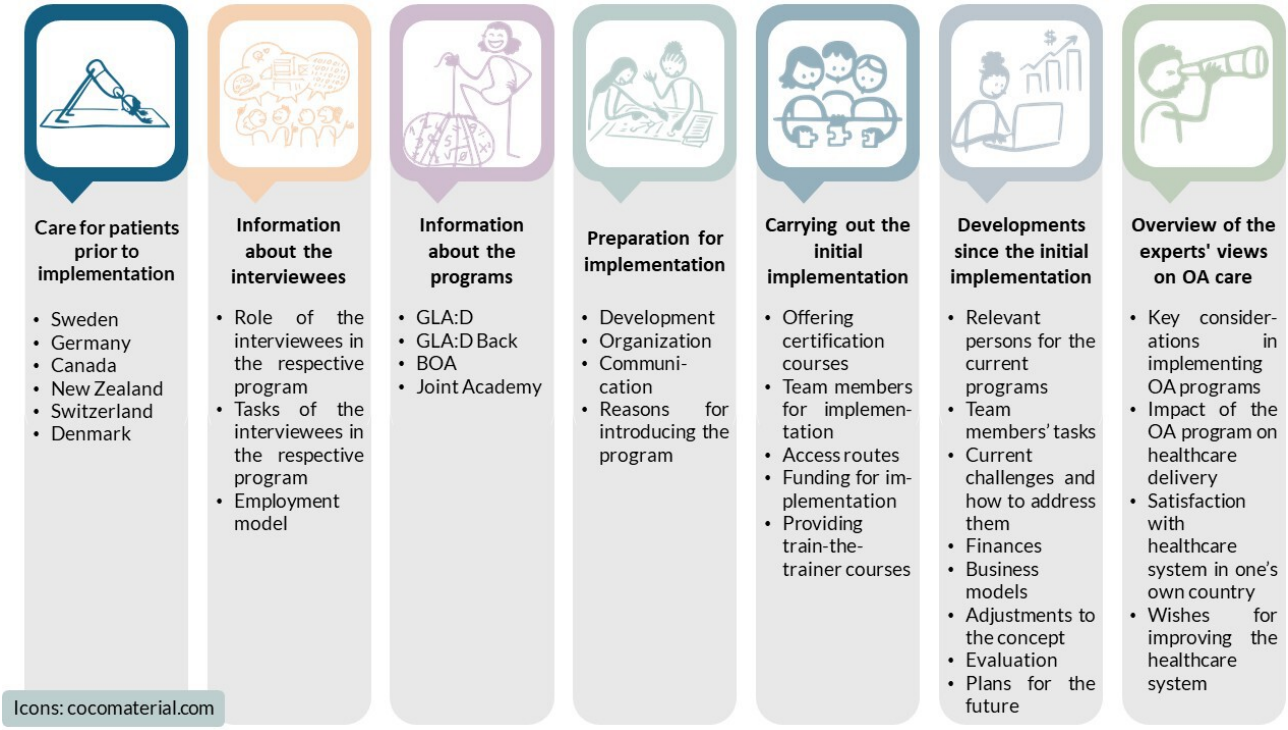
Figure 1 provides an overview of the programs in which the experts were involved, detailing their structural characteristics and the national context in which the interviewed experts had worked.

The age of participants as of 2024 ranged from 35 to 81 years, with an average age of 53.4 years (SD: 13.35). Three experts identified as female and 9 as male. To protect the anonymity of the participants, no further sociodemographic data are reported in this publication.

Figure 1. Overview of associated osteoarthritis treatment programs (own representation). BOA: Better Management of Patients with OsteoArthritis; GLA:D: Good Life with osteoArthritis in Denmark.

Results of the Data Extraction

Category System



During the analysis, the research team assigned 1043 codes to 7 main categories covering contextual information on care provision before implementation, interviewee and program characteristics, implementation processes, program development, and overarching reflections on OA care.

A detailed overview of the category system (first level) is provided in Figure 2. Although the overall coding combined deductive and inductive category development, the 3 implementation phases emerged inductively from the interview data and were subsequently used to structure the presentation of the findings.

A detailed overview of the category system (first level) is provided in Figure 2. Although the overall coding combined deductive and inductive category development, the 3 implementation phases emerged inductively from the interview data and were subsequently used to structure the presentation of the findings.

Across programs and countries, experts described implementation as a dynamic process consisting of 3 interrelated phases: preparation, early implementation, and consolidation. Although individual programs differed in their design and organizational context, similar implementation challenges and enabling factors emerged across settings. The following sections present the findings according to these implementation phases.

These implementation phases provide the framework for the presentation of the results in the following sections. Despite variations in program design (see Figure 1), a collective reporting approach addresses the research questions comprehensively.

Preparation and Development

Reasons for Introducing the Program

Across programs, implementation was primarily motivated by perceived deficiencies in existing OA care pathways. Experts described the introduction of OA programs as an opportunity to improve access to evidence-based treatment, reduce regional inequalities, and standardize care delivery. Established implementation models, particularly GLA:D, frequently served as inspiration and provided practical guidance for local adaptation.

> *The main goal is to give a more equal healthcare to patients with OA in [Country]. Because we knew back in the days it was a little bit different depending on where you're living if you're getting an education, a training or not. So, I think equality was the first goal.* [Interviewee 9]

Experts reported that, in several programs, the COVID-19 pandemic accelerated the adoption or expansion of digital and blended forms of delivery and that these models were subsequently valued for their scalability and potential to increase access to care.

Adaptations and Development

The development process ranged from entirely new programs to adaptations of evidence-based programs. One program, for example, began as a small university pilot that underwent multiple iterations before public rollout. Development tasks included designing analog materials (eg, screening tools, educational content, training modules, preparation materials) and digital components for blended care, as well as setting up data registries.

With the help of train-the-trainer models, therapists were able to deliver the program independently.

In the case of GLA:D adaptations, the Danish team was consulted for linguistic and cultural fit. One interviewee advised building on existing programs:

> *So don't reinvent the wheel yourselves. Even though you might not be happy with all parts of it, I would really encourage you to take on something that is already developed and structured.* [Interviewee 10]

Program adjustments considered country-specific conditions and multicultural environments. Cost-effective equipment, intensive simple training units, and well-developed educational concepts were also highlighted as helpful elements.

Initial Team and Actors Involved

During preparation, work was mainly driven by small core teams consisting of research managers, developers, or project leads. Legal advisors, patients, and therapists provided feedback. Experts emphasized that practitioners from the relevant field should be involved to ensure practical understanding:

XSL•FO
RenderX

> *But you do need to have someone driving it who has a really good understanding of the research and understanding of how that works, the business model, but also the whole training program. [...] And don't get them to do it for free.* [Interviewee 2]

Organizational Tasks

Organizational efforts involved contracts, bureaucracy, university resource allocation, and securing legal permissions, as well as GLA:D license agreements with Danish developers for data transfer.

> *Plus, in the [Country] healthcare context, in the vast majority of cases, universities do not have the resources to enter a program, no matter how good it is, into the healthcare sector.* [Interviewee 5]

Financing

Experts emphasized that securing sustainable financing for program development and initial establishment was a prerequisite for implementation. While funding models differed between countries and health care systems, experts consistently emphasized the importance of reimbursement mechanisms, institutional support, and early engagement with payers. Reliance on short-term project funding was widely viewed as insufficient for long-term implementation.

> *And because we have had good experiences in [Country] with the 18 units that we bill and charge to the health insurance companies, we have decided to adopt this structure identically, but this has meant that we first carry out four times two exercise units in the first four weeks, followed by four times one exercise unit, so that in the end we also have a total of 18 units, which we then bill to the health insurance companies and payers.* [Interviewee 11]

Communication

Communication activities focused on building legitimacy and awareness among key stakeholders. Experts highlighted the importance of engaging professional associations, health care providers, patient representatives, and policymakers early in the process. Public visibility through media appearances, conferences, and awareness campaigns was perceived as an important facilitator of implementation.

> *So I think, looking back (...) the kick-off was really great for us with this TV appearance, even if it took an incredible amount of time and energy to get everything off the ground.* [Interviewee 1]

Carrying Out the Initial Implementation

During rollout, responsibilities expanded to include trained therapists (chiropractors, physiotherapists, physicians, and nurses), scientists, software developers, and regional coordinators. Interviewees emphasized the importance of creating local ownership among clinicians, who frequently acted as ambassadors and facilitators within their professional networks:

> *And on the first, I would say, five, ten courses we were also very focused on ensuring that the new clinicians that had received the course were also ambassadors for the program in their local community.* [Interviewee 12]

Rollouts varied from regional pilots scaling nationally to single-insurer collaborations or multiregion launches.

Initial funding during the rollout phase came from associations, grants, or public sources, though high license fees and missing reimbursements hindered progress.

Consolidation and Ongoing Development

Members of the Program Team and Actors Involved

After implementation, operational responsibility increasingly shifted from the original developers to coordinators, database managers, analysts, and regional contacts. Initial developers stepped back as physiotherapists and coordinators took the operational lead.

> *But then gradually their role was less and less, [...] in the early days they were really important.* [Interviewee 12]

The recruitment of therapists emphasized openness without pressure.

> *So it's usually not so difficult to get a physiotherapist to try. But don't try to convince anyone [...]* [Interviewee 8]

Further Development of the Program

The teams initiated an exchange with physicians on points of criticism regarding the program and regular strategy meetings of the team. Annual reports and health services research supported this process. They facilitated active exchange with patients, providers, health policymakers, and payers.

Feedback From Patients and Providers

Following implementation, experts reported generally positive feedback from both patients and providers. Perceived benefits included improved access to evidence-based care, greater standardization of treatment practices, enhanced professional knowledge among participating clinicians, and low equipment requirements. However, providers also identified barriers related to workload, reimbursement structures, organizational demands (lack of experience with group training and duplication of documentation), and the practical challenges of delivering group-based interventions.

> *But we're getting more and more orthopedic surgeons who see the value of conservative management [...]* [Interviewee 2]

Adjustments Based on the Feedback and Research Findings

Following feedback and research findings, the teams introduced quality assurance measures such as recertification, knowledge checks, and additional support services (eg, support team, coaching, webinars, and information materials), refined program content, revised didactics, and adapted teaching materials.

Some interviewees nevertheless reported a lack of support during implementation.

XSL•FO
RenderX

Organizational Tasks

Team tasks included coordination, organizing, and ensuring data collection. Programs that established registries documented a wide range of clinical parameters at program entry and exit, enabling pre-post comparisons and cross-regional and cross-national analysis. The data ensure quality and help to demonstrate effectiveness to policymakers. In addition, programs with digital components supported adherence monitoring for both educational content and exercise sessions.

Financing

After implementation, financial issues primarily concerned long-term sustainability for registries, quality assurance, administration, and stable reimbursement. The interviewees reported that while therapists faced only minimal costs (eg, for room rental or digital access and the initial train-the-trainer course), initiators bore expenses for the registry, digital design, and administration. It was possible to cover costs through research projects, risk capital, private investments, or self-funding by patients. Payment models varied widely, including national coverage, regional schemes, private funding, coverage by health insurance, or mixed models. Interviewees emphasized the perceived legitimacy of the program:

> *Because if it's available publicly, people think it's got to work better. So, they will pay privately. But if it's not available publicly they go: 'Okay, obviously it's not a good thing.'* [Interviewee 3]

It was mentioned that no funding had been available for many years. To improve financing, interviewees recommended integrating the programs into the public health care system, negotiating with professional associations and health insurance companies, and conducting evaluations to demonstrate effectiveness. Positive developments were underway in some regions:

> *We were probably a year too early with trying to launch the program, because there's been significant funding change and now there is funding for osteoarthritis programs developed by physios from the state and the government.* [Interviewee 3]

Perceived Limitations

Interviewees pointed out that the current structure might meet the needs of highly active patients and that programs lacked long-term motivation methods since lifelong training should be supported. One interviewee reported that personal trainers were introduced to bridge this gap.

Perceived Effects on Care

Experts reported a variety of factors that influence the impact of the respective programs on the care of patients with OA. They highlighted the international exchange for continuous improvement, changes in perceptions of conservative and surgical care, as well as earlier, more consistent, or even initial treatment, and positive treatment outcomes.

> *And it's not such a big benefit for the few who already provide very, very good care. [...] But I think there are many who provide care that is far from the quality standard [...]* [Interviewee 6]

Experts perceived that the programs contributed to earlier access to conservative treatment, greater consistency in OA management, and improved patient outcomes. Several interviewees also reported that patients appeared better prepared when surgery eventually became necessary.

> *[...] it's very important that the patients are in the best possible shape [...] because that will make rehabilitation after surgery better and easier and they will reach a better result of the surgery as well.* [Interviewee 7]

Interviewees underlined the value of group treatment in addressing the shortage of skilled workers and praised the low costs and accessibility of digitally designed programs, especially for patients for whom analog services are not attractive. They additionally pointed out their relevance for highly educated patients, those with multiple comorbidities, those living in urban areas with limited access to programs, as well as those living in rural areas with the same problem. This also has advantages for therapists in view of increased workplace flexibility:

> *And there is a lot of young physiotherapists that like not to be in the office every day in the week [...]. Or you can make your own schedule and still get things going.* [Interviewee 8]

A Glimpse Into the Future

Despite perceived successes, experts identified several ongoing challenges, including insufficient reimbursement structures, continued reliance on surgical care pathways, limited implementation of evidence-based recommendations, and administrative burdens. To address these issues, interviewees emphasized the need for stronger political support, expanded digital services, improved professional education, and sustainable financing models.

> *We need to replace some of our traditional ways with digital ways which are smarter, which are faster, which are lower cost to the system and the patient. And we need to find smarter ways and other ways, many of them digital, to find the resources without getting more money.* [Interviewee 7]

Future priorities included increasing public visibility, strengthening quality assurance mechanisms, expanding programs to new settings and populations, and generating further evidence through registry and health services research.

Discussion

Principal Findings

This study provides in-depth insights into international implementation processes for evidence-based care programs for musculoskeletal disorders, with a primary focus on knee and hip OA and 1 related back pain program derived from an OA model. The findings were obtained from 12 expert interviews. Beyond documenting persistent challenges across preparation, initial implementation, and consolidation phases, our findings reveal a critical disconnect: while international

XSL•FO
RenderX

networks and evidence-based models like GLA:D are widely valued, systematic knowledge exchange and joint solutions remain rare. In some instances, international cooperation even required additional coordination and administrative effort. Nonetheless, the possibility of adapting and translating existing program materials, rather than developing entirely new ones, was seen as a major advantage. Westerlund et al [16] highlight that implementation science encompasses a growing range of frameworks, models, and theories aimed at bridging the gap between knowledge generation and its application in health care practice [9]. Evidence suggests differing perceptions between researchers (knowledge producers) and policymakers (knowledge users) [8]. Knowledge producers tended to underestimate their influence on policy while overemphasizing barriers to implementation [8]. While opinions differ on whether this gap can be bridged by theoretical approaches in implementation science, it can be assumed that the application of theory is explicit and verifiable but might lead to problems being overlooked that are not addressed in theory. Applying common sense for implementations is often based on implicit assumptions and beliefs [13]. Nilsen underlines that implementation needs to be connected to "the real world of implementation practice" [13].

Multiframework Interpretation

Connecting Knowledge, Barriers, and Implementation Practice

To situate the disconnect between available knowledge, perceived barriers, and actual implementation practice, we draw on 3 complementary implementation frameworks following Nilsen's typology of (1) process models guiding the implementation, (2) determinant frameworks, classic theories, and implementation theories explaining determinants of implementation outcomes, and (3) frameworks evaluating implementation [13]. These frameworks did not guide data collection or coding but served to contextualize the generated findings.

Process Perspective: Knowledge-to-Action

The Knowledge-to-Action (KTA) Framework [10] is frequently used in different health care settings for the design, delivery, and evaluation of implementation activities [11]. The action cycle includes central, iterative phases that can be interpreted as conceptually corresponding to the phases presented in the inductively derived categories of our study. Our phase (1) preparation matches the KTA steps 1 - 3 (problem identification, knowledge adaptation, barrier assessment), since experts described their motivations (equity, COVID-driven digitalization) and development tasks (cultural adaptation, train-the-trainer materials). Our phase (2) early implementation matches KTA steps 4 - 5 (tailoring, execution), since regional pilots expanded through local champions and coordination gaps persisted. Phase (3) consolidation matches KTA steps 6 - 7 (evaluation, sustainment), where registries enabled pre-post comparison, although short-term research funding threatened sustainability. The KTA cycle breaks down the phases into specific steps and shows in step 4 (tailoring implementation) that systematic cross-national knowledge exchange was rare, and this gap in the action cycle might prevent scale-up.

Determinant Perspective: Consolidated Framework for Implementation Research

Nilsen underlines that implementation needs to be connected to "the real world of implementation practice" [17]. One suitable framework for the determinant perspective is the Consolidated Framework for Implementation Research (CFIR), originally developed in 2009 [18] and revised in 2022 [19]. It identifies constructs influencing implementation success and effectiveness in 5 main areas (innovation, outer setting, inner setting, individuals, and implementation process), as well as 3 areas in the addendum (antecedent assessments, implementation outcomes, and innovation outcomes).

In the innovation domain, the evidence base of the programs needs to be mentioned (construct of innovation evidence base). The possibility of continuing to use existing evidence-based OA treatment programs and the possibility of adaptation to different (regional) contexts fit the construct of innovation adaptability. Ensuring the program's advantage over other types of treatment (eg, conservative vs surgical treatment; digital vs analog vs blended care) fits the construct of innovation relative advantage. Regarding the outer setting domain, financing emerged as a dominant barrier across phases (construct financing). This prominence of financing across all implementation phases confirms previous implementation research identifying sustainable funding as one of the strongest determinants of successful implementation. Project funding ended post-efficacy proof, while reimbursement negotiations and license costs hindered rollout. Research costs are identified as a frequently mentioned hurdle to implementation [20]. This reflects the broader challenge of insufficient funding for implementation research in health care, where many projects support development but fail to ensure integration into routine care, a problem widely documented across different areas of the health care system [18]. Political support was mentioned as essential but slow (construct policies and law). Political challenges discussed in the interviews relate primarily to national reimbursement policies and regulatory frameworks. As described in the review by Gesulga et al [21], political support constitutes a major challenge when it comes to implementation.

In the inner setting domain, interviewees noted that structured communication channels significantly enhanced program satisfaction and quality, especially in the consolidation phase (construct communications).

In the individuals domain, it became clear that an initially well-connected team with knowledge from the field is particularly important (construct implementation team members). Interviewees emphasized the importance of motivation (construct motivation), technical expertise (eg, in project management, research, and therapy) (construct capability), and existing networks for effective implementation (construct opportunity).

In the implementation process domain**,** the gradual rollout from the regional to national level through local pioneers reflects the CFIR constructs (construct planning). Engaging stakeholders such as national opinion leaders, formally appointed implementation leads, and local pioneers among therapists

XSL•FO
RenderX

accelerated awareness (construct engaging). Registry analyses, annual reports, and feedback loops informed adjustments to content, didactics, and quality assurance measures (construct reflecting and evaluating).

Our findings extend previous CFIR-based work by illustrating how the relevance of specific determinants changes across different implementation phases.

Evaluation Perspective: Reach, Effectiveness, Adoption, Implementation, Maintenance Framework

The RE-AIM (Reach, Effectiveness, Adoption, Implementation, Maintenance) Framework conceptualizes the impact on public health across its name-giving key dimensions, highlighting the importance of evaluating outcomes at the individual and organizational levels [22]. Interviewees prioritized reach (eg, patient access, offering programs in various cost systems), while digital formats addressed accessibility for rural/urban patients, and group training mitigated workforce shortages. Participants perceived improvements in precomparisons and postcomparisons and better preparation for surgery after the programs. Registries enabled cross-national comparisons, supporting policy advocacy from the participants' point of view. Program adoption is hindered by limited therapist uptake, which is further challenged by heavy workloads, reimbursement gaps, and group logistics. Implementation was influenced by train-the-trainer fidelity. Regarding maintenance, recertification ensured consistency, although smaller practices struggled. Feedback loops (patient satisfaction, provider critiques) drove refinements such as recertification and didactics.

Comparison With Existing Guidelines

In 2019, the OA Research Society International published an international consensus guideline on priorities for the effective implementation of OA care, emphasizing, among other objectives, the need for standardized implementation approaches that align with international best practices [23]. Our findings suggest that several of these objectives remain only partially achieved, particularly regarding sustainable financing models (objective 3: operational funding for programs) and consistent reimbursement structures (objective 12: reimbursement of out-of-pocket costs for participants), as well as systematic implementation support and training for clinicians (objective 5: skills, confidence, and training of health care professionals). The experts perceived a persistence of implementation challenges since 2019 and attributed this to slow policy responses, unchanged or fragmented funding arrangements, and insufficient alignment between health system incentives and guideline recommendations.

Synthesis of the Interpretation

Taken together, the 3 frameworks shed light on complementary aspects of implementation. While the KTA framework helps us understand implementation as a dynamic process spanning various phases, CFIR explains the determinants that influence the success of implementation within these phases. RE-AIM complements this perspective by focusing on long-term adoption and maintenance. Our synthesis underscores Nilsen's approach [13], because the combined application of these frameworks and guidelines enables a more comprehensive understanding of the implementation of evidence-based OA care programs in different health care systems.

Limitations

This study represents an important exploratory step toward understanding the implementation of evidence-based OA treatment programs in different international contexts. However, some limitations must be considered.

By focusing on experts, we were able to extract subject-specific expertise regarding the practical implementation of OA programs. On the other hand, the exclusive reliance on expert interviews restricts the range of perspectives, particularly as patient views are therefore not included.

Regarding the selection of interviewees, the overrepresentation of experts affiliated with GLA:D-related programs may have influenced the thematic emphasis of the findings. In addition, the international sample was recruited through purposive and snowball sampling, which may have favored well-established professional networks and highly visible programs while excluding less prominent initiatives and perspectives.

Another limitation relates to the fact that most participants were directly involved in the development, implementation, or management of the programs under investigation. Their close engagement may have influenced the way implementation successes and challenges were described, potentially resulting in a more favorable assessment of the programs.

Although the interview guide covered the main aspects of implementation, it was not explicitly developed using a comprehensive implementation framework. Consequently, some contextual aspects, such as regional or federal policy influences, may not have been explored in equal depth.

By focusing exclusively on qualitative interviews, the study did not include methodological triangulation (eg, additional quantitative data). Consequently, the results could not be supported by multiple types of evidence.

Similarly, the findings were not externally validated through participants or additional stakeholder validation in the sense of member checking. While participant validation is not considered essential in all qualitative research traditions, its absence may have limited the opportunities to further enhance the confirmability of the findings.

Although purposive sampling allowed us to maximize variation in implementation experiences across countries and program types, transferability of the findings depends on similarities between health care systems, reimbursement structures, regulatory environments, and organizational contexts. The findings should therefore be interpreted in relation to the specific health care contexts in which the included programs were implemented.

Future research should address specific gaps identified in this study, including the cost-effectiveness of implementation strategies, the contextual adaptation of programs to diverse health system contexts, and implementation in resource-limited settings.

RenderX

Conclusion

This qualitative study explored facilitators and barriers influencing the international implementation of evidence-based nonsurgical OA programs from the perspective of experts (n=12) involved in established international programs.

Participants emphasized the importance of international collaboration, established program structures, and access to implementation experience. They highlighted the importance of stakeholder engagement, effective communication, and interdisciplinary collaboration throughout the implementation process. Furthermore, participants emphasized that context-appropriate combinations of digital, analog, and blended care models may improve accessibility, scalability, and long-term sustainability of OA programs. Fragmented reimbursement structures and short-term funding were consistently described as key barriers to sustainable implementation.

These insights provide practical guidance for researchers, clinicians, and policymakers seeking to implement evidence-based OA care programs across diverse health care systems while acknowledging the importance of adapting implementation strategies to local contexts.

Acknowledgments

We would like to thank all experts for their time and valuable insights. Many thanks to Professor Kai Bernsmann, who came up with the idea for the original application and supported us in refining the guidelines with his orthopedic expertise. We would like to thank Georgius Agricola Stiftung Ruhr for funding this research. Special thanks to our research assistant for supporting the recruitment process.

ChatGPT (GPT 5.5, GPT 5.6; OpenAI) and DeepL Text translation (DeepL SE) were used to improve the wording.

Funding

This research was funded by the Georgius Agricola Stiftung Ruhr.

Authors' Contributions

JB and TSB developed the concept of the interview study. Both authors developed the guidelines for the interview and conducted the interviews. Both authors wrote the original manuscript of the publication, drafted the included figures and tables, and were responsible for editing the manuscript.
TSB and JN performed the content analysis of the interviews. JB reviewed the results of the content analysis.
NC, BJ, and HCV contributed to the publication through funding acquisition, support in reviewing the interview guidelines, as well as reviewing and editing the manuscript.
ICO contributed to the publication through funding acquisition, reviewing and editing the manuscript. ICO was further responsible for project administration together with TSB and provision of resources for JB and TSB.

Conflicts of Interest

None declared.

Abstract

Background: The global incidence of spinal cord injury (SCI) is between 10 and 80 new cases per million people each year. This equates to between 250,000 and 500,000 injuries worldwide per year. In the United Kingdom, approximately 4400 people per year sustain an SCI. People with tetraplegia report upper limb function as their highest priority for improvement after SCI. Using immersive virtual reality (VR) headsets, physical rehabilitation exercises can be completed in engaging digital environments. Immersive VR therefore has the potential to increase the amount of therapy undertaken, leading to improvements in arm and hand function. There is little evidence supporting immersive VR as exercise in SCI, especially while patients with SCI are undergoing acute rehabilitation. In SCI research, co-design of new interventions is not a widely adopted approach, yet people with tetraplegia want to contribute with their expert knowledge on their experiences of SCI.

Objective: This study aims to explore the lived experiences of people with tetraplegia and specialist SCI therapists related to acute upper limb rehabilitation and identify design considerations for VR-based interventions targeting the upper limb.

Methods: We conducted 7 online focus groups using Microsoft Teams: 4 with people with tetraplegia (n=15; age range, 36-65 years) and 3 with occupational therapists and physiotherapists specializing in SCI rehabilitation (n=11). Participants were asked to discuss their experiences and expertise about acute SCI upper limb rehabilitation and their opinions and ideas on the use of VR for upper limb rehabilitation. The transcripts were analyzed using content analysis, enabling the proposition of design characteristics of a VR-based intervention for upper limb exercise.

Results: The study identified 5 major themes describing the clinical features, treatment, and recovery of people with SCI during the acute stage of SCI, their motivations for participating in therapy, and suggestions for the design of a VR intervention in treating the upper limbs following SCI.

Conclusions: The themes identified in this study allow the elicitation of software requirements for a bespoke immersive VR platform for upper limb rehabilitation following SCI. They can also contribute to a better understanding of the advantages of using VR as an adjunct to upper limb rehabilitation. Additionally, participants used their expertise to suggest factors that would enable the development of a usable and effective intervention, as well as identifying potential pitfalls and software features to avoid during intervention development. These findings can be used to design accessible VR applications for use by people with tetraplegia and their therapists.

KEYWORDS

acute/sub-acute tetraplegia; co-design; focus groups; secondary care; spinal cord injury; upper limb rehabilitation; virtual reality

Introduction

A spinal cord injury (SCI) results from an insult to the spinal cord and impacts nearly every aspect of a person's life. People with SCI usually have a degree of permanent neurological disability, including muscular paralysis and impaired sensory and autonomic function below the level of their injury [1]. The global incidence of SCI is between 10 and 80 new cases per million people each year [2], with 4400 new cases per year in the United Kingdom [3]. The lifetime costs of SCI are estimated to total £1.43 billion (US $1.97) for 1270 cases per year in the United Kingdom [4].

The level of SCI is a major factor determining the degree of independence a person will achieve following injury [5]. Typically, the higher the level of injury, the lower the level of independence [6]. Damage to the cervical spinal cord results in tetraplegia, where function of all 4 limbs is impaired [7]. As well as physical and sensory issues, people with SCI are at risk of pressure ulcers, urinary tract infections, spasticity, autonomic dysreflexia, depression, neuropathic pain, difficulty breathing, and circulatory problems [8]. This multitude of impairments following SCI is associated with lower quality of life [9].

Immediately following injury, patients with SCI require acute medical management. This is followed by a period of rehabilitation as an inpatient. The aim of rehabilitation post SCI is to optimize recovery, restore and maximize function by leveraging activity-dependent plasticity for neurological recovery, learn compensatory techniques for lost function, and prevent secondary complications [10]. Central nervous system plasticity, where neural pathways can be altered in response to an injury and promote recovery, can occur spontaneously and/or as a result of rehabilitation [11]. In the last 30 years, the primary aim of physical rehabilitation of SCIs has moved away from compensatory strategies to neurological recovery, particularly in people with incomplete SCI [12]. Incomplete SCI refers to the preservation of sensory and/or motor function below the level of injury, as opposed to complete injuries, which do not have preservation of sensation or movement [7]. Rehabilitation is lifelong, but it is recommended that rehabilitation starts early after injury to maximize functional status and clinical outcomes [10].

Reducing reliance on care and achieving higher levels of independence with respect to activities of daily living is a major goal for patients and therapists [13]. Improving motor function, especially of the upper limbs, through rehabilitation [14] enables patients to carry out tasks, such as dressing, bladder and bowel care, transferring in and out of a wheelchair, and feeding which may otherwise require a carer [15-17]. Even small improvements in upper limb function can have large effects on a patient's independence [18,19]. It is understandable, therefore, that improving upper limb function is a high priority for people with tetraplegia [13,20-22].

Improvements in upper limb function can be achieved through Activity-Based Therapy (ABT) [23]. ABT, a rehabilitation approach, refers to any intervention that involves high-intensity, repetitive exercises that target activity-dependent plasticity in spinal circuits [24]. The improvements in upper limb function from ABT have greater effects on quality of life when compared to traditional physical interventions targeted above the level of injury [19].

Virtual reality (VR) technology has the potential to deliver upper limb therapy by providing engaging interventions for patients as part of their rehabilitation [25,26]. Immersive VR delivers to the user a real-time digital environment that incorporates multimodal sensory paradigms, including proprioception, kinesthesia, stereopsis (the perception of depth via a stereoscopic display), and spatial audio, along with the ability to interact within the digital environment via head and hand tracking [27]. In these environments repetitive upper limb movements, like ABT, can be performed. VR-based therapy can facilitate greater adherence to therapy [28] and increase access to the most effective rehabilitation strategies for people with neurological disorders [27]. However, currently there are few studies that have investigated the use of VR in rehabilitation of the upper limbs, with most focusing on the chronic stage after injury.

VR-based upper limb therapy has the potential to provide engaging interactive environments within which patients can undertake the same type of movement repetitions as they would in conventional therapy. Due to its immersive qualities, patients may be more motivated to engage in therapy and may be able to complete more repetitions than they would compared to conventional treatment. A total of 6 reviews published between 2019 and 2024 have evaluated the evidence for VR for upper limb rehabilitation following SCI. These reviews included between 3 and 7 studies involving the upper limb. The overall findings from these reviews suggested that the evidence base is limited and that immersive VR appears to be more beneficial than non- or low-immersive VR [28-31]. However, these studies also suggested that exercises delivered in immersive VR could be used as an adjunct to conventional rehabilitation, which requires further investigation.

The VR devices, software, and methodology surrounding implementation used for upper limb therapy vary widely. VR-based interventions also vary in terms of their intended clinical use, fidelity, and cost, and the design and production of the software have rarely incorporated the lived experiences of SCI experts (people with SCI and health care professionals). The input of end users into the development of software, particularly in health care, is important in delivering successful products [32-34]. This process allows highly customized and bespoke projects to be developed, ensuring that the service or intervention is targeted toward the needs of patients [33].

This study forms the first part of a cocreation process for the design of a suite of VR-based exercises for upper limb rehabilitation in the acute SCI rehabilitation context. The aim of this study was to explore the lived experiences of people with tetraplegia and specialist SCI therapists related to acute upper

XSL•FO
RenderX

limb rehabilitation and to co-design immersive VR-based upper limb activities.

Methods

Overview

In this qualitative study, 7 focus groups were conducted online from August to October 2022 to gather opinions and insights from the lived experiences of people with tetraplegia and, separately, SCI specialist therapists with experience of upper limb rehabilitation.

Recruitment (Procedure)

A convenience sample of people with (1) tetraplegia and (2) therapists specializing in SCI rehabilitation were recruited. Although the VR intervention was to be developed for inpatient SCI rehabilitation, in order to fully explore lived experiences of participants with tetraplegia, the study recruited people who had been discharged from hospital having completed rehabilitation.

Participants with tetraplegia were recruited through the third sector organization Spinal Injuries Scotland. Recruitment material was also shared on social media channels (Twitter and LinkedIn). Inclusion criteria for participants with tetraplegia were a diagnosis of nonprogressive tetraplegia, aged ≥18 years, able to attend focus groups and contribute in spoken English, and having been discharged from hospital after receiving upper limb rehabilitation in a spinal injuries unit as part of their treatment. Exclusion criteria were any comorbidities that could preclude participants from attending and contributing to focus groups.

Therapists (occupational therapists and physiotherapists) were recruited through similar social media channels and a WhatsApp group of United Kingdom and Ireland–based SCI rehabilitation specialists. Inclusion criteria for therapists were being aged 18 years or older and able to attend and contribute to focus groups in spoken English.

Respondents to recruitment material emailed AG to register interest in participating in the study. Participant information sheets were provided to these interested parties by email. Participants provided informed consent prior to taking part in the study by either printing and physically signing a digital consent form or completing the form digitally. Participants without the physical ability to sign consent forms provided consent by designating a witness to sign on their behalf [35].

After providing informed consent, participants were asked to complete a demographic information form; for people with tetraplegia, this included their age, sex, Spinal Cord Independence Measure self-reported score [36], and for therapists, this included sex, occupation, and years of professional experience.

Focus Groups

Focus groups were chosen over individual interviews to promote discussion and ideation between focus group participants. Question schedules were created to enable semistructured discussion between participants (Multimedia Appendices 1 and 2). The questions were devised to enable future software design and software requirements specification. The difference between the question schedules and conduct of each focus group was minimal. Participants with tetraplegia focus groups aimed to explore the topic of VR through the lived experience of participants with tetraplegia, and therapist focus groups aimed to explore the topic through the lens of clinical practice. Each focus group had 2 facilitators, AG (male) and LP (female). A total of 3 focus groups of therapist participants and 4 focus groups of participants with tetraplegia were conducted. The duration of focus groups ranged between 45 and 75 minutes.

Participants with tetraplegia were asked to recall their experiences of the acute stage of inpatient SCI rehabilitation. They were then asked to discuss upper limb impairments caused by SCI and how these relate to prehension, strength, and range of motion. Therapists were instead asked about the current practice surrounding delivery of upper limb therapy. Both groups were introduced to the concept of VR as a commercial product for immersive entertainment. They were shown a video promoting a high-immersion head-mounted display being used by able-bodied people to play interactive games [37]. Both cohorts were then asked to discuss their opinions on VR as an adjunct to usual upper limb rehabilitation and the potential facilitators and barriers to its use in the acute rehabilitation setting. Finally, specifications for the design of a VR system to promote upper limb exercise were gathered from both groups.

Analysis of Transcripts

Focus groups were audio-recorded, and recordings were transcribed verbatim following pseudonymization of participants. Transcriptions were generated manually to enable familiarization with the data. Content analysis was used to count the responses and determine the meaning of participants' discussions via code generation [38]. Therapist and tetraplegia focus groups were analyzed separately. After codes were generated by AG, they were independently reviewed by LP, M Poyade, and M Purcell. AG, LP, M Poyade, and M Purcell discussed codes to come to a consensus on identification of codes and naming of themes in the theme hierarchy. Quotes are presented with participant identifiers and their focus group number. Data were managed using NVivo (version 20; Lumivero) [39].

Codes (units of meaning) were typically sentences, phrases, or longer portions of text. Shorter phrases and sometimes single words were coded if they related specifically to recommendations for the design of the VR games. Initially, codes were organized under categories deduced from the schedule of questions. Subthemes were abstractions of groups of similar codes and were created during coding. Major themes were then generated from groups of subthemes and replaced the organizational categories. Transcripts were not returned to participants for comments or corrections.

Reflexivity

Relationships with study participants were not established prior to study commencement. LP had previous experience facilitating focus groups and interviewing research participants, but AG did not. Neither facilitator worked in SCI rehabilitation and, as

XSL•FO
RenderX

such, reduced the likelihood of inhibiting frank discussion about patient care with participants [40].

Results

Participants (Demographics)

A total of 18 participants with tetraplegia and 14 therapists expressed interest in the study. Of these, 3 therapists and 3 participants with tetraplegia did not attend the focus groups; thus, 15 people with tetraplegia and 11 therapists took part (Table 1). We conducted 3 focus groups with therapists and 4 focus groups with participants with tetraplegia. A total of 7 participants with tetraplegia did not complete the demographic information forms. Reasons for not completing the information form included technical difficulty completing the form (reported only by participants with tetraplegia). A total of 3 therapists did not report their years of professional experience. Therapists reported not having enough time or opted out of form completion, with no reason given. Half of the participants with tetraplegia had experienced immersive VR at least once, but none had used VR extensively.

Table 1. Summary demographic information for participants with tetraplegia and therapist participants.

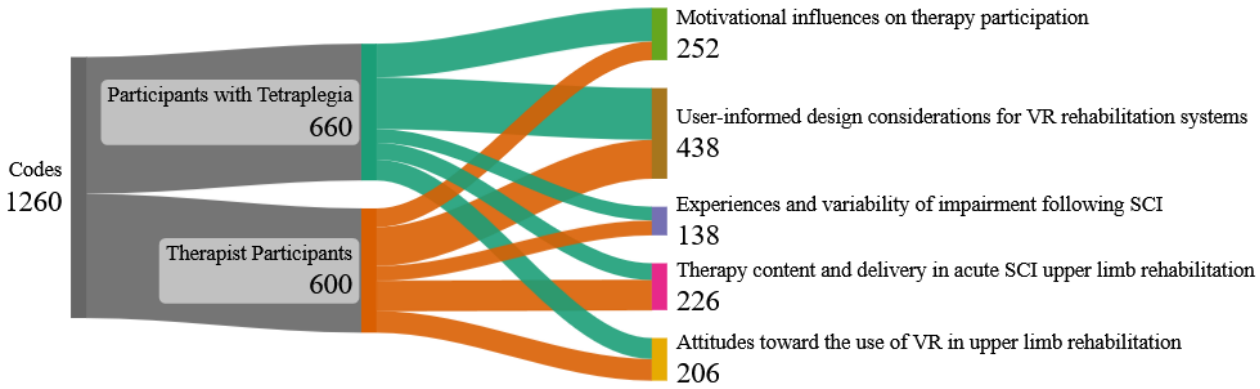
Characteristic	Value
Participants with tetraplegia (n=15)	
SCIM[a] score[b] (n=8), mean (SD)	17.9 (6.4)
Age (years; n=8), mean (SD)	54.5 (8.6)
Sex (n=13), n	
Male	10
Female	5
Experience with VR[c] (n=8), n	
None	4
Some	4
Therapist participants (n=11)	
Professional background (n=11), n	
Occupational therapists	7
Physiotherapists	4
Mean years of professional experience[d] (n=8)	14.8 (SD 8.6)
Sex (n=11), n	
Male	2
Female	9

[a]SCIM: Spinal Cord Independence Measure.

[b]Only 8 out of 15 participants with tetraplegia completed the SCIM and age information; 13 participants reported sex. Lower SCIM scores indicate lower independence (total score range, 0-75). Only 15 out of 19 subscales were included, comprising 6 self-care items and 9 mobility items.

[c]VR: virtual reality.

[d]A total of 3 therapists did not report their years of professional experience.



Major Themes and Subthemes

Overview

Analysis of the focus group transcripts identified 5 major themes shared by the therapists and participants with tetraplegia: descriptions of impairment, descriptions of acute rehabilitation, factors affecting participation in therapy, perspectives on VR, and suggestions for VR design. A total of 35 subthemes were generated from 660 and 600 individual codes from the tetraplegia and therapist groups transcripts, respectively (Figure 1).

XSL•FO
RenderX

Figure 1. Visual summary of the number of major themes (listed in the right column) identified from the 1260 codes (shown in the left column) generated by content analysis of focus groups with participants with tetraplegia and therapists. SCI: spinal cord injury; VR: virtual reality.

Major Theme 1: Experiences and Variability of Impairment Following Spinal Cord Injury

A total of 5 subthemes were identified that described impairments resulting from SCI immediately after injury and during the acute stage of rehabilitation (Table 2). Participants described profound loss of upper limb movement following injury, with variable patterns of recovery.

Table 2. Summary of subthemes for the major theme "experiences and variability of impairment following spinal cord injury."

Subtheme	Therapist codes, n	Participant codes, n	Total, n
Impairment of upper limb movement	17	28	45
Other impairments	27	8	35
Impairment of function, including activities of daily living	9	19	28
Heterogeneous presentations and demographics	16	2	18
Impairment of upper limb strength	3	9	12

> *My arms, I wasn't able to move them at all after I had my accident.* [PwT27, FG 3]

Impairments were described as highly variable across individuals and influenced by the level and severity of SCI.

> *I suppose [the degree of upper limb impairment] depends on the severity of your tetraplegic-ness, you know. Some people might, might be really bad and some people might still have a bit of movement.* [PwT27, FG 3]

Both groups, but especially therapists, discussed "other impairments." These included spasms, pain, and mental health issues, with therapists also raising age-related comorbidities and complications.

Therapists specifically raised the concept of "heterogeneous presentations and demographics" in acute SCI, with a growing prevalence of central cord syndrome in older adults, presenting as greater weakness in the upper limbs (than lower limbs) and greater involvement of distal muscles [7].

> *You could have somebody who's got, you know, full shoulder movement, full elbow movement, but they've got some weakness in the hands. Or the opposite, you know you could have someone who has got good hands but reduced movement at the shoulder.* [TP3, FG 1]

Major Theme 2: Therapy Content and Delivery in Acute Spinal Cord Injury Upper Limb Rehabilitation

A total of 7 subthemes described the nature of inpatient rehabilitation following SCI (Table 3). Upper limb therapy was described as a combination of functional and remedial activities, with a strong focus on maintaining range of movement and developing task-specific skills.

XSL•FO
RenderX

Table 3. Summary of subthemes for the major theme "therapy content and delivery in acute spinal cord injury upper limb rehabilitation."

Subtheme	Therapist codes, n	Participant codes, n	Total, n
Upper limb therapy	92	51	143
Patient-centered care	31	0	31
Assistive devices, orthotics, and neck stabilization	0	16	16
Barriers to effective therapy	12	0	12
Psychological adjustment and treatment	4	9	13
Bed rest and ventilation	0	5	5
Symptom management	6	0	6

> *[…] we do work on range of movement, you know shoulder, elbow, wrist, fingers.* [TP7, FG 2]
>
> *There were various things that we used—we had these games where we had little pegs that we had to move around the board, or also another one with a bucket full of the marbles.* [PwT16, FG 4]

Therapists also discussed upper limb functional improvement, particularly where patients have incomplete injuries:

> *If they're an incomplete injury we might be looking for more of a normal movement. […] Whereas if they're more of a complete, it's obviously looking at function and how we can use what they've got—what muscles they've got working to functionally achieve the task.* [TP9, FG 2]

Both groups highlighted the common use of "assistive devices" during rehabilitation, which included arm and hand stabilization using orthotics and neck stabilization, which hindered movement.

> *I had to use the Active Hand, which are the Velcro gloves so I could hold things.* [PwT16, FG 4]
>
> *I was 12 weeks in a neck brace, so I ended up with a very, very weak neck.* [PwT13, FG 3]

Under therapist-only subthemes, patient-centered care was achieved through collaborative goal setting. Barriers to therapy delivery included delayed referral and limited resources. Psychological adjustment was described by both groups, with participants with tetraplegia emphasizing loss of independence and therapists focusing on expectation management.

> *We would set those goals collaboratively with the patient based on a little bit of, kind of advice and guidance from us as to what we anticipate their outcomes might be.* [TP5, FG 1]
>
> *Unfortunately, the later we get someone sometimes the more issues we can have with contractures and upper limb pain and things, which then makes it harder for us then to, to rehab them.* [TP9, FG 2]
>
> *Trying to deal with everything and I found it really hard to be having to rely on other people for your personal care just day in, day out for everything.* [PwT21, FG4]
>
> *In their mind they want [a goal] to be achievable. So it, again comes down to communication and managing those expectations of patients and their families.* [TH9, FG2]

"Bed rest and ventilation" and "symptom management" were less commonly raised in both groups.

Major Theme 3: Motivational Influences on Therapy Participation

A total of 10 subthemes described factors influencing participation in therapy. Subthemes were then classified as "motivational" or "demotivational" (Table 4). Motivational influences included task enjoyment, goal setting, peer interaction, and visible improvement. Participants with tetraplegia described greater engagement with game-like and functional activities compared to repetitive remedial exercises.

XSL•FO
RenderX

Table 4. Summary of subthemes for the major theme "motivational influences on therapy participation." Subthemes are categorized as either promoting motivation or reducing motivation.

Subtheme	Motivational or demotivational	Therapist codes, n	Participant codes, n	Total, n
Useful or enjoyable rehabilitation	Motivational	1	39	40
Goal setting and therapist support	Motivational	6	31	37
Understanding tasks and prognosis	Motivational	30	0	30
Peer support and competition	Motivational	5	11	16
Seeing improvement	Motivational	0	10	10
Boring, repetitive, or difficult rehabilitation	Demotivational	5	41	46
Limiting symptoms	Demotivational	22	6	28
Low mood	Demotivational	11	6	17
Downtime	Demotivational	0	15	15
Limited resources and lack of supervision	Demotivational	10	3	13

> *We had some games to play, which is quite good fun. Like maybe like playing dominoes. Uh, so fiddling about with them things and also trying to build things with Lego was quite motivational and we had a tower of blocks that was probably my favourite thing.* [PwT26, FG 4]

In contrast, "boring, repetitive, or difficult rehabilitation," which included pointless, tedious, and humiliating activities, was demotivational.

> *You know what it's like sometimes you go and do a bit of exercise, you know you're pulling on a TheraBand and [imitates snoring] 'boring!'.* [PwT1, FG 1]

Sometimes strategies that were intended to make therapy more enjoyable, such as creative activities using putty or interactive cycling, were frustrating for patients.

> *[…] most days doing the exercises with the putty and so on, it felt like a really kind of childish, I don't know. Like, 'what's this doing?'* [PwT21, FG 4]

> *And [patients] found that really—you know they were cycling [FES cycling] away, cycling away along this road but they never went anywhere. And they got really frustrated by that.* [TP9, FG 2]

Some activities were too difficult or too easy for participants with tetraplegia, which resulted in them disengaging from therapy.

> *I also had a board with different sizes of bolts and nuts that I had to screw and I hated that because I thought, you know, 'I can't do this! Why are they making me do this when I cannot do it? This is so humiliating'.* [PwT16, FG 4]

Therapist discussions described patients were more motivated if they understood their injury, prognosis, and purpose of therapy ("understanding tasks and prognosis").

> *[Patients need] to have a good understanding of their injury and what the task is working towards. If they don't then often they're: "What's the point?" or "I don't really know why I'm just rolling this putty out". Umm "I'm not gonna get any better" or "How's this gonna strengthen?". So how much they understand about their injury is really important in their engagement.* [TP5, FG 1]

Both groups also raised that "peer support and competition" could be motivational.

> *Some of our patients…. a kind of element of challenge or competition almost with themselves in some of the more repetitive remedial tasks, um, can be really beneficial—like if they get 10 pegs one day - the next time they want them to get 15.* [TP4, FG 1]

> *I think being in the group as well gave you a bit more, you know, just a bit more reason to sort of get on with it and people would be chatting and you had that, you know, nice social aspect as well.* [PwT27, FG3]

Demotivational factors included repetitive or infantilizing tasks, symptom burden, low mood, and comparisons with faster-progressing peers.

> *Other people were whizzing through, and you just sat there doing like one at a time. And it was just demoralizing.* [PwT21 FG 4]

> *[…] a lot of the time I was just knackered, it turned out that I had an underlying infection due to the metalwork in the back of my neck.* [PwT1, FG1]

> *A lot of pain can be difficult for them to kind of adhere to upper limb therapy (or any therapy).* [TP4, FG 1]

> *I mean, some people in the unit—when I was there for 12 months didn't do anything. And they just lay in bed. They gave up.* [PwT4, FG 2]

Disengagement could occur if therapists could not always be present during therapy ("limited resources and lack of supervision").

> *[…] you know people who never do what's asked of them unless someone's standing over them making them do it.* [TP12, FG 3]

XSL•FO
RenderX

> *You know, they did their best to keep things fresh and, and try introducing, but obviously they had a limited amount of resources available to them, but equally limited staff time.* [PwT13, FG 3]

Finally, participants with tetraplegia identified "downtime," especially at the weekend, which meant there was nothing to do, and, as such, was demotivational.

> *The weekends at the spinal unit are, are very long and you just you know everything finishes on a Friday and you do nothing till Monday and you just feel I could I could be doing [something].* [PwT27, FG 3]

Major Theme 4: Attitudes Toward the Use of VR in Upper Limb Rehabilitation

A total of 8 subthemes captured attitudes toward VR (Table 5). Participants described VR as a potentially engaging and meaningful adjunct to therapy, particularly for individuals who struggle to engage with conventional rehabilitation.

Table 5. Summary of subthemes for the major theme "attitudes toward the use of virtual reality in upper limb rehabilitation." Subthemes are categorized as having a positive or negative sentiment.

Subtheme	Positive or negative sentiment	Therapist codes, n	Participant codes, n	Total, n
VR[a] could/should be engaging and meaningful	Positive	14	31	45
VR could/should be used for rehabilitation	Positive	9	18	27
Younger patients will like VR	Positive	9	0	9
VR could alleviate symptoms	Positive	5	4	9
Consumer equipment is not suitable	Negative	29	15	44
VR could cause adverse effects/be inappropriate	Negative	17	33	50
Resources are limited	Negative	15	0	15
Training is required	Negative	7	0	7

[a]VR: virtual reality.

> *So I think VR would have a very big use in a spinal injury centre there's a whole range of things it could cover. It's exciting it would be fun to use with people.* [TP8, FG 3]

> *I think [VR] is great because as I said earlier, there are other people [in hospital] who, you know, their mindset is totally negative. […] they need that stimulation, that encouragement, and VR might be the way.* [PwT4, FG 2]

> *[VR could] make any training or rehab more, more interesting, more exciting, more varied. Yes, I think… huge potential.* [PwT13, FG 3]

Both groups said that VR could encourage engagement in therapy by reducing symptoms such as pain and improve mood ("VR could alleviate symptoms").

> *And [VR is] good, actually help people to get involved in activities without even imagining the pain they are in.* [PwT19, FG 3]

> *I do quite like that element of escapism for them, I think. It could psychologically really help them as well.* [TP3 FG 3]

Conversely, concerns were raised from both groups regarding equipment suitability, adverse effects, staffing capacity, and training requirements. Head-mounted displays were described as potentially heavy and unsafe for individuals with high-level injuries.

> *If [devices] are too labour intensive or take a while to set up or need someone there then when we're short-staffed as we have unfortunately been for quite a long time, um, you tend to go for things that are quicker and easier to use if you've only got quite a short treatment session.* [TH9, FG2]

> *The other thing as well is our very high injury levels, [who are] struggling just holding their head up—or that kind of movement with the head [TP8 demonstrates neck rotation] a lot—it can tire them.* [TP8, FG 3]

Both groups warned that "VR could cause adverse effects" such as nausea, or that the specific activities in VR that could remind them of their SCI.

> *I think when you're already feeling self-conscious about yourself as an individual and how you move… VR might have a bit of a negative effect on people as well.* [TP5, FG 1]

> *When you take [the VR headset] off and you go 'Oh shit. It's true, this is where I am'.* [PwT21, FG 4]

Therapists speculated that their younger patients would be more suited to VR games ("younger patients will like VR").

> *So I think the younger people will probably get [VR], you know they'll understand a lot better how it works.* [TP4 FG 1]

Major Theme 5: User-Informed Design Considerations for VR Rehabilitation Systems

A total of 5 subthemes described participant recommendations for VR system design (Table 6). Suggested activities ranged from functional or vocational tasks, suggested mostly by therapists, to leisure, sporting, and creative environments, which were suggested predominantly by participants with tetraplegia.

XSL•FO
RenderX

Preferences varied widely, reflecting differences in interests and functional abilities.

Table 6. Summary of subthemes for the major theme "user-informed design considerations for virtual reality rehabilitation systems."

Subtheme	Therapist codes, n	Participant codes, n	Total, n
Activities and scenarios	86	150	236
Usability and training	32	33	65
Measuring performance and achievement	38	27	65
Movements	21	23	44
Immersion, presence, and engagement	11	17	28

> *[…] it's down to the individual what interests they have and you know what would benefit them the most and… I mean, metalwork is obviously not gonna be the same as scuba diving and, you know, skiing, or playing the piano. One's having loads of fun, one's more sort of creative and you're constructing something in VR. Yeah. So yeah, just depends.* [PwT4, FG 2]

Therapists also discussed providing a range of different activities for their patients. Both groups recommended incorporating concepts such as relaxation and escapism into the design ("immersion, presence, and engagement").

> *So we are really trying to provide a variety of different type of games that we offer but obviously when you've got a patient who's had a long (and all of our spinal injury patients have quite a long) admission with us, it's like the variety that's key.* [TP14 FG 3]

> *What about making really realistic sound, […] soaring noises, painting noises of the paint going on to the wall and those kind of things where it actually feeds back extra reality to the experience?* [PwT16, FG 4]

Additionally, participants with tetraplegia and therapists suggested outdoor spaces such as hills, glens, mountains, underwater spaces, outer space, and jungles would be good environments for VR activities.

> *[I have] a static bicycle at home. I get a bit bored because I'm always in the same place, while if you could have the feeling that you're actually outside and going places that might make it more interesting.* [PwT16, FG 4]

Both groups said that VR games should enable a range of movements, from fine to gross ("movements"), including reaching, grasping, and wrist flexion and extension.

> *[VR] could be something that could be really useful for larger gross movements but also for really drilling down to repetition of very fine motor movements.* [TP12, FG 3]

Therapists also recommended the quality of movements in VR was of high importance.

> *Sometimes it's not the number of movements, it's quality as well. So, you know, we'd be looking at the quality of someone's reach, not just that they are able to reach, but maybe not recruiting the right muscle groups to perform that task.* [TP9, FG 2]

Both groups gave recommendations for "measuring performance and achievement" of users. These included giving encouragement and providing feedback to increase engagement. Therapists discussed providing incremental levels of difficulty to accommodate progression and achievement.

> *[…] like you get a big tick or a big thumbs up or something. Not something annoying but something that shows you've reached the level of the activity that's actually doing something.* [PwT27, FG 4]

Therapists recommended incorporating easily comprehensible progress reports and feedback to users to help with motivation.

> *[…] and patients love seeing kind of that—we can put it—display it on a graph for them to kind of say like this is what you did like a month ago and this is what you're doing now.* [TP8, FG 3]

Therapists and participants with tetraplegia recommended that the movements should be configurable for users, and that training should be provided to patients and therapists ("usability and training").

> *So there's gonna have to be sort of that adjustability with the system to make it relevant to that patient's rehab and what muscles you want to work on and that, yeah.* [TP7, FG 2]

Furthermore, under this subtheme, it was highlighted that adding straps to the controllers might be required, and for those with limited hand function, participants with tetraplegia also requested interaction mechanisms using head-movement, gaze, hand tracking, and voice input.

> *I think you'd have to be really aware of even things like how people could grip any hand controls, you know, just the simple things like holding them, putting headsets on, how much assistance was needed to make it as practical as possible.* [PwT21, FG 4]

Ethical Considerations

Ethical approval for this study was granted by the Psychology, Social Work, and Allied Health Sciences (PSWAHS) Research Ethics Committee of Glasgow Caledonian University (reference: HLS/PSWAHS/21/247). Participants with tetraplegia were recruited via a gatekeeper (Spinal Injuries Scotland). Therapist participants were recruited via social media. Both groups were provided with participant information sheets that detailed the

XSL•FO
RenderX

aims of the study and, if they chose to take part, the requirements of participation and the information collected about them. This information would be stored on Glasgow Caledonian University's OneDrive for 5 years and shared only with the study team. All information would be anonymized after consent was given, and participants assigned an ID number to comply with the General Data Protection Regulation (GDPR). Prior to participation, all participants provided informed consent either by printing and physically signing a digital consent form or by completing the form digitally. Participants who were unable to physically sign the consent form provided consent through a designated witness who signed on their behalf [35]. The study abided by the guidelines set out in the Declaration of Helsinki. Participants were not compensated for their participation and were informed they were free to withdraw from the study at any time without giving a reason. Participants could have their information removed from the study but were informed that this would not be possible after anonymization.

Discussion

Principal Results

The aim of this qualitative study was to explore the lived experiences of people with tetraplegia and SCI specialist therapists in terms of upper limb rehabilitation to inform the design of a VR-based intervention. A total of 5 major themes and their associated subthemes were identified that enabled the specification of software requirements, which have subsequently been implemented in a prototype VR intervention. The focus groups indicated that VR has the potential to help improve function and build strength, as well as learning skills, by adapting to loss of function. This suggests that end users of potential VR-based interventions understand its possible benefits, as well as pitfalls. The results also show that end users see a place for co-designed interventions in the acute/subacute setting and showed interest in VR, which is critical for "buy-in" for the adoption of new technologies.

Major Themes 1 and 2

The findings indicate that VR-based interventions must accommodate substantial variability in upper limb impairment following SCI. To account for diverse user profiles and needs, software must adapt to the personal rehabilitation needs of the user. Although some therapists anticipated uptake among younger patients, and therefore specific targeting toward this demographic, restricting designs to this group would misalign with the clinical diversity of the population. Design should therefore prioritize broad accessibility and usability across impairment, age groups, and levels of technological expertise.

Major Theme 3

This study highlights how motivation and engagement are shaped by both individual and service-level factors during acute/subacute rehabilitation. The findings align with established barriers to engagement in therapy in the SCI literature, including comorbidities (eg, urinary tract infections, pressure sores, fatigue, pain, and low mood), alongside the resource limitations of health care providers, periods of "downtime," variation in individual rehabilitation needs, and patients' desire for more control over their therapy [41-44]. Patients with SCI were generally described by both groups as highly motivated, with engagement closely linked to perceived progress and the pursuit of greater independence. This finding may be influenced by sampling bias, as individuals willing to participate in research may be more motivated than the broader inpatient population. Motivational drivers suggest that interventions incorporating visible progress indicators and structured challenges may be particularly effective. Such features could also increase acceptability of novel interventions, including VR therapy, when used as an adjunct to conventional rehabilitation.

Major Theme 4

Participants with tetraplegia described VR as an assistive technology to enhance function and therefore improve independence, a factor shown to be of high importance to people with SCI [45]. In addition, VR was perceived as a tool to give participants with tetraplegia independence during their rehabilitation. Participants' emphasis on autonomy and meaningful activity suggests that VR may be most effective when it enables users to exercise choice and engage in personally relevant tasks. These factors could also enable therapists in administering or prescribing therapy by facilitating movements that are typically difficult to achieve in usual treatment or that are more appealing to people with tetraplegia.

The repetitive nature of upper limb rehabilitation presents an opportunity for VR to embed prescribed movements within more engaging tasks. VR could maintain motivation by using repetitive input to drive engaging game mechanics, such as firing a bow and arrow, hitting boxing targets, or completing puzzles. Progress-based feedback and structured challenges may further promote sustained participation.

Users could be engaged in gameplay and rewarded in immersive scenarios for repeating movements. This concept relies on the immersive capabilities of VR to provide positive distraction, which is a term inferred from participants' discussion regarding "escapism," from typical therapy while still enabling prescribed movement.

The acute context of rehabilitation is relevant, as patients must adapt to both sudden functional loss and prolonged hospitalization. Participants highlighted the importance of experiences that offer psychological relief from this environment via relaxation and escapism, which are achievable with immersive VR systems [46].

Resource limitations were identified as a barrier to therapy delivery by both groups. Participants implied that a VR-based system could mitigate these limitations by enabling self-guided, semi-independent practice. This could allow therapists to allocate time more efficiently while maintaining a supervisory role in therapy sessions.

The group-based nature of rehabilitation suggests that future VR systems could benefit from supporting multiuser networked environments to encourage peer-to-peer interactions.

Major Theme 5

Both therapists and participants with tetraplegia made many suggestions about what type of activities and upper limb

XSL•FO
RenderX

movements they would like to see implemented in VR. There was no consensus on particular types of VR scenarios with which patients with tetraplegia would engage, reflecting the heterogeneity of the tetraplegic population. This supports the development of flexible systems capable of offering varied activities and environments to their users.

VR is most likely to add value when repetitive therapeutic movements are embedded within adaptive, gamified tasks. These findings are consistent with existing research on rehabilitation during acute/subacute tetraplegia [45,47-50]. Participants' emphasis on independence, motivation, and shared decision-making reinforces the important of human-centered design principles. Unique to this population is the complexity of SCI, which remains a central factor for consideration during intervention development.

These findings add to the growing body of research concerning the recommendations for implementing VR for people with upper limb impairments and their rehabilitation [51-54]. VR interventions must be designed to take advantage of their attributes, which include real-time feedback and immersive environments. These designs must be informed by the specific populations who are intended to use these systems [55-58].

Recommendations for the Design of a VR Upper Limb Rehabilitation Intervention for People With Tetraplegia

The following recommendations outline key design considerations for VR-based upper limb rehabilitation interventions targeting people with tetraplegia. They are structured around practical software development domains to support systematic intervention design and informed by the themes identified in the focus group data.

Domain 1: Accessibility

VR applications should be usable by the widest possible range of people with tetraplegia and accommodate the wide variation in upper limb function of users for control of the system. They should be usable to the same extent for all users, irrespective of upper limb function, and support patient autonomy while maintaining the therapeutic role of clinicians. VR applications should be usable across age groups and comorbidities associated with tetraplegia, allow all prescribed movements to be specified and configured by the user, and must be comfortable to use. They should target as many movement domains as possible and support movement or activity that is difficult to achieve in standard upper limb treatment.

Domain 2: Implementation

VR applications should be feasible, fit into existing clinical workflows, and aim to alleviate resource limitations. They should support collaborative goal setting between patients and therapists and minimize physical and psychological adverse effects associated with, and attributable to, VR. Applications should consider the appropriate intensity and duration of an intervention and prevent overexertion during use. They should also be able to monitor usage and performance and be supported by appropriate training for end users to ensure safe implementation and effective integration into clinical services.

Domain 3: Immersion and Engagement

VR applications should increase and maintain engagement beyond what is achieved in usual treatment by encouraging repetitions of prescribed movements through meaningful virtual activities and environments. They should avoid factors that cause disengagement from therapy by providing an optimal degree of challenge for each user, ensuring that the experience is neither frustrating nor too difficult or too easy. Applications should provide motivational feedback on performance, such as scores and progress, and make use of the immersive and enjoyable qualities of VR technology to ensure users feel present within virtual environments and benefit from escapism or positive distraction.

Limitations

Participants with tetraplegia sometimes had difficulty recalling their time as inpatients, typically when years or decades had passed following discharge. However, it was important to prioritize the perspective of individuals with a full retrospective view of inpatient care.

Separate focus groups were conducted for therapists and participants with tetraplegia to remove the effect of the relationships or perceived power differences between patients and clinicians. For example, when discussing opinions about particular types of upper limb therapy, participants with tetraplegia may have been reluctant to express negative opinions about care if therapists were present. Interaction between participants with tetraplegia and therapists may, however, have been beneficial in terms of ideating suggestions for the design of VR scenarios.

Data saturation was not achieved as the final focus groups in both groups yielded additional insights, though at a lower frequency compared to earlier groups. However, the information power of the focus groups was improved by revising the question schedules after each focus group. In particular, follow-up questions and prompts were added to explore new areas of discussion that had not been covered by previous groups. The inclusion of different rehabilitation disciplines with experience of working in different specialist centers across the United Kingdom ensured diverse groups were assembled, which was a strength of this study and allowed for more varied discussion.

Conclusions

This study reported the perspectives and suggestions of people with tetraplegia and SCI therapists about the use of VR for upper limb rehabilitation in the acute setting. As a result, it presents valuable first-hand information about the design of VR technology for SCI rehabilitation. A total of 5 themes were generated that designers and developers of immersive applications for rehabilitation can use to create their applications. People with tetraplegia have a large variation in upper limb impairments, for which many different movements are prescribed by therapists. This variation must be accommodated by applications in a usable and accessible way. Applications must also implement features that motivate patients to attend and adhere to therapy, such as providing useful feedback and appealing to the broad range of patients' interests, and also

XSL•FO
RenderX

avoid factors that can cause disengagement from therapy. The findings of this study facilitated the cocreation of a novel immersive VR intervention for upper limb rehabilitation for people with tetraplegia while they are inpatients.

Future Work

The next part of this project is to use the results from this study to produce software requirements and a software architecture for a suite of VR games for upper limb therapy. This study enabled the development and deployment of the proposed software and its continued improvement.

Acknowledgments

The authors would like to thank all the participants (co-designers) who took part in this study, Spinal Injuries Scotland for helping recruit participants, and Stoke Mandeville Spinal Research for funding this PhD through their Assistive Technology for Upper Limb Rehabilitation PhD Studentship.

Authors' Contributions

The “Co-designers” members are Ray Brown, Lauren Cope, Graham Cullen, Sheena Egan, Amanda Howat, Donald Hutton, John Lynch, Samantha Maguire, and Sylvia Merino. AG, LP, M Poyade, and M Purcell designed and conceptualized this study. AG and LP facilitated the focus groups. AG and LC were responsible for project administration, including recruitment of focus group participants. AG, LP, M Poyade, and M Purcell performed the analysis. AG and LP wrote and prepared the original draft of the manuscript. AG, LP, M Purcell, M Poyade, and LC reviewed and edited the manuscript.

Conflicts of Interest

Abstract

Background: Single-camera markerless pose estimation may support accessible knee movement assessment, but performance can depend on task, joint angle, and detection quality, and evidence across complementary measurement properties remains limited.

Objective: This study aimed to evaluate agreement of MediaPipe BlazePose Heavy knee-flexion estimates with goniometer-set static target positions and with Kinovea 2D video annotation for dynamic tasks, to assess interrater agreement of the Kinovea annotations, and to explore repeated-session performance in a small retest subsample.

Methods: Squat, sit-to-stand, and bilateral single-leg stance tasks were performed by 15 healthy adults during standardized lateral-view smartphone recording. Static knee flexion was assessed at 4 goniometer-set targets (30°, 60°, 90°, and 120°). Native hip-knee-ankle included angles were converted to clinical knee flexion (0° at full extension). Agreement was assessed using the intraclass correlation coefficient (ICC), specifically $ICC_{2,1}$, signed bias and 95% limits of agreement, mean absolute error (MAE), and root mean square error (RMSE). Primary intervals used participant-cluster bootstrapping, and limits of agreement accounted for repeated measurements. Dynamic primary estimates were conditional on BlazePose target-frame confidence ≥0.3; low-confidence observations were also reported as detection failures and included in an all-output stress test. Four participants returned after 21 days to 29 days (median 25 d) for exploratory repeated-session analyses.

Results: Dynamic measurement was available in 177 of 210 observations (84.3%); 33 of 210 observations (15.7%) failed the confidence criterion. Conditional task-specific ICCs were 0.773 (95% CI 0.564 to 0.875; n=71, 15 participants) for squat, 0.632 (95% CI 0.455 to 0.726; n=58, 12 participants) for sit-to-stand, and 0.136 (95% CI −0.078 to 0.482; n=48, 15 participants) for combined single-leg stance. Task-specific availability was present for 71 of 75 observations (95%), 58 of 75 observations (77%), and 48 of 60 observations (80%), respectively. Without the quality gate, squat ICC was 0.428, and RMSE was 25.43°. Static agreement with set targets resulted in an ICC of 0.874 (95% CI 0.770 to 0.953), with RMSE of 15.49° and angle-dependent signed error. Kinovea interrater ICC was 0.999 (95% CI 0.998 to 0.999) overall, which did not establish 3D accuracy. Repeated-session estimates with the 4 participants remained exploratory.

Conclusions: With dynamic measurement available in 177 of 210 observations (84.3%), agreement among retained outputs depended on task, flexion angle, and detection quality. The findings support further feasibility and screening-level evaluation under controlled acquisition with per-recording quality checks; they do not support replacement of clinical goniometry, precise longitudinal decision-making, absolute 3D kinematic accuracy, or generalization to clinical populations or other smartphones.

Introduction

Background

Accurate measurement of knee joint kinematics is fundamental to the assessment and management of musculoskeletal conditions, including anterior cruciate ligament reconstruction recovery and knee osteoarthritis rehabilitation. Clinicians routinely monitor knee flexion and extension range of motion (ROM) to guide treatment progression, set discharge criteria, and evaluate surgical outcomes. In conventional clinical practice, the universal goniometer is used for static ROM measurement and offers acceptable intrarater reliability when used by trained clinicians [1]. However, the goniometer requires in-person contact, is limited to static or quasistatic postures, and cannot capture the dynamic joint behavior that characterizes functional tasks such as squatting, sit-to-stand transfers, and single-leg balance—tasks that more closely reflect the demands of daily living and return-to-activity benchmarks.

Laboratory-based, marker-based, motion-capture systems (eg, Vicon and Qualisys) are commonly used reference methods for 3D joint-kinematic analysis. However, they require dedicated space, specialized hardware, marker placement by trained personnel, and substantial postprocessing expertise [2,3]. These requirements limit their availability for routine or remote assessment, where neither an in-person goniometer nor laboratory motion capture is readily deployable.

The rapid development of markerless pose estimation technologies has created new possibilities for accessible, low-cost movement analysis. Deep learning–based frameworks can estimate joint positions from standard video without physical markers. Stenum et al [4] demonstrated the feasibility of automated gait analysis from single-camera 2D pose estimation. Among single-camera 2D approaches, Gupta et al [5] compared MediaPipe Pose with Kinovea 2D video annotation for knee flexion during gait, reporting a Pearson correlation of 0.941 and a mean absolute error (MAE) of 5.88°. Langley et al [6] compared both smartphone-based Deep Vision and Kinovea with 3D motion capture in patients with knee osteoarthritis. For Deep Vision, limits of agreement for peak flexion and ROM were within or equal to the study's clinical thresholds. Koul et al [7] reported high intrarater reliability for knee flexion measurements using DETROM (intraclass correlation coefficient [ICC]=0.98) in healthy adults. Agreement with a universal goniometer was evaluated separately using Bland-Altman analysis. Akturk et al [8] applied MediaPipe to joint-angle and joint-moment estimation during sit-to-stand transfers, extending single-camera pose estimation to a functional task.

Multicamera and 3D markerless systems have also been evaluated during functional tasks. Lima et al [9] evaluated OpenCap, a multicamera system for 3D kinematic reconstruction, across functional tasks. For single-leg squatting, root mean square error (RMSE) ranged from 2.9° to 13.6° across joint angles. Peak-angle intersession ICCs across joints were 0.60 to 0.92 for single-leg squatting and 0.62 to 0.93 for the jump phase of a countermovement jump. Yoma et al [10] reported mean between-day root mean square differences <5° and mean ICCs of 0.77 to 0.83 across kinematic variables for Theia3D during single-leg squat and landing tasks, although hip flexion errors exceeded 5°. These findings provide context for single-camera studies, but differences in tasks, populations, and analysis methods limit direct performance comparisons.

Single-camera markerless measurements can be affected by self-occlusion and out-of-plane motion [3]. This study therefore focused on task-dependent agreement, the consistency of the 2D reference annotations, and repeated-session uncertainty. These measurement properties require evaluation before longitudinal or remote uses can be considered.

To our knowledge, few studies have evaluated an open-source single-camera pose-estimation system across multiple knee-related functional tasks in one cohort while examining complementary measurement properties, including agreement with a clinical instrument and a 2D video reference, interrater agreement of that 2D reference, and exploratory repeated-session performance. The selection and reporting of measurement properties were informed by COSMIN (Consensus-Based Standards for the Selection of Health Measurement Instruments) terminology [11].

Objectives

The purpose of this study was to evaluate the MediaPipe BlazePose Heavy model for knee-flexion measurement in healthy young adults. We examined (1) interrater agreement of Kinovea 2D video annotation; (2) static agreement of BlazePose with goniometer-set target flexion across 4 angles; (3) dynamic agreement of BlazePose with Kinovea during squat, sit-to-stand, and bilateral single-leg stance; and (4) exploratory repeated-session agreement of BlazePose, Kinovea, and their between-method differences. We expected performance to vary by task, joint angle, and detection quality. This study did not evaluate absolute 3D kinematic accuracy, clinical populations, or cross-device equivalence.

Methods

Study Design

This cross-sectional validation study evaluated agreement of smartphone-based MediaPipe BlazePose knee-flexion estimates with goniometer-set targets for static positions and with Kinovea 2D video annotations by 2 trained raters for dynamic functional tasks. Secondary analyses assessed interrater agreement of the Kinovea annotations and exploratory repeated-session performance in a 4-participant subsample. Kinovea was treated as a 2D reference, not as an absolute biomechanical standard.

Participants

We recruited 15 healthy adults (8 men, 7 women; mean age 20.8, SD 0.6, range 20 - 22 years; mean height 171.1, SD 9.4 cm; mean weight 70.7, SD 15.7 kg; mean BMI 23.9, SD 3.4, range 18.8 - 31.3 kg/m²) via convenience sampling from a university community. Inclusion criteria were age 18 years to 45 years, no current lower-extremity pain, and ability to perform a full-depth squat independently. Exclusion criteria included a history of lower-extremity surgery, current lower-extremity injury, or any musculoskeletal condition limiting knee range of motion. The study was approved by the Academic Ethics and

XSL•FO
RenderX

Integrity Review Committee of Shanghai Sanda University (approval number 2026006). All participants provided informed consent prior to data collection. The sample size of 15 was determined by feasibility considerations (participant availability and resource constraints within a single-semester data collection window) rather than an a priori power calculation; this is acknowledged as a limitation, and the achieved precision of ICC estimates is reported via 95% CIs throughout.

A subset of 4 participants (S01–S04) returned for an exploratory second session 21 days to 29 days after their initial session (median 25 d). The second session used the same static and dynamic task protocol. The dataset comprised 15 initial-session datasets plus 4 repeated-session datasets, yielding 342 videos processed through the BlazePose pipeline (228 static and 114 dynamic). The primary cross-sectional static analysis used the 180 Session 1 trials from S01-S15; the 48 Session 2 static trials were reserved for the exploratory repeated-session analysis.

Equipment and Setup

All videos were recorded with the same iPhone 17 Pro rear camera mounted on a tripod in a lateral view at knee height and 2.0 m from the participant. The device was selected because it was available and readily accessible to the research team; using one device throughout kept acquisition hardware constant. Recordings used 1920×1080 H.264 video. Participants S03-S15 and all repeated-session recordings were captured at 60 frames per second (approximately 23 Mbps), whereas S01-S02 were captured at 120 frames per second (approximately 43 Mbps) during the pilot phase. Codec profile, pixel format (yuv420p), and color space (BT.709) were verified with FFprobe. Floor markings standardized participant and camera position. The study did not compare smartphones, lenses, device-specific image processing, or frame rates.

We placed 3 small reflective markers on each participant's test limb to support manual Kinovea annotation: the greater trochanter (hip), the lateral femoral epicondyle (knee), and the lateral malleolus (ankle). The BlazePose pipeline used MediaPipe's native keypoint detection and did not rely on these external markers. An anterior superior iliac spine marker was placed during some pilot trials but was not used in the final analysis pipeline. Participants wore dark-colored tight-fitting trousers or compression pants and a short-cropped top and were barefoot. The background was a plain pale wall with even lighting and no harsh shadows.

Data Collection Protocol

Static Validation

For static validation, participants were seated at 4 target knee-flexion angles (30°, 60°, 90°, and 120°). Target positions were set with a digital limb goniometer (GemRed model 82311‐00; transparent polycarbonate arms; manufacturer-stated resolution 0.1°, accuracy ±1°, and range 0°-180°). The fulcrum was placed at the lateral femoral epicondyle, the stationary arm was aligned with the greater trochanter, and the moving arm was aligned with the lateral malleolus. For each of the 3 trials at each target, the goniometer was reapplied, and the angle was reread. The limb was adjusted so that the displayed value, rounded to the nearest degree, equaled the target; floor tape served only as a positional guide. Thus, all recorded integer values equaled their targets after rounding, corresponding to displayed readings within approximately ±0.5° of the target at positioning, not exact independent measurements of the recorded posture. Positioning was performed by a physiotherapist (DPT) or a trained student assessor, and a research assistant (Rater B) verified the setup. This check was not an independent criterion measurement. The goniometer was removed before recording, and participants held the position for approximately 5 seconds. The angle was not remeasured after recording. There were 180 Session 1 trials (15 participants × 4 targets × 3 trials) and 48 additional trials from 4 retest participants. The comparison therefore assessed agreement with goniometer-set target positions, not simultaneous criterion validity.

Dynamic Validation

We selected 3 functional tasks to represent a range of clinically relevant knee movements and to align with prior markerless motion capture validation literature [4,12]: squat, sit-to-stand, and single-leg stance.

Squat

The participants performed 5 consecutive repetitions at a self-selected pace, with feet shoulder-width apart and arms extended forward for balance. This task produced the greatest clinical knee flexion and a clearly identifiable target frame.

Sit-to-Stand

The participants performed 5 consecutive sit-to-stand transitions from a standard-height chair (approximately 45-cm seat height) at a self-selected pace, with arms extended forward for balance.

Single-Leg Stance

The participants stood on 1 leg for 15 seconds per trial; 2 trials were performed per leg (left and right), yielding 4 single-leg stance trials per participant. The supporting (standing) leg was the annotated limb for both BlazePose and Kinovea measurements. Beginning with S03, participants were instructed to position the nonstance leg so that it did not occlude the supporting leg in the camera view.

Assessment

Each participant completed 6 dynamic videos: 1 squat video containing 5 repetitions, 1 sit-to-stand video containing 5 repetitions, and 4 single-leg stance videos. For squat and sit-to-stand, raters identified the frame of maximum clinical knee flexion, equivalent to the minimum native hip-knee-ankle included angle. For single-leg stance, raters selected a steady midstance frame and measured the supporting leg, which remained near full extension (approximately 0°-20° of clinical flexion). This produced 14 target-frame observations per participant (5 squat, 5 sit-to-stand, 2 left single-leg stance, and 2 right single-leg stance) and 210 observations across 15 participants. The right knee was the default measurement side for bilateral squat and sit-to-stand; the supporting limb was measured for each single-leg stance trial.

Automated Pose Estimation: MediaPipe BlazePose

Overview

All videos were processed using MediaPipe BlazePose [13] via the PoseLandmarker Task API (mediapipe 0.10.33, Python 3.9.6) with the Heavy model (pose_landmarker_heavy.task). The model outputs 33 body landmarks per frame. Processing was configured in VIDEO running mode (frame-by-frame with temporal tracking) with a single-pose constraint (num_poses=1) and a default minimum pose-detection confidence of 0.5. All processing was performed on a local workstation (Apple M2 Max).

For each detected frame, the pipeline first computed the native 2D hip-knee-ankle included angle at the knee from pixel-coordinate vectors. Native-included angles approach 180° at full extension and decrease with flexion. For reporting and all analyses, this value was converted to clinical knee flexion as 180° − included angle, so that 0° represents full extension and larger values represent greater flexion. Right-knee landmarks 24, 26, and 28 and left-knee landmarks 23, 25, and 27 were used. Per-frame confidence was defined as the minimum visibility score of the hip, knee, and ankle landmarks. Unless otherwise specified, positive signed error denotes greater clinical flexion from BlazePose than from the comparator.

Detection Threshold Protocol Deviation

The default minimum pose detection confidence was 0.5. We reprocessed 5 static videos with insufficient detections at 0.3: S09_static_120deg_2, S10_static_120deg_2, S10_static_30deg_3, S04_retest_static_120deg_2, and S04_retest_static_120deg_3. This threshold reduction was a protocol deviation and was not applied to the remaining videos. The first 3 videos contributed to the Session 1 static analysis, and the latter 2 contributed to paired Session-2 static analyses.

The primary analyses retained the threshold-rescued videos. Sensitivity analyses repeated the Session 1 static analysis after excluding the 3 affected Session 1 videos and repeated the exploratory static repeated-session analysis after excluding the 2 affected pairs.

Automated Video-Minimum Extraction (Exploratory Use Only)

The pipeline also generated one automated video-minimum native-included angle per dynamic recording after excluding values below the implemented 10° anatomical-plausibility bound. This corresponds to the maximum reported clinical flexion after conversion. Raw-peak confidence was the minimum hip, knee, and ankle landmark visibility score at that automated video-minimum frame. These video-level automated minima were not used for the primary time-matched concurrent agreement analysis. They were used only in the exploratory n=24 all-output repeated-session stress test described in the following sections, without a raw-peak confidence gate.

Confidence-Based Frame Filtering

For static videos, frames with confidence ≥0.8 contributed to the filtered trial mean. For the primary dynamic BlazePose-versus-Kinovea comparison, the BlazePose clinical flexion value at the Kinovea-selected target time was classified as a detection failure when target frame confidence was <0.3. This criterion yielded 33 failures among 210 available observations; the conditional primary agreement analysis used the remaining 177. An all-output sensitivity stress test retained all 210 numeric outputs to characterize performance in the absence of this quality gate; it was not treated as a replacement for the conditional analysis. The target frame cutoff was established during analysis, not prespecified before data analysis. The April 16 interim analysis of S01-S06 included all 84 observations; the April 27 full-sample script introduced the 0.3 cutoff as an operational flag for low-confidence pose estimation failure. No calibration nor documented rationale for the numerical cutoff was available. It was distinct from the 0.3 pose detection parameter used to reprocess 5 static videos. A stricter target frame cutoff of ≥0.5 was also examined as a sensitivity analysis.

Kinovea 2D Video Reference

Two trained raters independently annotated task-specific target frame knee angles using Kinovea 2025.2. Each rater selected maximum clinical knee flexion for squat and sit-to-stand and a steady midstance frame for single-leg stance then digitized the greater trochanter, lateral femoral epicondyle, and lateral malleolus using the reflective markers as guides. The native 2D-included angle was converted to clinical knee flexion as 180° − included angle. Kinovea served as a 2D video-analysis reference; it was not assumed to provide absolute 3D joint kinematics.

Raters were blinded to each other's annotations and to BlazePose output. Their mean clinical flexion angle was used as the Kinovea 2D reference for dynamic agreement, and their mean target frame time stamp was used for BlazePose time matching. High interrater agreement reduces uncertainty from rater inconsistency but does not remove systematic 2D reference error.

BlazePose–Kinovea Time Matching

For the primary dynamic comparison, BlazePose was evaluated at the Kinovea-selected target time rather than at BlazePose's automated video minimum. For each of the 210 observations, the mean of the 2 rater time stamps was calculated, and the closest time stamp in the BlazePose per-frame output was selected. The native-included angle at that frame was converted to clinical flexion before analysis. This separates target-time selection by the 2D reference from BlazePose angle estimation at that time.

Descriptive Data Quality Grading

Each of the 342 videos received a descriptive A-D quality assurance grade based on the proportion of frames with confidence ≥0.8: Grade A (≥80%), Grade B (50% - 79%), Grade C (20% - 49%), or Grade D (<20%). These trial-level labels did not determine inclusion, weighting, or statistical inference and are not equivalent to target frame detection success. For a post hoc descriptive acquisition sequence summary, participants were grouped as S01-S06, S07-S10, and S11-S15; these groups were used only to describe target frame confidence and failure rates, without inferential testing. Detailed grade and detection

XSL•FO
RenderX

quality distributions are reported in Tables S1-S5 in Multimedia Appendix 1 .

Statistical Analysis

The original analyses used Python 3.9.6, pingouin for ICCs, and scipy.stats. The revision-stage participant cluster analyses used Python 3.12.14, NumPy 2.3.5, pandas 2.2.3, and SciPy 1.16.2. $ICC_{2,1}$ was recomputed from the same ANOVA formula and verified against the frozen results. Figures were generated using matplotlib.

Concurrent Validity

Agreement was summarized using the 2-way random effects, single-measure, absolute agreement ICC, $ICC_{2,1}$. Signed bias and limits of agreement (LoA) used the Bland-Altman framework [14]; MAE and RMSE quantified error magnitude. Static bias was BlazePose minus goniometer target clinical flexion, dynamic bias was BlazePose minus Kinovea clinical flexion, and interrater bias was Rater A minus Rater B. Pearson *r* described association not absolute agreement. ICC interpretation followed Koo and Li [15].

Primary cross-sectional inference retained the observation-level ICC and error estimands. We calculated percentile 95% CIs by resampling eligible participants with replacement, retaining all paired observations from each sampled participant (10,000 resamples; master seed 20260923; stable analysis-specific seeds). No trials were sampled independently. Dynamic agreement remained conditional on target frame confidence ≥0.3: Squat and combined single-leg stance each had 15 contributing participants, whereas sit-to-stand had 12. Participants with no retained observations remained in availability denominators. Repeated-measures LoA were calculated as bias ±1.96 times the square root of the sum of within- and between-participant variance components, allowing unequal repeats [16]. Negative estimated between-participant variance components were set to zero. Bootstrap CIs were also computed separately for bias and each LoA endpoint (Tables S16-S19 in Multimedia Appendix 1). Task-specific dynamic and angle-specific static results guided interpretation; pooled results are descriptive mixtures. Participant-mean analyses are supplementary and estimate agreement after averaging, not single-observation agreement. Participant-by-task or participant-by-angle cells from the same individual were not treated as independent for primary inference. Four-participant repeated-session results retained unadjusted descriptive intervals and were not used for primary inference.

For static analysis, the filtered-mean native BlazePose angle was converted to clinical flexion and compared with the goniometer target. Angle-specific results were reported to characterize error across 30°, 60°, 90°, and 120° of target flexion. For dynamic analysis, time-matched BlazePose clinical flexion was compared with the mean Kinovea clinical flexion value. Squat, sit-to-stand, and combined single-leg stance estimates were the main task-level results; side-specific single-leg stance and pooled cross-task estimates were secondary descriptive results.

Interrater Reliability

Interrater agreement of the Kinovea 2D annotations was assessed across 210 paired clinical flexion measurements using $ICC_{2,1}$, bias and 95% LoA, MAE, RMSE, and Pearson *r*. Estimates were reported overall and by task. The a priori descriptive benchmark for acceptable interrater ICC was 0.90. Between-task significance tests were not performed because trial-level implementations would not account for repeated observations within participants.

Exploratory Repeated-Session Analyses

Four participants (S01-S04) completed a second session after observed intervals of 21 days to 29 days (median 25 d). All repeated-session analyses were exploratory and addressed distinct measurement questions rather than constituting a single reliability claim.

First, BlazePose repeated-session agreement was evaluated for 48 paired static trial means and, as an all-output stress test, for 24 paired automated video-minimum dynamic values (4 participants × 6 videos). The dynamic estimand used 1 automated video minimum per recording rather than a Kinovea-selected time-matched frame and applied no raw-peak confidence gate; 10 of the 24 pairs had at least one raw-peak confidence value <0.3.

Second, repeated-session agreement of the Kinovea 2D reference was explored using 56 paired task/trial clinical flexion observations (4 participants × 14 observations).

Third, conditional BlazePose-versus-Kinovea agreement was described for Session 2. The same target-frame confidence criterion used in Session 1 retained 35 of 56 available observations. This 4-participant analysis was not treated as a replication study.

Fourth, the between-method clinical flexion difference was calculated in each session for 34 observations valid at both sessions. The ICC of these paired differences was used as an exploratory indication of whether the observed between-method offset might be consistent across sessions. Given the 4-participant sample and repeated observations, the estimate was not interpreted as proof of either stability or instability.

Repeated-session analyses used $ICC_{2,1}$, signed bias and 95% LoA, MAE, and RMSE. The analysis unit for these descriptive calculations was the repeated task/trial observation nested within 4 participants; the F-distribution ICC intervals did not adjust for participant-level clustering. Estimates were therefore presented with their denominators and uncertainty and were not used as headline clinical evidence.

Interpretation Thresholds

ICC values were described using the categories from Koo and Li [15]: <0.50, poor; 0.50 - 0.75, moderate; 0.75 - 0.90, good; and >0.90, excellent. Following Langley et al [6], ±5° for signed mean difference and ±10° for LoA were used only as descriptive contextual anchors for those same metrics, not as universal clinical acceptability thresholds. MAE and RMSE were reported as error-magnitude measures without assigning them a universal cutoff. Statistical association and agreement were interpreted

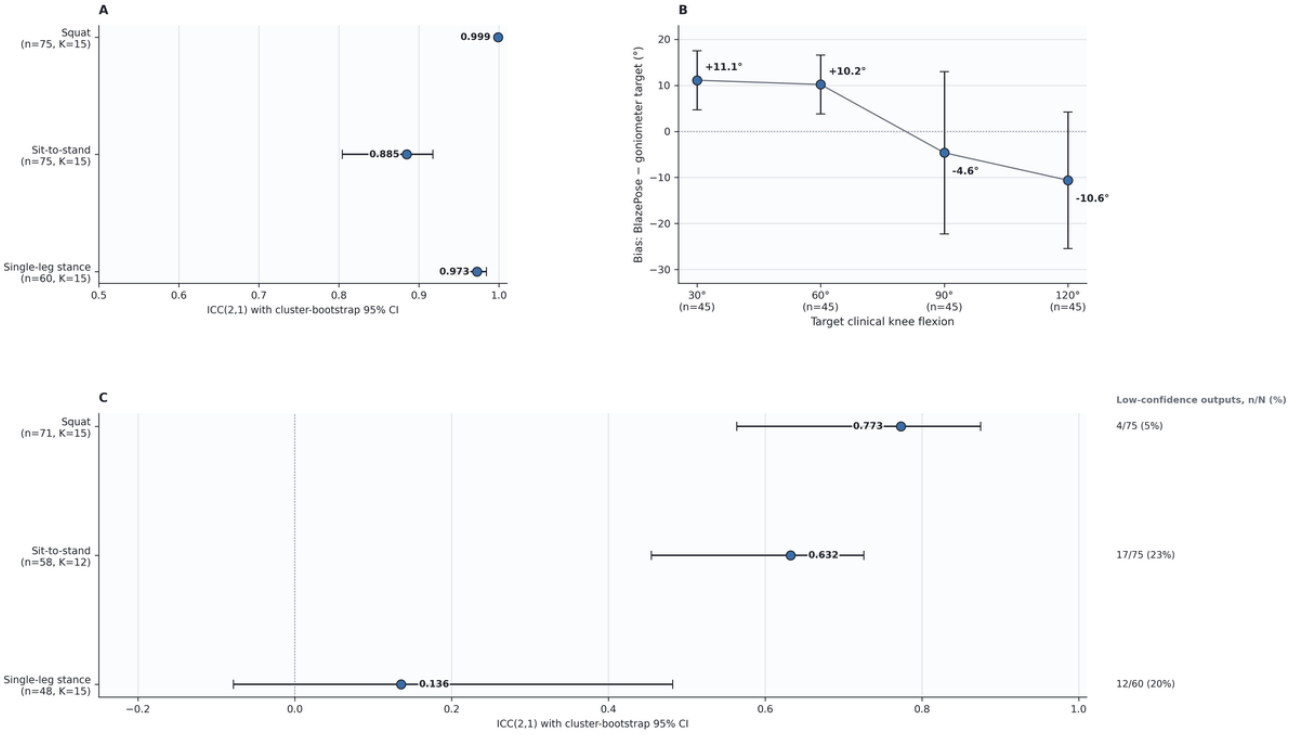
XSL•FO
RenderX

separately, and no multiplicity-adjusted confirmatory inference was claimed for exploratory strata.

Ethics Approval

This study was approved by the Academic Ethics and Integrity Review Committee of Shanghai Sanda University (approval number 2026006, April 14, 2026). The study was conducted in accordance with the Declaration of Helsinki. All participants provided informed consent prior to enrollment.

Results



Participants

The cross-sectional analysis included 15 healthy adults (8 men, 7 women; mean age 20.8, SD 0.6, range 20 - 22 years; mean height 171.1, SD 9.4 cm; mean weight 70.7, SD 15.7 kg; mean BMI 23.9, SD 3.4, range 18.8 - 31.3 kg/m²). All 15 participants completed the full data collection protocol without reported adverse events. Four participants (S01-S04; 2 men, 2 women) returned for the exploratory repeated-session assessment after 21 days to 29 days (median 25 d).

For the primary cross-sectional analyses, 180 static trials (15 participants × 12 conditions) and 210 dynamic Kinovea-annotated target-frame observations were available.

Figure 1 summarizes the task-specific interrater agreement, angle-specific static signed error, and task-specific conditional dynamic agreement with detection failure rates. Detailed results are presented in Tables 1–5 and Multimedia Appendix 1.

Figure 1. Task- and angle-specific measurement results: (A) task-level interrater reliability between Kinovea Raters A and B, with points showing the intraclass correlation coefficient (ICC)$_{2,1}$, horizontal bars showing participant-cluster bootstrap 95% CI, K indicating the number of eligible participants, and n indicating the number of observations; (B) static BlazePose bias relative to goniometer target flexion, with points showing mean bias and error bars showing ±1 SD of paired differences not CIs and positive values indicating greater flexion estimated using BlazePose; (C) task-level dynamic agreement with the Kinovea 2D reference, conditional on target-frame BlazePose confidence ≥0.3, with the adjacent column reporting low-confidence outputs using all attempts as denominators. Single-leg stance combines left and right sides. All angles are clinical knee flexion, with 0° at full extension.

Table . Static agreement of BlazePose clinical knee flexion with goniometer target flexion (n=180; S01-S15).

Target flexion	Observations, n	Bias[a]	95% LoA[b,c,d]	MAE[e]	RMSE[f]	SD(diff)[g]	SEM[h,i,g]
Overall[j,k]	180	+1.51°[l]	−28.85° to +31.87°	10.01°	15.49°	15.46°	10.93°
30°	45	+11.11°	−1.73° to +23.94°	11.15°	12.79°	6.41°	4.53°
60°	45	+10.18°	−2.66° to +23.03°	10.82°	11.99°	6.40°	4.53°
90°	45	−4.64°	−39.36° to +30.07°	7.45°	18.02°	17.60°	12.45°
120°	45	−10.60°	−39.71° to +18.50°	10.60°	18.10°	14.84°	10.49°

[a]Bias: BlazePose clinical flexion−goniometer target flexion.

[b]LoA: limits of agreement.

[c]LoA endpoint CIs are in Table S17 in Multimedia Appendix 1.

[d]LoA use repeated-measures variance components (15 participants per row).

[e]MAE: mean absolute error.

[f]RMSE: root mean square error.

[g]SD(diff) and SEM remain descriptive trial-level summaries.

[h]SEM: standard error of measurement.

[i]SEM =SD(diff)/√2.

[j]Overall $ICC_{2,1}$=0.874 (95% CI 0.770 to 0.953).

[k]The ICC CI uses participant-cluster bootstrapping.

[l]Overall pooled bias is descriptive because angle-specific errors reverse direction.

Table . Conditional agreement of BlazePose with the Kinovea 2D clinical flexion reference at target frames with BlazePose confidence ≥0.3, with all values reflecting clinical knee flexion.

Task	Retained observations, n	Available observations, n	Failures from the available observations, n (%)	Bias[a] (95% LoA[b,c])[d]	MAE[e]	RMSE[f]	Pearson *r*[g]	$ICC^{h}_{2,1}$ (95% CI[i])
Squat (n=15 participants)	71	75	4 (5)	+6.17° (−6.45° to +18.78°)	7.10°	8.78°	0.885	0.773 (0.564 to 0.875)
Sit-to-stand (n=12 participants)	58	75	17 (23)	+6.43° (−1.82° to +14.67°)	6.68°	7.59°	0.896	0.632 (0.455 to 0.726)
Single-leg stance, both legs combined (n=15 participants)	48	60	12 (20)	+2.01° (−23.42° to +27.44°)	7.51°	12.88°	0.173	0.136 (−0.078 to 0.482)
Overall, secondary descriptive (n=15 participants)	177	210	33 (15.7)	+5.12°[j] (−11.30° to +21.55°)	7.07°	9.73°	0.987	0.982 (0.967 to 0.992)

[a]Bias: BlazePose−Kinovea 2D reference; positive values indicate greater flexion from BlazePose.

[b]LoA: limits of agreement.

[c]LoA use repeated-measures variance components.

[d]Bias and LoA endpoint CIs are in Tables S16-S19 in Multimedia Appendix 1.

[e]MAE: mean absolute error.

[f]RMSE: root mean square error.

[g]Describes an association, not absolute agreement.

[h]ICC: intraclass correlation coefficient.

[i]ICC CIs use participant-cluster bootstrapping.

[j]The overall pooled ICC is range-sensitive and is not a headline result.

Table . Exploratory repeated-session analyses with 4 participants (S01-S04; observed interval 21 - 29 d, median 25 d); pooled estimates may be influenced by between-task or between-angle range and are not headline clinical evidence.

Exploratory analysis	Observations, n	Bias definition	Bias (95% LoA[a])	MAE[b]	RMSE[c]	ICC[d]$_{2,1}$ (95% CI)[e]
BlazePose static, Session 1 versus Session 2	48	Session 2−Session 1	−7.30° (−42.65° to +28.04°)	10.32°	19.28°	0.782[f] (0.617 to 0.877)
BlazePose dynamic automated video-minimum stress test[g]	24	Session 2−Session 1	+18.92° (−82.04° to +119.89°)	34.71°	53.86°	0.522 (0.174 to 0.757)
Kinovea 2D reference, Session 1 versus Session 2	56	Session 2−Session 1	+1.19° (−12.05° to +14.42°)	5.63°	6.80°	0.991 (0.985 to 0.995)
BlazePose versus Kinovea, Session 2 conditional	35	BlazePose−Kinovea	+8.10° (−14.69° to +30.89°)	8.95°	14.03°	0.969 (0.889 to 0.988)
Between-method difference, Session 1 versus Session 2	34	Session 2 difference−Session 1 difference	+2.45° (−14.01° to +18.91°)	5.19°	8.63°	0.094 (−0.225 to 0.405)

[a]LoA: limits of agreement.

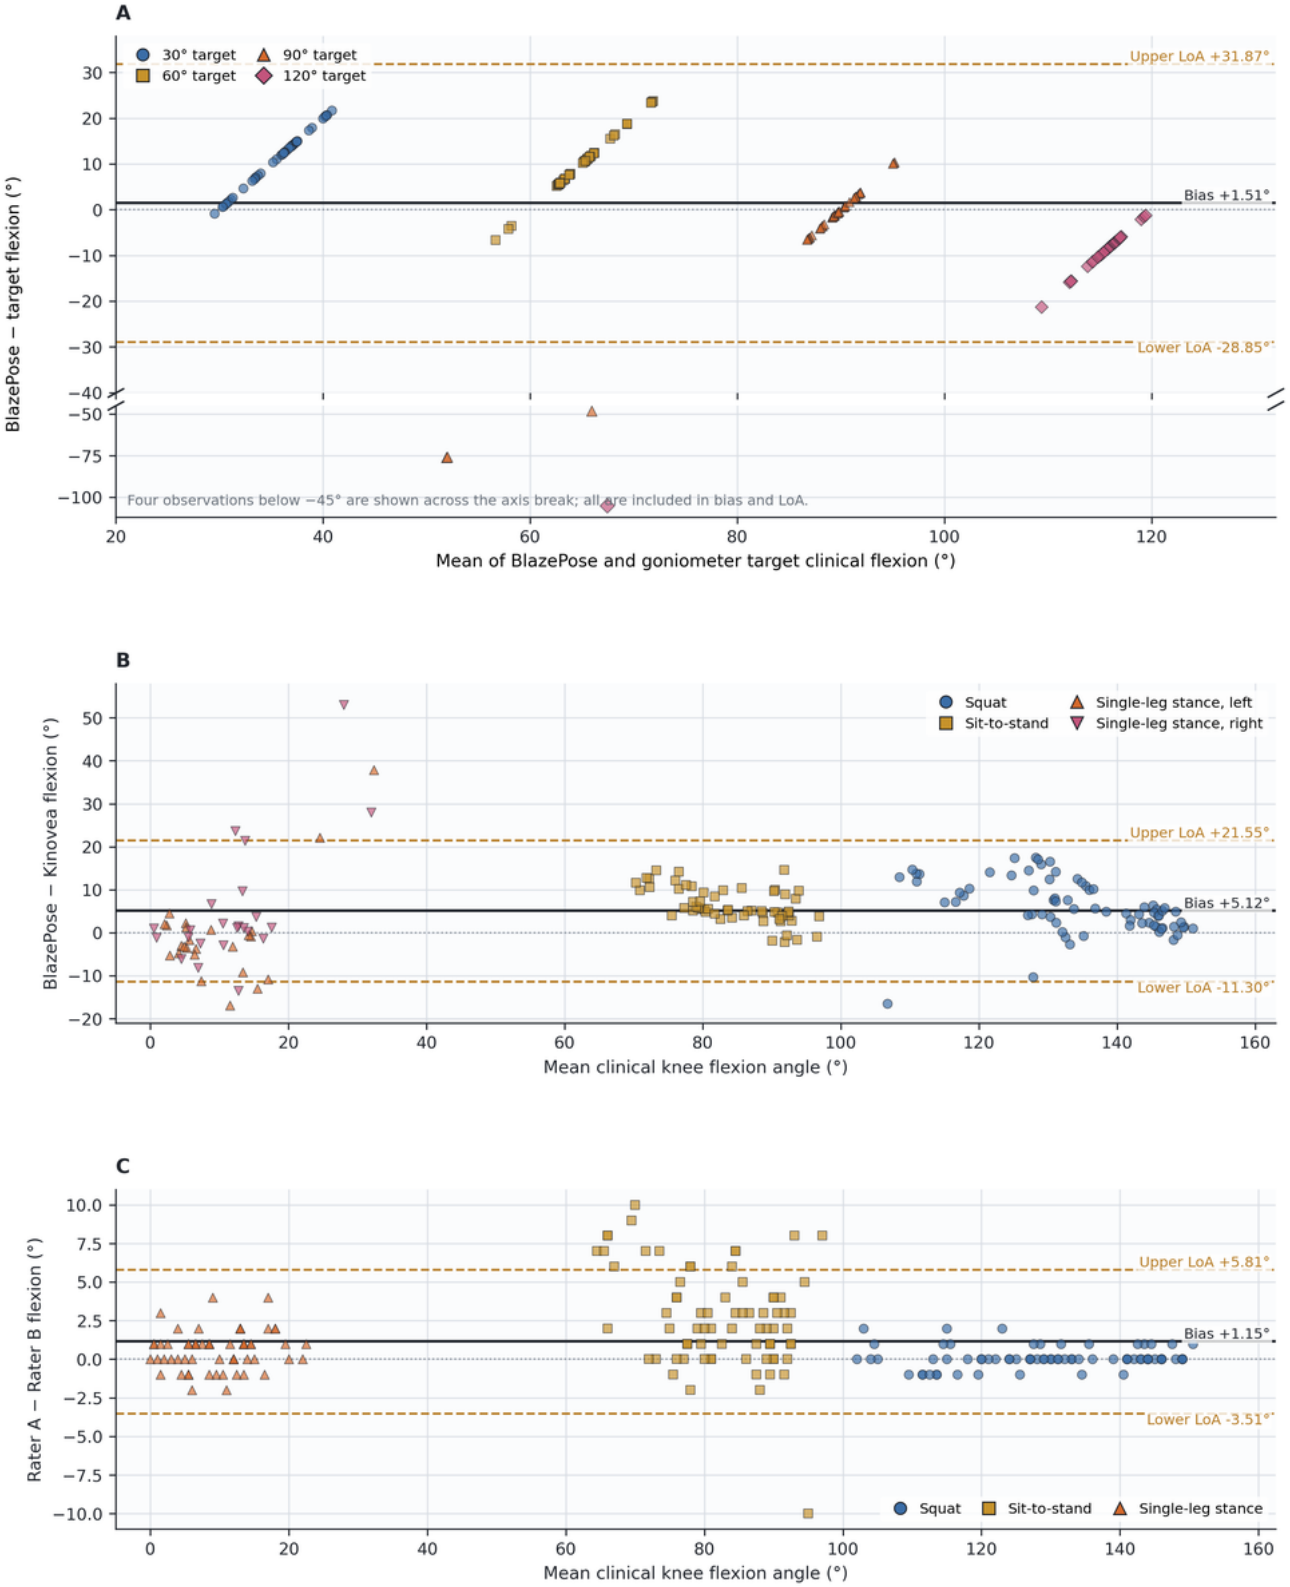
[b]MAE: mean absolute error.

[c]RMSE: root mean square error.

[d]ICC: intraclass correlation coefficient.

[e]Do not adjust for participant-level clustering.

[f]Excluding the 2 retest threshold-rescued static pairs changed the static repeated-session ICC from 0.782 to 0.766.



[g]Uses 1 automated video minimum per recording, applies no raw-peak confidence gate, and includes 10 of 24 pairs with at least one raw-peak confidence value <0.3.

Interrater Agreement of Kinovea 2D Annotations

Overall interrater agreement for the Kinovea 2D clinical flexion annotations was high ($ICC_{2,1}$=0.999, cluster-bootstrap 95% CI 0.998 to 0.999; MAE=1.56°; n=210 observations from 15 participants; Table 2; Figure 2C). This indicates consistent annotation between these 2 raters but does not establish absolute accuracy against 3D kinematics.

XSL•FO
RenderX

Figure 2. Bland-Altman plots using clinical knee flexion angles and showing the mean of paired angles on the x axis and the first-named measurement minus the second on the y axis, with positive differences indicating greater flexion from the first measurement: (A) BlazePose versus goniometer-set targets (n=180, 15 participants; bias +1.51°; 95% limits of agreement [LoA] –28.85° to +31.87°), with 4 observations <−45° shown across a broken y axis and included in all calculations; (B) BlazePose versus Kinovea 2D reference among outputs with target-frame confidence ≥0.3 (n=177, 15 participants overall; bias +5.12°; 95% LoA –11.30° to +21.55°); (C) Kinovea Rater A versus Rater B (n=210, 15 participants; bias +1.15°; 95% LoA –3.51° to +5.81°). The solid dark line is the mean bias, the dashed lines are repeated-measures 95% LoA from within- and between-participant variance components, and the dotted line is zero. These limits are not CIs; CIs for their endpoints are in Table S17 in Multimedia Appendix 1. Points are repeated observations. Pooled lines summarize mixtures of angles or tasks; they do not imply constant bias or uniform coverage across those conditions. Angle- and task-specific limits guide interpretation (Tables 2–4).

XSL•FO
RenderX

Task-specific ICCs were 0.999 for squat, 0.885 for sit-to-stand, and 0.973 for single-leg stance. The sit-to-stand point estimate of 0.885 was less than the a priori descriptive benchmark of 0.90, and its cluster-bootstrap 95% CI was 0.804 to 0.918. Sit-to-stand had the largest interrater MAE (3.13°) and a clinical-flexion bias of +2.65° for Rater A minus Rater B. The lower sit-to-stand ICC may reflect the more gradual transition around peak flexion, which makes the selection of a single target frame less distinct than in squat; this is a plausible explanation rather than a demonstrated mechanism.

Static Agreement With Goniometer-Set Targets

Across 180 static observations from 15 participants, $ICC_{2,1}$ was 0.874 (cluster-bootstrap 95% CI 0.770 to 0.953), MAE was 10.01°, and RMSE was 15.49° (Table 3; Figure 2A). These differences include uncertainty in target positioning and holding as well as BlazePose estimation and are reported without a universal clinical acceptability cutoff.

Signed error varied by target angle. BlazePose overestimated clinical flexion at 30° (+11.11°) and 60° (+10.18°) and underestimated it at 90° (−4.64°) and 120° (−10.60°). Dispersion was substantially wider at 90° and 120° than at 30° and 60°. This range compression did not support a single fixed correction across the tested angles and did not identify one causal mechanism.

Excluding the 3 static Session 1 videos reprocessed at the lower pose detection threshold changed static ICC from 0.874 to 0.870 and RMSE from 15.49° to 15.58°. This sensitivity analysis quantifies the effect of the protocol deviation; full results are reported in Multimedia Appendix 1 (Table S14).

Dynamic Conditional Agreement With the Kinovea 2D Reference

Dynamic measurement was available for 177 of 210 (84.3%) observations. The remaining 33 of 210 (15.7%) observations had target-frame confidence <0.3. Availability reached 71 of 75 (95%) observations for squat, 58 of 75 (77%) observations for sit-to-stand, and 48 of 60 (80%) observations for combined single-leg stance. Failures occurred for 5 of 30 (17%) observations on the left and 7 of 30 (23%) observations on the right. Participant counts and distributions are reported in Tables S1 and S5 in Multimedia Appendix 1.

Failures were concentrated in S10 (11/14, 79%), S13 (6/14, 43%), and S12 (5/14, 36%). Kinovea flexion medians for failed versus retained observations were 113.2° versus 131.0° for squat, 89.0° versus 81.0° for sit-to-stand, and 10.2° versus 8.8° for combined single-leg stance. These are descriptive contrasts not evidence of why detection failed; only 4 squat observations failed. Quartiles, ranges, and participant counts are in Table S5 in Multimedia Appendix 1.

Detection performance also varied by acquisition group. Target-frame median confidence and failures were 0.939 and 2 of 84 (2%) observations, respectively, for S01-S06; 0.643 and 14 of 56 (25%) observations, respectively, for S07-S10; and 0.694 and 17 of 70 (24%) observations, respectively, for S11-S15. No recorded device nor encoding variable changed uniquely at S07 or aligned with the persistent later-group decrease; the known 120-to-60 frames-per-second change occurred earlier, between S02 and S03. Because lighting, exact camera geometry, exposure and focus, attire, and background were incompletely recorded, the cause remains unresolved.

Task-specific ICCs were 0.773 (95% CI 0.564 to 0.875; n=71, 15 participants) for squat, 0.632 (95% CI 0.455 to 0.726; n=58, 12 participants) for sit-to-stand, and 0.136 (95% CI −0.078 to 0.482; n=48, 15 participants) for combined single-leg stance (Table 4). Squat and sit-to-stand had high Pearson correlations (r=0.885 and r=0.896), but their absolute-agreement ICC point estimates were good and moderate, respectively. BlazePose overestimated clinical flexion by +6.17° and +6.43°, respectively. The restricted near-extension range in single-leg stance reduced between-participant variance and made the ICC sensitive to modest error; occlusion, out-of-plane rotation, perspective shortening, side selection, and landmark localization are additional plausible contributors.

Across 177 retained observations, the pooled cross-task ICC was 0.982 (cluster-bootstrap 95% CI 0.967 to 0.992), with bias +5.12° and repeated-measures LoA −11.30° to +21.55° (Figure 2B). This is a secondary descriptive mixture because between-task angle range inflates between-observation variance; it does not imply uniform agreement across tasks.

Participant mean results are provided in Table S18 in Multimedia Appendix 1. These compare the average retained measurements per person and task, not individual observations. The numbers averaged varied because of detection failures. Earlier exploratory participant-by-task summaries in Tables S10-S11 in Multimedia Appendix 1 are retained with their distinct units and unadjusted intervals explicitly identified.

In the all-output stress test, retaining all 210 numeric outputs produced the largest deterioration for squat, for which the ICC decreased from 0.773 to 0.428 and RMSE increased from 8.78° to 25.43°. The sit-to-stand ICC decreased from 0.632 to 0.596, and the combined single-leg stance ICC decreased from 0.136 to 0.119. The pooled ICC decreased from 0.982 to 0.942. These estimates characterize performance without the quality gate and do not replace the conditional primary analysis.

At the stricter target-frame threshold of ≥0.5, availability was 158 of 210 (75.2%) observations; task-specific ICCs were 0.770 (n=70) for squat, 0.670 (n=50) for sit-to-stand, and 0.204 (n=38) for combined single-leg stance (Table S15 in Multimedia Appendix 1). This sensitivity analysis describes the availability-agreement tradeoff and does not establish an optimal threshold.

Exploratory Repeated-Session Findings

Kinovea 2D Reference Across Sessions

Across the 56 repeated task/trial observations collected 21 days to 29 days apart, the pooled Kinovea repeated-session ICC was 0.991 (95% CI 0.985 to 0.995), with an MAE of 5.63° (Table 5). This pooled value reflects the wide range across tasks and repeated observations of only 4 participants. These 4-participant repeated-session data were insufficient to determine whether Kinovea agreement differed by task.

XSL•FO
RenderX

BlazePose Across Sessions

Static repeated-session agreement was an ICC of 0.782 (95% CI 0.617 to 0.877; n=48), with Session 2-minus-Session 1 clinical-flexion bias of −7.30° and a wide LoA (−42.65° to +28.04°). The dynamic all-output automated video-minimum stress test yielded an ICC of 0.522 (95% CI 0.174 to 0.757; n=24), an MAE of 34.71°, and an LoA of −82.04° to +119.89°. At least one raw-peak confidence value <0.3 was present for 10 of the 24 dynamic pairs. These values describe an ungated stress test of repeated automated video minima for 4 participants, not time-matched repeated-session validity.

Session 2 Conditional Agreement

In Session 2, 21 of the 56 target-frame observations failed the confidence criterion, leaving 35 for conditional agreement analysis. The pooled cross-task ICC among retained observations was 0.969 (95% CI 0.889 to 0.988), with a bias of +8.10° and an MAE of 8.95°. Because this estimate pools tasks and derives from 4 participants after substantial selection, it is presented as an exploratory descriptive result rather than evidence that Session 1 performance was replicated.

Between-Method Difference Across Sessions

Among 34 observations valid in both sessions, the ICC for the paired BlazePose-minus-Kinovea clinical-flexion differences was 0.094 (95% CI −0.225 to 0.405). This wide interval from 4 participants is insufficient to support a stable fixed-offset assumption; it is also insufficient to establish that bias instability is a general property of the method. Larger repeated-session samples are required before calibration or longitudinal change interpretations can be evaluated.

Data Quality and Detection Reproducibility

Across all 342 videos, the descriptive quality-grade distribution was Grade A, 164/342 (48%); Grade B, 21/342 (6.1%); Grade C, 31/342 (9.1%); and Grade D, 126/342 (36.8%; Table S4 in Multimedia Appendix 1). These video-level quality assurance labels did not determine target-frame inclusion, weighting, or statistical inference and are not measures of target-frame detection success.

Detailed detection quality, retest, subject mean, and sensitivity results are provided in Multimedia Appendix 1.

Discussion

Principal Findings

Agreement of single-camera BlazePose knee-flexion estimates with the study references depended on task, flexion angle, and detection quality. With measurement availability of 177 of 210 observations (84.3%), task-specific conditional ICC point estimates ranged from good for squat to poor for single-leg stance. The primary cross-sectional CIs now account for repeated observations through participant-cluster resampling, and LoA incorporated within- and between-participant variance. These changes did not remove the uncertainty from only 12 to 15 contributing participants per dynamic task. Static differences changed direction across target angles and included target-setting and holding uncertainty. Kinovea interrater agreement did not establish 3D accuracy, and 4-participant repeated-session findings remained exploratory.

Kinovea as a 2D Reference

High Kinovea interrater agreement indicates that 2 raters produced similar 2D annotations and reduced 1 source of uncertainty in the BlazePose comparison. It did not establish Kinovea's accuracy against 3D kinematics or show that every between-method difference originates from BlazePose. Both methods used a single sagittal view and may have shared projection, landmark, and out-of-plane error.

Task- and Quality-Dependent Dynamic Agreement

Task-specific estimates are more informative than the pooled cross-task ICC because pooling squat, sit-to-stand, and near-extension single-leg stance greatly expanded the angle range. Squat and sit-to-stand showed strong relative association but only good-to-moderate absolute agreement, illustrating why correlation cannot substitute for agreement metrics. In the clinical-flexion space, BlazePose overestimated flexion by approximately 6° for these tasks, and every task-specific LoA interval extended beyond at least one of the descriptive ±10° anchors. If reproduced clinically, this error direction could make recovery appear greater than it is; the healthy sample cannot quantify that clinical consequence.

The conditional analysis also described performance only when target-frame confidence was adequate. Retaining all numeric outputs produced marked deterioration for squat, and failure rates varied by task, participant, and acquisition group. The unresolved confidence decrease after S01-S06 shows that a constant camera model and file format did not guarantee consistent detection. Any future deployment would therefore require explicit measurement availability reporting and a per-recording quality gate rather than relying only on accuracy among successful detections.

Angle-Dependent Static Error

Static signed error changed from flexion overestimation at 30° and 60° to underestimation at 90° and 120°. The angle-specific signed bias exceeded the descriptive ±5° anchor at 30°, 60°, and 120°, and every angle-specific LoA interval extended beyond at least one of the descriptive ±10° anchors. Together with the overall RMSE, this direction reversal and dispersion did not support a single calibration offset across the tested range. The result was agreement with goniometer-set targets in healthy participants not evidence that BlazePose can replace clinical goniometry. The goniometer was reapplied and reread before every trial but removed for recording and not reapplied afterward. Consequently, target-setting error, rounding, drift during the hold, and goniometer error cannot be separated from BlazePose error; the manufacturer-stated accuracy is not an in-study calibration estimate.

Plausible contributors included mismatch between image-based and palpated anatomical landmarks, perspective shortening, out-of-plane limb rotation, occlusion or crossing limbs, side-selection errors, and amplification of small landmark displacements when segments approach collinearity. These mechanisms are consistent with the observed angle and task

XSL•FO
RenderX

dependence but were not isolated experimentally and should not be stated as proven causes.

Single-Leg Stance: Restricted Range and Plausible Failure Mechanisms

Single-leg stance had poor concurrent agreement. Because the supporting knee occupied a narrow range near full extension, between-participant variance was small, and ICC was especially sensitive to modest measurement error. Occlusion by the nonstance limb, out-of-plane rotation, perspective, and landmark localization may add error in a single lateral view. Exploratory repeated-session findings from 4 participants did not resolve whether this uncertainty was task-related, method-related, or sample-related and did not establish that instability is intrinsic to the task.

Exploratory Repeated-Session Findings

The repeated-session analyses were based on 4 participants assessed 21 days to 29 days apart and cannot support definitive reliability or bias stability claims. The n=24 dynamic analysis was an ungated, automated, video-minimum stress test not a time-matched measure, and 10 of the 24 pairs included at least one low-confidence raw peak. The ICC for the between-method difference was imprecise and is best interpreted as insufficient evidence for a stable fixed offset not proof of universal bias drift. The 21 - to-29-day interval also permits real within-person change to contribute to disagreement, so measurement error and biological variation cannot be separated here.

Limitations

The cross-sectional sample was small (n=15) and recruited by convenience from healthy young adults at one university, and no a priori power calculation was performed. The repeated-session subsample contained 4 participants, producing imprecise estimates from repeated observations nested within individuals. Findings cannot be generalized to older adults, knee osteoarthritis, anterior cruciate ligament reconstruction, total knee arthroplasty, or other clinical populations. One readily available iPhone 17 Pro was used throughout to hold hardware constant; equivalence across phones, lenses, frame rates, and device-specific image processing was not tested.

The static comparator was a rounded goniometer-set target rather than an independent measurement of the recorded posture, and the dynamic comparator was Kinovea 2D annotation rather than marker-based 3D kinematics, so absolute biomechanical accuracy remains unknown. We reprocessed 5 static videos at a lower pose-detection threshold, which was a protocol deviation; sensitivity analyses excluding them changed the estimates only slightly. The 33 failures from the 210 dynamic detection observations were unevenly distributed, making the retained-observation agreement estimates conditional on adequate detection. Target-frame confidence decreased after S01-S06 and did not recover in S11-S15; because acquisition conditions were incompletely recorded, the cause could not be identified. Participant-cluster CIs and repeated-measures LoA addressed clustering in the primary cross-sectional analyses, but with only 12 to 15 contributing participants per dynamic task, all interval procedures remained approximate; bootstrap intervals may have had inadequate coverage. The LoA variance model assumes approximately normal differences, common within-participant variance within a stratum, and conditionally independent residual differences. Consecutive repetitions may violate the last assumption. Resampling whole participants preserves the observed dependence but does not validate those distributional assumptions or guarantee future coverage. Across-angle and cross-task pooled LoA are descriptive only. The target-frame cutoff was established during analysis without a documented calibration basis, and sensitivity analyses did not make it a validated deployment threshold. Four-participant repeated-session intervals remained unadjusted and descriptive. Detailed angle-, side-, participant-, and sensitivity-level estimates are exploratory and were not adjusted as multiple confirmatory tests. The study assessed 1 BlazePose model, sagittal-plane angles, and selected task frames only; frontal/transverse motion and temporal variables were not evaluated.

Clinical Implications and Future Directions

This evidence supports only feasibility or screening-level research use under controlled acquisition with explicit quality checks. It does not support replacing a clinical goniometer, making precise longitudinal treatment decisions, assuming that a fixed calibration is stable, or using the method as an unconditional remote clinical measurement. Because BlazePose overestimated clinical flexion in squat and sit-to-stand, an unverified reading could overstate apparent recovery or mask a residual deficit; measurements that would affect care should be confirmed with an established clinical assessment.

Priorities for future work are larger, prospectively sized, and multisite cohorts; validation against 3D motion capture; testing in relevant clinical populations; direct cross-device evaluation; and controlled experiments that vary camera geometry, lighting, attire, occlusion, and out-of-plane motion. Repeated-session studies should prespecify the estimand, retain participant-level sampling in the analysis, and report both measurement availability and agreement conditional on successful detection.

Conclusions

Single-camera MediaPipe BlazePose had dynamic measurement availability of 177 of 210 (84.3%) observations: This included 71 of 75 (95%) observations for squat, 58 of 75 (77%) observations for sit-to-stand, and 48 of 60 (80%) observations for single-leg stance. Among the retained observations, the corresponding ICCs for squat, sit-to-stand, and single-leg stance were 0.773, 0.632, and 0.136, respectively with participant-cluster intervals showing substantial uncertainty. Static agreement with goniometer-set targets varied by angle and included uncertainty in the reference positioning. Four-participant repeated-session findings did not establish stable calibration or reliable longitudinal change measurement. These data support further controlled feasibility and screening-level evaluation with per-recording quality checks not replacement of clinical measurement or routine remote clinical decision-making.

Abstract

Background: Many stroke survivors experience chronic cognitive deficits that, together with motor impairments, negatively impact well-being and daily function. Critically, poststroke cognitive deficits can interfere with successful engagement in rehabilitation programs aimed at improving participation in home and community activities. To address this issue, we developed a new telehealth intervention that integrates brief, functional cognitive rehabilitation (COG) into an existing upper extremity-focused, activity-based occupational therapy (OT) telerehabilitation program.

Objective: To describe the development and specification of a telehealth intervention (COG+OT) that integrates functional cognitive rehabilitation into activity-based stroke telerehabilitation.

Methods: COG+OT was developed using a multi-disciplinary, theory-informed process guided by principles of functional cognitive rehabilitation. It is reported according to the Template for Intervention Description and Replication checklist for rehabilitation (TIDieR-Rehab). The intervention was developed by a team with expertise in stroke rehabilitation from the fields of OT, neuropsychology, clinical psychology, and speech-language pathology. Cognitive rehabilitation content was adapted from an evidence-based compensatory strategy program and condensed into a brief "primer" format. The COG component was iteratively integrated into an existing upper-extremity, activity-based OT telerehabilitation program to support engagement and transfer of strategies to real-world functional tasks. In this paper, we describe the intervention structure, content, delivery, and tailoring procedures.

Results: COG+OT is an 8-week, 13-session telehealth intervention delivered in three phases: (1) cognitive strategy training ("primer"; sessions 1-4), (2) review and guided application of strategies within OT activities (sessions 5 - 10), and (3) integration of strategies to support generalization to everyday contexts (sessions 11-13). The intervention combines individualized, strategy-based cognitive rehabilitation with goal-oriented OT using a titrated approach. Patient-facing materials, structured session workflows, and therapist-guided metacognitive strategies support tailoring and real-world application.

Conclusions: COG+OT is a theory-informed, user-centered intervention that provides a structured approach for integrating functional cognitive rehabilitation into stroke telerehabilitation. This work establishes a well-specified, replicable intervention model and supports future feasibility, effectiveness, and implementation studies.

Introduction

Poststroke cognitive deficits occur in up to 70% of stroke survivors, most commonly in the domains of memory, attention, and executive function [1]. These multifaceted cognitive deficits are consequential for stroke recovery, as they are associated with lower mood and quality of life, reduced participation in daily activities, and more protracted disability [2,3]. Cognitive rehabilitation interventions are effective at remediating cognitive dysfunction across many clinical conditions [4], and growing evidence indicates that functional cognitive rehabilitation, defined as strategy-based training aimed at enhancing real-world cognitive functioning, is particularly useful for improving everyday functioning poststroke [5]. However, cognitive rehabilitation is underutilized in stroke care due to prioritization of physical over psychosocial and cognitive recovery [6], limited access to cognitive rehabilitation services, lack of a well-defined replicable intervention model, and the burden of conventional multiweek treatment schedules. Furthermore, it is typically delivered as a stand-alone intervention, separate from other therapies in which cognitive strategies could be practiced and applied, creating a missed opportunity for integrated rehabilitation that enhances generalization of skills into daily life routines. With the increasing recognition of cognitive health as critical for functioning and quality of life, poststroke therapies combining physical and cognitive rehabilitation are an urgent need.

In prior work, we developed a telerehabilitation occupational therapy (OT) program that integrates upper-extremity task practice [7] with metacognitive strategy training (ie, teaching individuals to plan, monitor, and evaluate their own performance) based on the Cognitive Orientation to daily Occupational Performance approach [8]. In a recent study in adult stroke survivors, we showed that this activity-based telerehabilitation OT program improved paretic upper extremity motor skills, activity performance, self-efficacy, and skill generalization [9]. However, because this program is cognitively demanding, with metacognition components (ie, the process of thinking about one's own thinking and adjusting accordingly [10]) that require collaborative goal setting, self-reflection, error analysis, and problem solving, stroke survivors with cognitive deficits may struggle to fully engage and benefit. This challenge served as the motivation for integrating functional cognitive rehabilitation into this activity-based OT program.

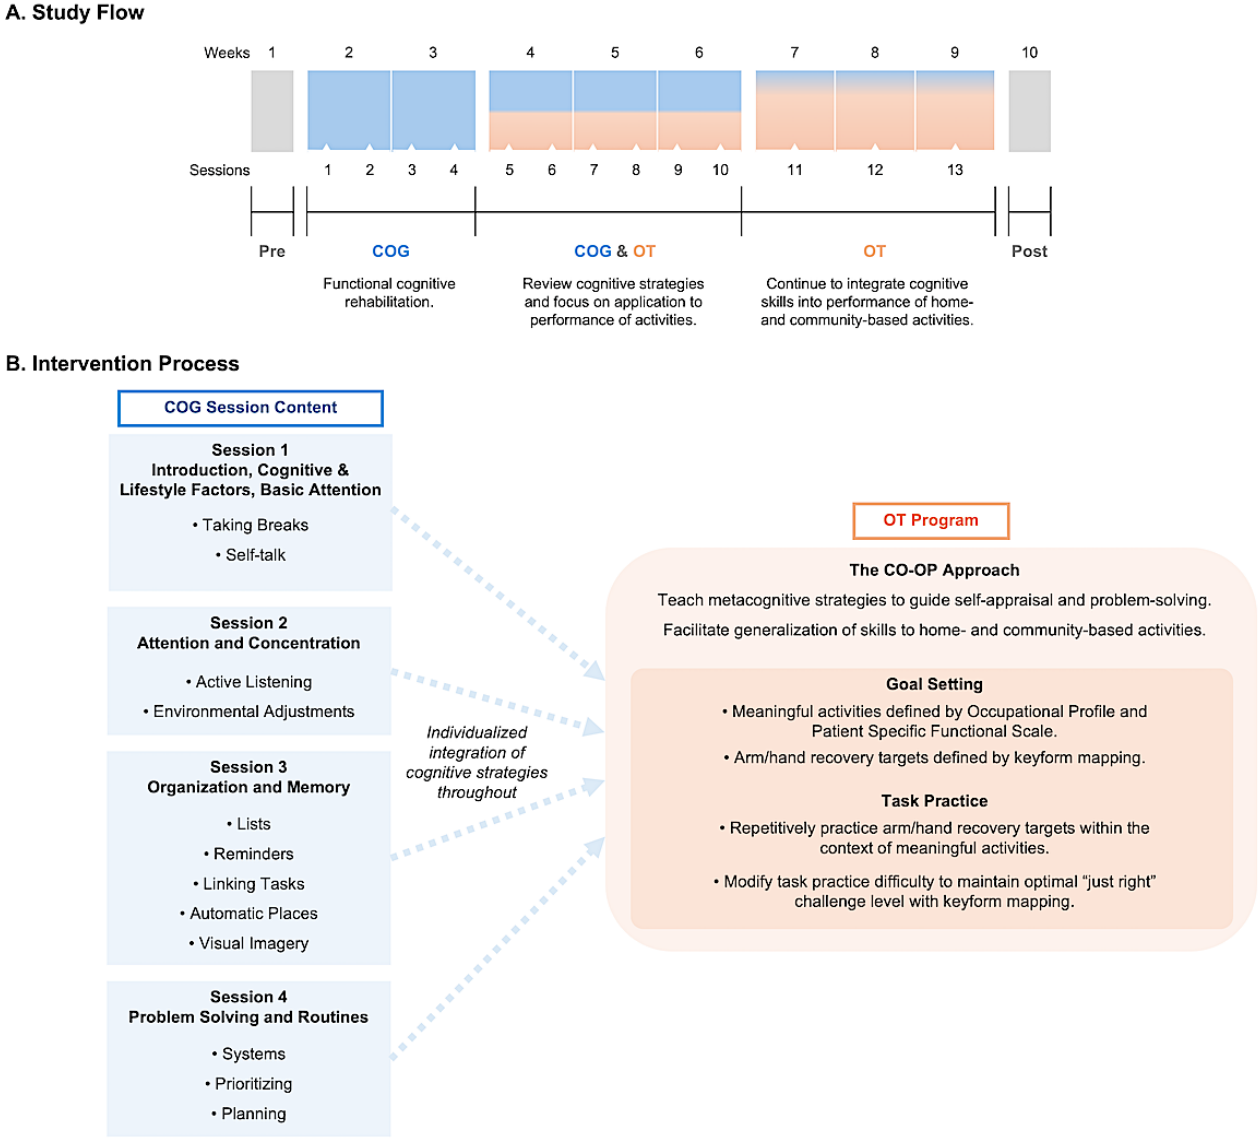
This new intervention, called COG+OT, pairs a brief, functional cognitive rehabilitation "primer" (COG; this abbreviation specifically refers to the brief cognitive rehabilitation component of this intervention) with the previously developed activity-based OT program. The rationale for combining these approaches is based on evidence that compensatory cognitive strategies enhance the attention, metacognition, and goal management skills needed for therapy engagement [5], and cognitive strategies generalize most effectively when practiced within meaningful everyday activities [4]. The cognitive rehabiliation intervention we adapted was based on compensatory cognitive training approaches that have demonstrated benefits for cognition, functional capacity, and quality of life in randomized controlled trials including individuals with acquired brain injury and other neuropsychiatric conditions [11]. Our central hypothesis is that delivering COG before and alongside OT may enhance cognitive readiness, thereby supporting engagement in activity-based OT and yielding greater gains in real-world activity performance and participation.

We recently completed a single-arm pilot feasibility trial of 8-week COG+OT with 20 adults with chronic stroke and upper extremity paresis. Initial pilot testing supported the feasibility and acceptability of the intervention, as reported previously [12]. Given these findings, the purpose of the current paper is to describe the COG+OT intervention to support transparency, replication, and future intervention evaluation. The primary objective of this manuscript is to detail the conceptualization, design, and specification of the COG+OT intervention using systematic reporting via the Template for Intervention Description and Replication checklist for rehabilitation trials (TIDieR-Rehab) [13].

Methods

Ethical Considerations

The intervention was developed and tested in a pilot feasibility trial that was approved by the Medical University of South Carolina Institutional Review Board (Pro00136303) and registered with ClinicalTrials.gov (NCT06555302). All participants provided informed consent.



Intervention Development Process

Theoretical Rationale

The intervention embeds functional cognitive rehabiliation into an existing 9-session stroke telerehabilitation program [9] (OT) by using brief COG sessions as a "primer" to boost engagement in and benefit from OT (Figure 1A). Compensatory cognitive training was selected based on theoretical models emphasizing that functional cognitive improvement is best achieved through metacognitive strategy training, habit learning, environmental scaffolding (ie, external supports that facilitate performance), and contextualized practice rather than isolated restorative exercises [4,14]. These models highlight mechanisms such as teaching compensatory strategies (ie, working around deficits and capitalizing on intact abilities), enhancing self-regulatory and metacognitive processes, and applying strategies in meaningful real-world contexts to promote transfer. These principles align closely with a person-centered, goal-oriented, activity-based OT program.

Figure 1. Study flow and intervention overview. Panel A shows the procedures conducted during each week of the study, including outcomes assessments ("Pre" and "Post"), and the 3-phase intervention delivered across 13 sessions. Panel B lists the core topics covered in each of the 4 COG sessions (with additional optional topics such as calendar use available, when relevant), depicts the integration of these cognitive strategies into the pre-existing OT program, and provides an overview of the key components of the OT program. COG: cognitive rehabilitation; CO-OP: Cognitive Orientation to Daily Occupational Performance; OT: occupational therapy.

Relevance to the Existing OT Program

The existing OT program [9] is cognitively demanding, combining (1) upper-extremity task practice within the context of individualized activity goals identified using the American Occupational Therapy Association (AOTA) Occupational Profile [15] and the Patient-Specific Functional Scale [16] and (2) metacognitive strategy training based on the Cognitive Orientation to Daily Occupational Performance approach [8] (Figure 1B). Therapists encourage participants to use the "Goal-Plan-Do-Check" global cognitive strategy as a framework to plan, perform, and evaluate task performance. These elements require cognitive flexibility, self-monitoring, problem-solving, and sustained attention. Thus, the COG "primer" was intentionally designed to bolster functional cognition so participants could more effectively engage in the OT program. Specifically, COG session content focuses on learning and applying attention, organization, memory, and problem-solving strategies to facilitate performance of real-world tasks. Examples include planning a modified approach to challenging daily tasks, eliminating distractions to improve attention during functional activities, using reminders to implement learned strategies while completing activities, and engaging in a structured reflection process to self-analyze performance during the OT sessions.

Conceptual Intervention Design

Unlike conventional cognitive rehabilitation programs delivered over multiple weeks, we condensed the content into a brief format that was delivered using a titrated model to reduce participant burden and facilitate integration of cognitive strategies directly into OT. This design aimed to optimize generalization by first introducing strategies, then applying them during functional activities. Titration occurred across three phases (Figure 1A): (1) individualized cognitive strategy instruction (sessions 1-4), (2) brief review and application of strategies within activity-based OT (sessions 5-10), and (3)

XSL•FO
RenderX

continued integration of strategies into OT to promote generalization and habit formation (sessions 11-13). Personalized homework assigned at each session supported skill generalization to home and community environments.

Adaptation of COG Materials

COG materials were adapted from the 8-week Motivationally Enhanced Compensatory Cognitive Training for Mild Cognitive Impairmentprogram (M Huckans, et al; Motivationally Enhanced Compensatory Cognitive Training for Mild Cognitive Impairment [ME-CCT for MCI]; unpublished treatment manual; 2013), an iteration of evidence-based Compensatory Cognitive Training and Cognitive Symptom Management and Rehabilitation Therapy (EW Twamley, et al; Cognitive Symptom Management and Rehabilitation Therapy [CogSMART] for Traumatic Brain Injury; unpublished treatment manual; 2010). Materials for ME-CCT/CogSMART are available on the CogSMART website [17] and were adapted with permission for research use and acknowledgment of the original sources. These interventions emphasize compensatory cognitive strategies and habit learning and have been delivered via telehealth in prior research studies and clinical care settings [18-20]. Study team members (occupational therapists [PF, SG, JL, KR, MLW] and a neuropsychologist [SA]) reviewed the ME-CCT manual, selected stroke-relevant content, and condensed it into four 1-hour sessions (Figure 1B). Intervention delivery was designed to be individualized in terms of time spent on each cognitive strategy (based on relevance), focus on improving vs optimizing skills (based on impairment level), and application to activities/settings (based on context and goals).

The intervention was developed by a multidisciplinary rehabilitation team with expertise in cognitive rehabilitation and stroke telerehabilitation, including a clinical neuropsychologist (SA), occupational therapists (PF, SG, JL, KR, MLW), a clinical psychologist (LMM), and a speech-language pathologist (DSB). The neuropsychologist led development of the COG component, including strategy selection and adaptation (SA in consultation with EWT), while the OT team led integration of cognitive strategies into the existing activity-based telerehabilitation program. The speech-language pathologist guided adaptation of patient-facing materials to accommodate individuals with mild-to-moderate aphasia.

Results

The intervention development process resulted in COG+OT, an 8-week, 13-session telerehabilitation program delivered across three phases: (1) cognitive strategy training (sessions 1-4), (2) guided application of cognitive strategies within activity-based OT (sessions 5-10), and (3) continued integration and generalization of strategies during OT sessions (sessions 11-13; Figure 1). The completed TIDieR-Rehab checklist [13] for the COG+OT intervention is reported in Checklist 1, and details are provided in the following sections.

Personnel

COG+OT is designed to be delivered by licensed occupational therapists with training in stroke rehabilitation and telehealth. In this implementation, therapists were experienced in both domains and received structured training in the COG component and its integration with the OT program as well as ongoing supervision via weekly group case consultation with lead clinicians (SA, MLW).

Setting

COG+OT is designed for delivery via synchronous telehealth using a Health Insurance Portability and Accountability Act (HIPAA)–compliant videoconferencing platform (in this study, doxy.me), enabling participation from home and community environments. This intervention uses participants' real-world contexts by incorporating personally meaningful activities and readily available household spaces and materials into therapy sessions. Therapists ensure camera positioning to allow clear visibility of movements and task performance. Assistance and training with the videoconferencing technology is provided as needed. When appropriate, caregivers may assist with technology setup or safety monitoring. This home-based delivery model is intended to enhance ecological validity, accessibility, and generalization of cognitive and motor strategies to everyday activities.

Target Population

The COG+OT intervention is intended for adults with subacute and chronic stroke experiencing upper-extremity motor impairment and co-occurring cognitive challenges who are able to participate in telehealth-based rehabilitation. The COG+OT model is intended to be broadly applicable to stroke survivors who would benefit from integrated cognitive and activity-based rehabilitation and is therefore applicable to individuals with mild-to-moderate cognitive deficits in various domains (eg, attention, memory, executive function). The intervention is also designed to accommodate individuals with mild-to-moderate aphasia through the use of adapted, "aphasia-friendly" materials [21,22] and multimodal communication supports (developed in consultation with the speech-language pathologist [DSB]). Consideration for safety (eg, fall risk) and the potential need for caregiver assistance are incorporated into intervention delivery.

Intervention Materials

Measures Used to Guide Individualized Delivery of the Intervention

Occupational Profile

At the pretreatment assessment visit, therapists complete an AOTA Occupational Profile [15] via semistructured interview to identify participants' occupational history, patterns of daily living, values, and participation priorities. Insights obtained through the occupational profile are used to inform individualized goal setting and intervention planning. As participants complete the 4 initial COG sessions, the occupational profile is used to guide collaborative conversations to help the therapist gain a deeper understanding of participants'

XSL•FO
RenderX

routines, habits, and roles in relation to their cognitive functioning.

Patient-Specific Functional Scale

At the pretreatment assessment visit, therapists administer the Patient Specific Functional Scale [16] to identify each participant's activity goals. Participants are asked to generate up to 5 meaningful activities that have been made difficult due to upper extremity motor impairment since having a stroke. Participants then rate their ability to perform each activity on a 0‐10 scale, with higher numbers indicating better self-perceived performance. Throughout the OT program, sessions focus on optimizing participant performance in the context of these goals. Therapists regularly reference and revisit the goals with the participant when identifying target activities for the treatment sessions. This scale is readministered at the posttreatment assessment to assess change in self-perceived performance of individualized activity goals.

Upper Extremity Motor Assessment

Prior to beginning the phase-2 COG+OT sessions (at the end of session 4), the participant's hemiparetic arm/hand impairment is measured using the Fugl-Meyer Assessment of the Upper Extremity [23], which is the gold-standard assessment of poststroke arm/hand motor impairment. In prior work, we modified this measure for use in telerehabilitation [9], reducing it to 22 items that can be assessed virtually. Administration involves the therapist observing the participant's performance of 22 movements (ie, moving the hemiparetic arm/hand through a series of postures), rating each on a 3-point scale (0=unable to perform, 1=partially performed, 2=near normal performance). Items are summed to a total score between 0-44 points, with lower scores indicating more severe motor impairment. Using a procedure described in detail previously [7], the participant's Fugl-Meyer item performance ratings are mapped onto an item hierarchy (ranging from easy to difficult) to indicate person-specific arm/hand movements that are optimally challenging targets for task practice therapy. This process, termed "keyform recovery mapping" (or "recovery ruler") [24], is an emerging evidence-based method that operationalizes how item difficulty and performance are used to select individualized treatment targets. To monitor progress and refine individualized movement targets, the Fugl-Meyer Assessment is readministered and mapped to the keyform at the intervention midpoint (end of session 7) and at the end of phase-2 COG+OT sessions (end of session 10). To evaluate change in motor function, it is administered again at the posttreatment assessment.

Materials Used to Implement the Intervention

Session Tracking Notes

Therapists document session activities and participant progress using study-developed Session Tracking Notes in REDCap. The notes differ slightly in structure across the 3 intervention phases, but each session's note contains the following content: (1) Subjective (participant report and direct quotes), (2) Objective Session Content (checklist of completed content, documentation of functional task practice activities, and notes on activity grading per therapist report), (3) Assessment (checklists capturing therapists' ratings of participant response to the intervention and barriers to progress), and (4) Notes/Follow-Up Plan, including assigned home activity program (therapist narrative). The narrative portions of the Subjective, Assessment, and Plan sections reflect best-practice rehabilitation documentation procedures.

COG Session Manual

A manual was developed to guide therapists during COG sessions (sessions 1-4). The manual outlines session procedures and content to be covered, provides examples that could be shared with participants, and includes guidance for adjusting the complexity of information to support participant comprehension in the presence of cognitive and/or language impairment.

Patient-Facing COG Worksheets

For each COG session, we created 1‐2-page patient-facing worksheets, written at an eighth-grade reading level, that can be screen-shared, mailed, and/or emailed to the participant to guide discussion. Each session's worksheet contains (1) an introduction section that included descriptions of core concepts, definitions of key terms, and educational content followed by (2) a "Let's Practice" section containing real-life examples, space for self-reflection, and discussion prompts focused on functional application of cognitive strategies. Participants (and/or caregivers when present) are encouraged to take notes and regularly reference the worksheets outside of sessions.

Intervention Process

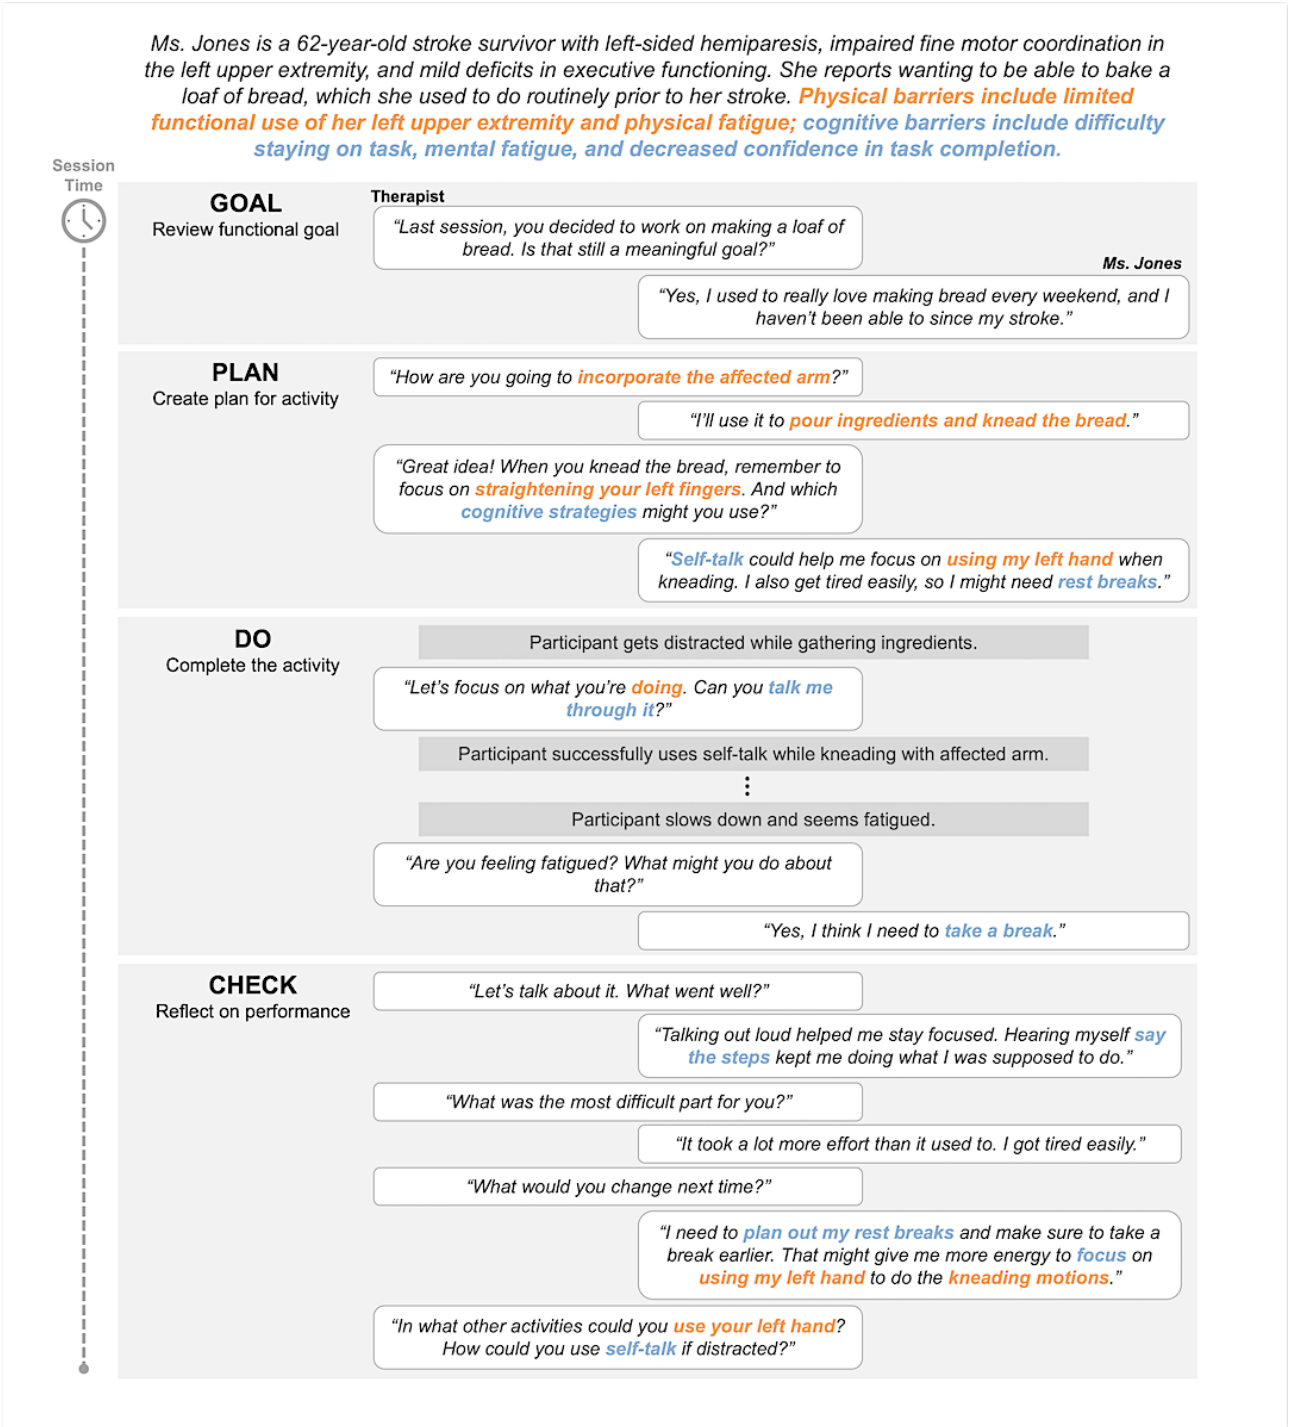
Overview

The intervention consists of 13 one-on-one telehealth sessions (45‐60 minutes each) over 8 weeks (Figure 1A). The schedule is 2 sessions per week for the first 5 weeks, followed by 1 session per week for the final 3 weeks. The reduction in session frequency during the latter phase is intended to promote greater independence and encourage skill generalization and transfer to real-world activities. To accommodate participant scheduling challenges, we allow make-up sessions to be added to any intervention week and for sessions to extend into one additional week (9 weeks total), if needed. The approximate proportion of each session allocated to COG vs OT activities varies over the 3 phases of the intervention (described in the following sections).

Sessions 1-4 (COG-Only)

Each COG session focuses on specific topics, listed in Figure 1B. Although the COG content follows a structured sequence, it is intentionally flexible to allow therapists to individualize the emphasis based on participant needs (eg, relevance, interest). Similarly, the use of cognitive strategies to compensate for deficits vs optimize intact abilities is personalized based on cognitive impairment level and contextual demands. Using the patient-facing worksheets via screensharing, therapists first introduce the session topic and review the associated compensatory strategies. The therapist and participant then collaboratively identify which strategies are most relevant to the participant's goals and cognitive challenges. Remaining session time focuses on practicing these strategies and discussing how they might be applied in daily activities. Personalized

XSL•FO
RenderX



homework is assigned to reinforce real-world use of cognitive strategies and is reviewed with the therapist at the beginning of each following session. Throughout these sessions, therapists make note of strategies that emerge as most relevant or useful for each participant. Additional worksheets covering topics beyond the core sessions (eg, calendar use, additional memory strategies) are available and may be incorporated when relevant and if time permits. No new strategies are introduced after session 4.

Sessions 5–10 (COG+OT)

Each session begins with a brief review of the participant's use of learned cognitive strategies in their daily lives (10-15 minutes). The remainder of the session focuses on direct application of the strategies during OT activities. During the first COG+OT session (session 5), the telerehabilitation version of the Fugl-Meyer Assessment of the Upper Extremity keyform (described in *Intervention Materials*) is completed, and the therapist and participant review item performance scores to identify optimally challenging hemiparetic upper extremity movements to target in therapy. Together with the participant's goals from the Patient Specific Functional Scale and Occupational Profile, this information guides selection of meaningful in-home activities. Participants then practice these activities while being coached by the therapist using metacognitive strategy training and guided discovery based on the Cognitive Orientation to Daily Occupational Performance approach [8] (Figure 1B). Therapists use the "Goal-Plan-Do-Check" global cognitive strategy as a framework (ie, participants identify the task "goal," verbalize the "plan" to achieve the goal, attempt to "do" the task, and then self-reflect to "check" their own overall performance) while encouraging the participant to apply relevant cognitive strategies to support task completion. See Figure 2 for an example session.

XSL•FO
RenderX

Figure 2. Example COG+OT session (sessions 5-13). A representative scenario illustrates how individualized goals, motor targets, and cognitive strategies are integrated during task practice, with therapist-guided coaching supporting performance and reflection.

Sessions 11 - 13 (OT With Integrated COG)

Cognitive strategies are no longer explicitly reviewed during these sessions, but participants are encouraged to continue applying the strategies during OT functional task practice (using the same procedures as sessions 5 - 10). For example, a participant who had identified self-talk as a helpful strategy in earlier sessions would be coached to verbalize task steps during OT functional task practice to enhance attention and performance (see Figure 2). Therapists reinforce effective cognitive strategy use during target activities and facilitate generalization of new cognitive and motor skills to home and community contexts.

Intervention Fidelity

Multiple procedures are implemented to support consistent delivery of the intervention. All therapists receive training in both the COG component from the study neuropsychologist (SA) and in the OT program from the lead occupational therapist (MLW). A treatment manual was developed to standardize procedures, and standardized session workflows are used to guide intervention delivery and promote consistency across therapists. Intervention session activities and participant progress

XSL•FO
RenderX

are documented using Session Tracking Notes (described in *Intervention Materials*) within a secure data management platform (ie, REDCap). These data are used to track progress and guide subsequent sessions. Protocol deviations, barriers to progress, and adverse events are systematically recorded in REDCap and reviewed. If the planned content is not fully covered in the allotted time or when additional practice is needed, this is noted in REDCap and addressed in subsequent sessions to ensure each participant is exposed to all the core material.

Discussion

We developed COG+OT, a theory-informed intervention that integrates brief, functional cognitive rehabilitation into activity-based stroke telerehabilitation. This work addresses the well-documented challenge in poststroke care of siloed services for cognitive vs motor rehabilitation and lack of a well-defined multidisciplinary intervention protocol, which limits opportunities to apply cognitive strategies to meaningful activities and contexts. By embedding cognitive strategy training within meaningful, goal-directed activities, COG+OT is intended to support both engagement in rehabilitation and transfer of skills to everyday life.

An innovative design feature is the titrated integration of cognitive and motor components across 3 phases. The initial "primer" phase introduces compensatory cognitive strategies in a structured but individualized format, allowing participants to develop awareness and understanding of their cognitive challenges and strategies for addressing them. This is followed by guided application of these strategies within activity-based OT sessions and then continued integration to promote skill generalization into daily activities to form routines and habits. This progression aligns with contemporary models of functional cognitive rehabilitation, which emphasize metacognitive strategy training, contextualized practice, and repeated application across settings to facilitate generalization to real-world activities [4,14].

The use of a brief cognitive "primer" is intended to reduce burden while retaining core elements of evidence-based compensatory approaches, including personalization and strategy use in everyday contexts. Crucially, the COG sessions make cognitive strategies explicit for participants, complementing the implicit use of these strategies within the therapists' metacognition-based coaching. For example, therapists may introduce visual imagery during COG sessions as a strategy for planning and organization, then prompt participants to visualize each step of a task during OT sessions to support more accurate and efficient motor performance. Although the COG component draws from evidence-based materials (ie, ME-CCT/CogSMART), there are several other established cognitive rehabilitation programs that could have been considered. Approaches such as the Multicontext Approach, Goal Management Training, and other functional cognitive interventions [5,25,26] also include theoretically grounded elements (eg, metacognitive strategy training, guided practice, contextualized transfer) that may further strengthen components of COG+OT. Future iterations of the intervention may therefore benefit from selectively integrating features from these programs, particularly those that support generalization. In addition, explicit incorporation of motivational interviewing techniques may further enhance engagement, goal alignment, and sustained strategy use in daily life.

COG+OT was designed for real-world implementation through its telehealth delivery and use of participants' home environments to enhance ecological validity. Structured yet flexible materials support intervention fidelity while allowing for individualized tailoring. Additional features, including patient-facing worksheets, aphasia-friendly materials, and optional caregiver involvement increase inclusivity and make COG+OT amenable to implementation in a variety of settings (eg, outpatient clinics, community-based rehabilitation, hybrid telehealth models). Moreover, because compensatory cognitive strategies and metacognitive training are relevant across many neurologic and medical conditions, there is strong potential to adapt COG+OT for use in other populations (eg, individuals with traumatic brain injury, mild cognitive impairment, or other chronic conditions in which functional cognition supports daily participation) or clinical services (eg, speech therapy, physical therapy). Therefore, a key next step is to evaluate the feasibility, effectiveness, and implementation of COG+OT across diverse populations and settings. To support future dissemination, additional work is needed to develop standardized training and fidelity-monitoring procedures alongside evaluation of scalable delivery models and factors influencing real-world adoption.

Initial pilot testing supported the feasibility and acceptability of COG+OT telerehabilitation for stroke survivors, as reported previously [12]. The current manuscript extends that work by providing a detailed description of the intervention's theoretical basis, structure, materials, and delivery procedures to support replication and ongoing research. Analyses are underway to examine preliminary effects on cognitive, psychosocial, and participation-related outcomes, while qualitative feedback from participants and therapists will inform continued refinement of the intervention. Although aphasia-friendly adaptations were incorporated into COG+OT, additional research including greater representation of people with aphasia will be needed to evaluate their appropriateness. Future studies will also examine the added value of integrating functional cognitive rehabilitation into activity-based telerehabilitation, informing the design of future randomized controlled efficacy trials.

This paper focused on the systematic specification of the COG+OT intervention, including its theoretical basis, structure, and delivery procedures. Overall, COG+OT provides a structured and adaptable model for integrating functional cognitive rehabilitation into stroke telerehabilitation. This development work lays the groundwork for future refinement, evaluation, and broader implementation of COG+OT as an evidence-based, manualized intervention.

Abstract

Background: Enhancing rehabilitation methods for patients with stroke is essential, particularly during the transition from inpatient to outpatient care. Digital applications are being developed to provide telerehabilitation programs. The existing virtual blended care platform Blended Clinic (Blended Clinic AI GmbH) offers app-based training for patients after a stroke and comprises 3 main components, including training, coaching, and monitoring.

Objective: This study assesses the usability and user experience of the novel Swiss Tele-Assisted Rehabilitation and Training (START) program within the Blended Clinic platform in patients after stroke and therapists.

Methods: The START program was developed within 3 workshops and an online survey. It contains 10 6-week exercise programs tailored to the levels of the modified Rankin Scale (mRS), 5 infographics, and 5 podcasts. Eight patients after stroke and 10 therapists took part in a single-center usability study. All participants were introduced to the Blended Clinic app and subsequently used it independently. The Blended Clinic platform, including the START program, was evaluated by both user groups based on the System Usability Scale (SUS) and the Mobile App Rating Scale (MARS-G). Additionally, feedback was collected, observations were documented, and program adherence metrics were calculated.

Results: The mean SUS scores were 87.2 (SD 10.8) for 8 patients and 83.3 (SD 11.3) for 10 therapists. The MARS-G scores were 3.9 (SD 0.5) for patients and 4.1 (SD 0.4) for therapists for categories A-D. User experience was rated 4.1 (SD 0.5) for patients, while device usability was 3.8 (SD 0.8) for patients and 4.2 (SD 0.5) for therapists. Adherence to the training schedule varied among patients (16.7%-80% of the planned sessions) and was rather low for many of the patients.

Conclusions: The START program, delivered via the Blended Clinic platform, was considered user-friendly and received good usability ratings from patients with stroke and therapists. Recommendations to enhance compliance are provided.

KEYWORDS

telerehabilitation; stroke; app-based training; usability; blended care

Introduction

Stroke is a leading cause of acquired disability in adults worldwide, significantly impacting individuals' quality of life due to persistent motor and cognitive impairments [1]. Importantly, these impairments in patients with stroke are often accompanied by other issues like fatigue and depressive symptoms, significantly impacting quality of life and independence [2]. Stroke is a significant contributor to cognitive decline and dementia, being the second most common cause after Alzheimer disease [2,3].

XSL•FO
RenderX

Rehabilitation strategies for individuals after a stroke primarily focus on restoring impaired motor control to enhance the independence of those affected [4]. An interdisciplinary approach that considers individual needs is essential for the success of rehabilitation and the overall quality of life for patients [5]. Thus, the advancement of options for improved, sustainable, and effective follow-up care in stroke rehabilitation is urgently needed [6]. Technological innovations can play an essential role in efforts to maintain the motor and cognitive abilities of affected individuals at the highest possible level. By integrating new technologies into rehabilitation programs, recovery outcomes can be enhanced, while early intervention and rehabilitation are crucial for improving outcomes and enhancing recovery after a stroke [7].

In addition to face-to-face rehabilitation, telerehabilitation has emerged due to advancing digitalization in the health care sector. It has been found that telerehabilitation in physiotherapy is comparable to in-person rehabilitation for conditions such as stroke [8,9]. In line with that, studies have shown that telerehabilitation can effectively deliver therapeutic interventions, maintain patient engagement, and achieve similar outcomes to traditional therapy, making it a valuable option for patients who may have difficulty attending in-person sessions [10].

Various mobile health apps have been developed for patients after a stroke, mostly focusing on upper extremity function, secondary prevention, or language skills [11]. Additionally, according to a review by Rintala et al [12], most studies investigating these apps focused on patients with chronic stroke, who are mildly impaired [13]. Although existing mobile health apps have shown positive effects on various stroke-related impairments, a substantial gap remains in the development of apps specifically targeting goal-oriented exercises and also integrating educational components [14].

The newly developed Blended Clinic platform (Blended Clinic AI GmbH) consists of a mobile app for patients (Blended Clinic, Version 1.0.1 [iOS]; 1.3 [Android]), a web-based portal for therapists, and a database. The system is designed to provide home-based exercise programs for different patient groups by integrating telerehabilitation with a blended care approach. Blended care itself refers to a health care approach that combines traditional in-person services with digital or remote care options. It aims to provide a more flexible and comprehensive approach to health care delivery, enabling diverse patient populations, including individuals after stroke in the subacute and chronic phases, to receive care through multiple modalities [15]. To date, an earlier iteration of a training program for patients after a stroke, in conjunction with a previous version of the Blended Clinic platform, has been evaluated for user interaction with the app and for acceptability among patients with chronic stroke [16]. It was found to be highly acceptable, with strong user engagement, good task adherence, and small clinical improvements in quality of life [16].

Based on these positive findings, the new Swiss Tele-Assisted Rehabilitation and Training (START) program was developed. It builds on the same core technology but extends the intervention and addresses the research gap in 2 ways: first, by further developing the content with a stronger focus on the needs of patients with moderate-to-severe impairments; and second, by evaluating its use in a new clinical context, the subacute phase of stroke rehabilitation, particularly the transition phase from inpatient to outpatient rehabilitation.

The aim of the present study was to describe the development process of the new START program and to assess the perceptions of both therapists and patients after a stroke regarding the usability and functionality of certain components of the START program, provided via the updated Blended Clinic platform, during test sessions.

Methods

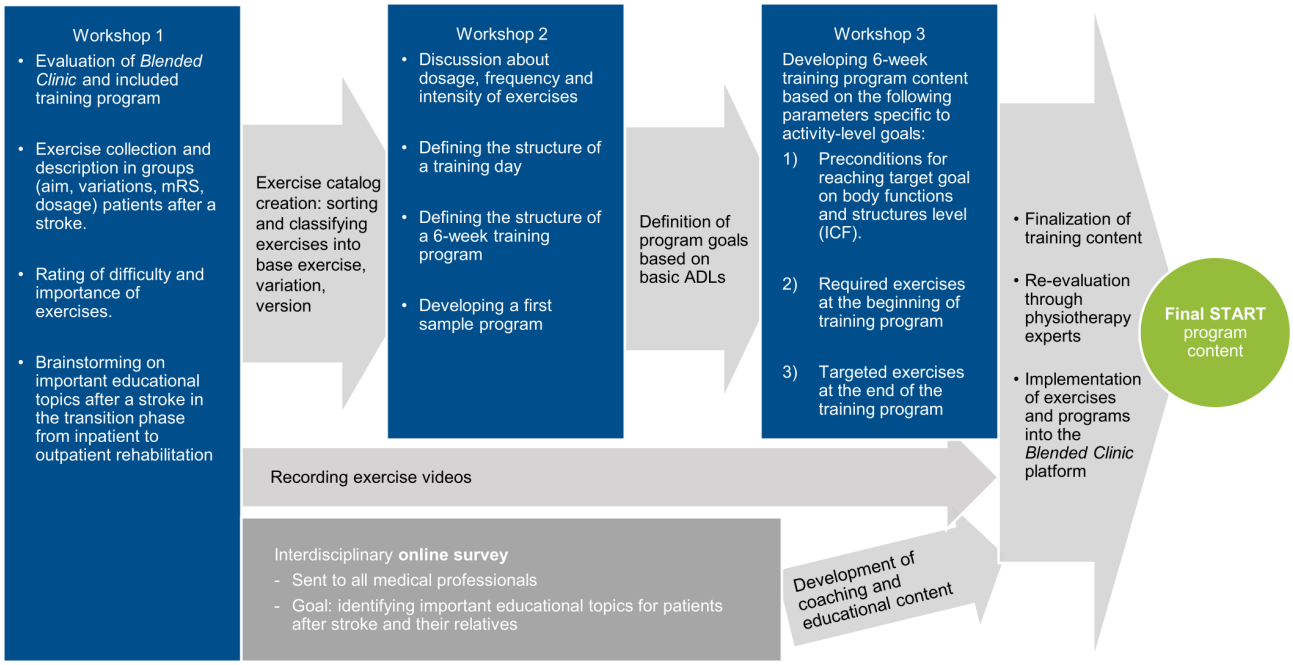
Hardware and Software Components of the Blended Clinic Platform

The Blended Clinic platform consists of a web-based portal for therapists and a mobile app for patients. It is intended to be installed on the mobile devices of patients and comprises components for training, coaching, and monitoring. The content for these components is provided by the respective program modules, such as START, which was developed and tested within this project.

1. Training: in conjunction with a targeted training program, exercises can be performed daily, individually, and to the necessary and feasible extent. Through the app, patients are provided with a personal training plan tailored to their individual impairments and rehabilitation goals, including exercise videos. The exercise content can be adjusted to the achieved functional level.
2. Coaching: the app ensures that individual training is supported by a personal therapist to maintain high motivation levels. Patients' questions about training and general topics related to stroke can be promptly addressed, both on-site and primarily through a digital chat function, with therapists available daily during working hours on weekdays.
3. Monitoring: the app also facilitates the collection of health-related, measurable parameters to support the ongoing individual optimization of the training plan. In this study, patient-reported outcome measures (PROMs), self-conducted blood pressure measurements, and activity tracking with a wrist-worn device (GENEActiv, Activinsights) were applied.

The START Program

The main objective of START was to create a training program to be used with the Blended Clinic app specifically designed for patients with moderate to severe motor impairments during the early subacute stages of rehabilitation. We developed the START content in line with recent exercise recommendations [17-20] and stroke guidelines [21,22]. While these guidelines offer valuable recommendations, they do not specify explicit exercise instructions or dosages.



Three workshops were performed with a group of 7 clinicians, including 2 clinical physiotherapy neurological experts with over 25 years of professional experience and one research

XSL•FO
RenderX

physiotherapist with a doctoral degree, 3 clinical physiotherapists with at least 3 years of neurological experience, and 1 sports scientist. The participating therapists served as clinical instructors in the clinic and, in part, as lecturers and researchers.

In these workshops, important exercises and exercise variations for patients after stroke were identified and classified into different disability levels based on the modified Rankin Scale (mRS) [23,24] scores 1-5 (Figure 1). Exercises were further categorized into lower extremity, trunk exercises, balance and coordination exercises, and breathing exercises. In total, this resulted in the creation of 224 new exercises, resulting in a pool of around 300 exercises. In addition, for the presentation within the Blended Clinic platform, an introductory text outlining the aim of each exercise and a video instruction demonstrating how to perform the exercise were developed. Please refer to the supporting information for further details regarding the exercises (Multimedia Appendix 1).

Figure 1. Development process of the Swiss Tele-Assisted Rehabilitation and Training (START) program content and the main focus of each workshop. ADL: activities of daily living; ICF: International Classification of Functioning, Disability and Health; mRS: modified Rankin Scale; START: Swiss Tele-Assisted Rehabilitation and Training

Patient exercises were compiled to create 10 6-week programs, each with an overarching goal. The activity goals of such a program were based on abilities that are necessary to perform activities of daily living (ADL). The experts identified key components necessary for establishing individualized program goals, such as the ability to transfer to the toilet. For instance, a target exercise could involve standing for at least 60 seconds while engaging in arm activities. For this, a preliminary exercise might consist of "standing independently for 30 seconds without any arm activity."

Within each 6-week program, exercises progressed in terms of the number of sets, number of repetitions, and difficulty level. The exercise sessions, each lasting around 15 minutes and conducted daily, consisted of 3 phases, including a warm-up that typically involved a breathing or sensory stimulation exercise; a main component focusing on balance, strength, or endurance; and a cool-down that incorporated flexibility exercises. Additionally, care was taken to alternate strength, endurance, and balance training each day. Patients received information regarding training safety, content, meaning, and purpose of each exercise through the app.

In addition to the training programs, informational and educational materials for patients were developed. Relevant topics were identified by conducting an in-house interdisciplinary survey using the Findmind tool (Findmind). Based on the results from 90 health care professionals, several topics were identified, and content was developed. Podcasts were recorded covering the topics of fatigue, sleep, training, nutrition, and psychological well-being, along with the creation of 5 infographics. In addition to the regular motivational and informational messages sent via chat, this content constitutes an essential component of patient coaching and education and the blended care approach.

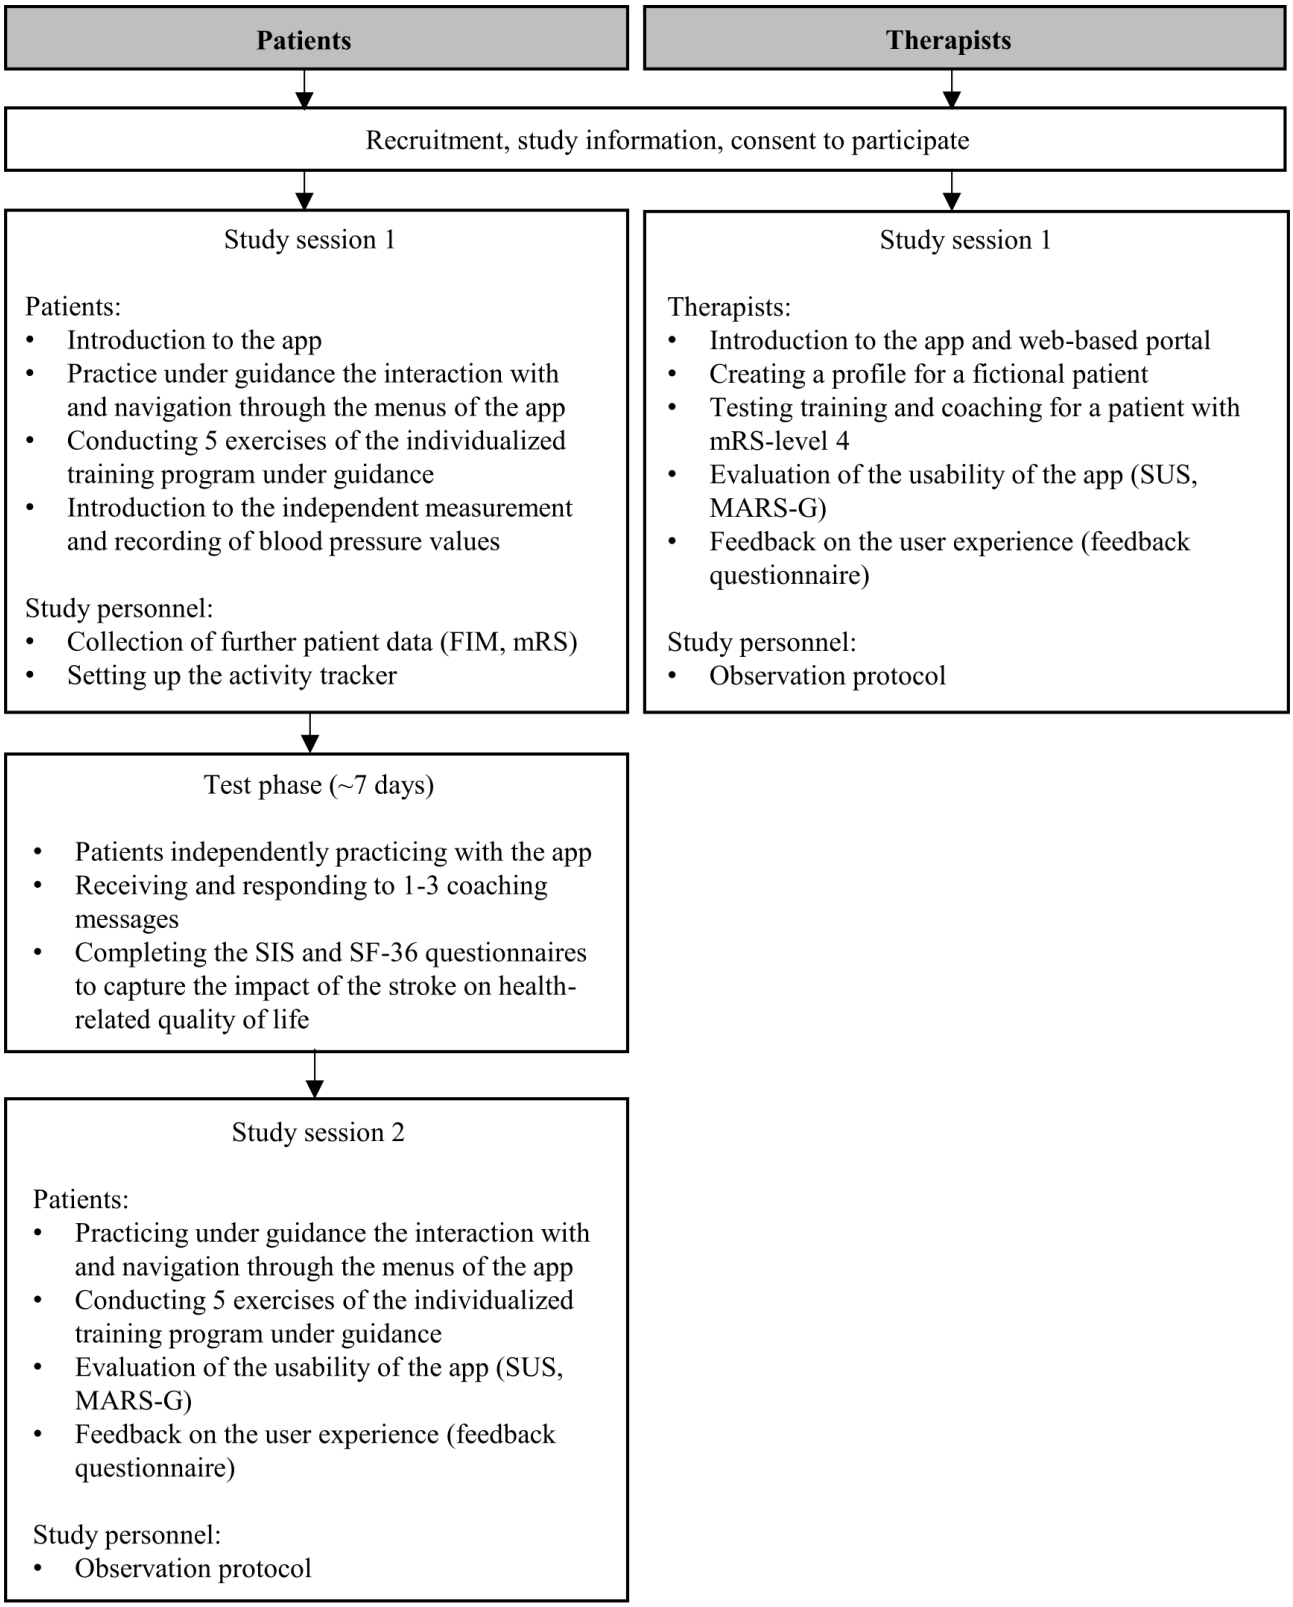
The START program was designed to be introduced in an inpatient rehabilitation setting and continue during the transition phase from inpatient to outpatient rehabilitation and then continue in the community. In the context of this usability study, not all the described content was used and investigated; rather, our focus was limited to an inpatient setting and specific components of START provided via the Blended Clinic platform.

Evaluation of Usability and Functionality of START

Participants

The evaluation of the usability and functionality of the app-based training was conducted as a single-center study primarily with patients after a stroke in their subacute stage and secondarily with therapists. The study took place in a neurological

XSL•FO
RenderX



rehabilitation clinic in northwestern Switzerland. We planned to include 10 patients and 10 therapists, starting in December 2023. Inpatients and outpatients attending the clinic's day center were recruited by screening internal patient lists against the predefined eligibility criteria. The criteria comprised age ≥18 years, mRS 3-5, no severe aphasia, severe visual, neurological, cardiopulmonary, psychiatric, or orthopedic impairments that would prevent a patient from following the instructions, and no recent surgery or fractures. Therapists were included in the study if they held at least a bachelor's degree in physiotherapy, occupational therapy, speech and language therapy, or sports and exercise science, and if they had at least one year of experience in stroke rehabilitation. Therapists were invited via email to participate in the study.

Procedures

For the course of the study, please refer to the study flow chart (Figure 2). As demonstrated here, the therapists participated in a single session, whereas patients underwent 2 sessions, with a one-week testing phase in between.

XSL•FO
RenderX

Figure 2. Study flowchart. FIM: Functional Independence Measure, MARS-G: Mobile App Rating Scale; mRS: modified Rankin Scale; SF-36: 36-Item Short Form Survey Instrument; SIS: Stroke Impact Scale; SUS: System Usability Scale.

Patients had the opportunity to familiarize themselves with the app under supervision. During the introductory session with the study personnel, patients were instructed in the exercises assigned according to their mRS score and were trained in safe exercise execution. Besides, patients were also instructed on blood pressure measurements and on how to complete 2 questionnaires through the app (Stroke Impact Scale [SIS; 25,26], 36-Item Short Form Survey Instrument [SF-36; 27,28]). Patients subsequently tested the functionality of the app independently for a duration of one week. Before starting a daily exercise session, they received an automatic message reminding them to pay attention to their own safety during training. Furthermore, patients were provided with 2 information sheets, one outlining the criteria for discontinuing the exercises (eg,

XSL•FO
RenderX

feeling unwell) and the other containing general information on the training environment (eg, ensuring that a table and chair were available for support). Patients wore an activity tracker (GENEActiv, Activinsights) for the week. During the second session following the testing phase, patients were asked to perform predefined tasks within the app under the guidance of the study personnel, for instance, to follow exercise instructions and to write a message to the coach. Patients were observed to document this process, to evaluate their performance, and thus the comprehensibility of the necessary interactive steps within the app.

Therapists were also introduced to the use of the app and had the opportunity to test it at the beginning of the session. They subsequently were instructed to perform specific tasks on the web-based dashboard platform, such as selecting and sending a questionnaire. Their performance was also observed and documented. Finally, the therapists themselves evaluated the usability of the system.

Outcome Measures

For the subsequent assessment of usability, the System Usability Scale (SUS) [29], the German version of Mobile App Rating Scale (MARS-G) [30-32] and a customized feedback questionnaire (Multimedia Appendix 2) were used.

The widely used SUS is a questionnaire that assesses the usability of a system through a 10-item survey. Each item is rated on a 5-point Likert scale, allowing users to express their level of agreement or disagreement with various statements about the system.

MARS-G assesses the multidimensional quality of mobile health apps and comprises 4 components, including engagement (Section A), functionality (Section B), esthetics (Section C), and information quality (Section D). Each domain is rated on a 5-point Likert scale, where 1 indicates “insufficient,” 2 denotes “poor,” 3 represents “acceptable,” 4 signifies “good,” and 5 reflects “excellent.” Additionally, the MARS-G includes 2 sections for the subjective evaluation of characteristics within the domains of subjective app quality (Section E) and perceived impact of the app (Section F). The German version of MARS-G that we used has been supplemented with a further section (Section T) that focuses on the therapeutic benefits associated with the app [32]. For all sections, the maximum achievable score is 5 points [32]. The therapists were asked to complete the entire MARS-G, while the patients were only provided with Sections A, B, C, D, E, and F for evaluation.

The training experiences with and the usability of the app were assessed using a self-constructed, standardized feedback questionnaire (Multimedia Appendix 2). This questionnaire used a 5-point scale and included specific questions regarding the app and was pilot tested with one patient. The feedback questionnaire aimed to provide deeper insights into the participants’ opinions about the training platform. For patients, the questionnaire contained 8 questions related to user experience, along with a section comprising 3 questions regarding the use of the blood pressure monitor, activity tracker, and smartphones or tablets. In contrast, therapists completed a questionnaire consisting of 9 questions about user experience.

During the study sessions for patients and therapists, the study personnel also completed an observation protocol (see Results for task details). This protocol facilitated the evaluation of the usability and user experience for both patients and therapists by an external observer, assessing the extent to which the app is useful and applicable, as well as identifying any existing issues. The study personnel also evaluated the emotional reactions by observation of the patients while they were navigating through the app and while performing the exercises, using the following categories (present and not present): attention, joy, curiosity, astonishment, boredom, nervousness, confusion, anger, and rejection.

Data Analysis

The adherence of the participating patients to the START program protocol was derived from the execution of the planned training sessions, the number of blood pressure measurements, the completion of the questionnaires, and the duration of activity tracker usage. For all parameters, adherence was assessed in relation (ratio) to the intended use, with the following classifications defined: adherence of ≥75% of the planned activities was categorized as high adherence, 50% - 74% as moderate adherence, 25% - 49% as low adherence, and <25% as no adherence [33]. In this study, the tracker was used solely to assess whether the patients would tolerate wearing it, with a view to planning further studies and monitoring activity levels over a longer period.

- Training: number of completed training sessions versus planned training sessions. Patients received an exercise program consisting of 5 exercises each day. An adherent training day was defined as having performed at least 3 out of 5 exercises, quantified by spending a minimum of 20 seconds and a maximum of 5 minutes for each exercise on the app screen.
- Monitoring:
  - Blood pressure measurements: patients were instructed to conduct 3 blood pressure measurements each morning. Days on which the respective patient entered data themselves (eg, blood pressure) were classified as adherent.
  - Activity tracker: an adherent day was defined as a day on which the activity tracker was worn for a minimum of 5 hours on the first and last day or for at least 10 hours on each intervention day, consistent with established practices [34]. In this study, the focus was solely on understanding whether the trackers were accepted and worn, in preparation for a larger study.

All data were analyzed descriptively using JASP (version 0.18.0, The Jasp Team), R Studio (version 2023.06.0; Posit PBC) and Microsoft Excel (Excel 2019; Microsoft Corporation).

Ethical Considerations

The study received approval from the independent ethics committee of Northwestern and Central Switzerland (EKNZ, reference number: 2023 - 01783). All participants provided written informed consent and all participant data were de-identified. The participating therapists received compensation for participation of approximately $190.

Results

Overview

From December 2023 to March 2024, a total of 161 patients with stroke were screened for eligibility (Figure 3). Eight patients (6 females) completed the study. The patient group had a mean age of 61.5 (SD 12.7) years with an average duration since the stroke of 180 days (265 days, range: 15-618 days) and a Functional Independence Measure (FIM) [24,35] score of 93.8 (SD 12.8; see Table 1).

[a]FIM: Functional Independence Measure.

[b]Not available.

Ten therapists (8 females) with a mean age of 35.3 (SD 11.2) were enrolled. They were mostly physiotherapists (n=7) and occupational therapists (n=3).

Outcome Measures

The patients rated the usability of the app, including training content and monitoring, with an average SUS score of 86.6 out of 100, which is slightly higher than the score of the therapists, who reported a score of 83.3 out of 100 (Tables 2 and 3).

[a]SUS: System Usability Scale.

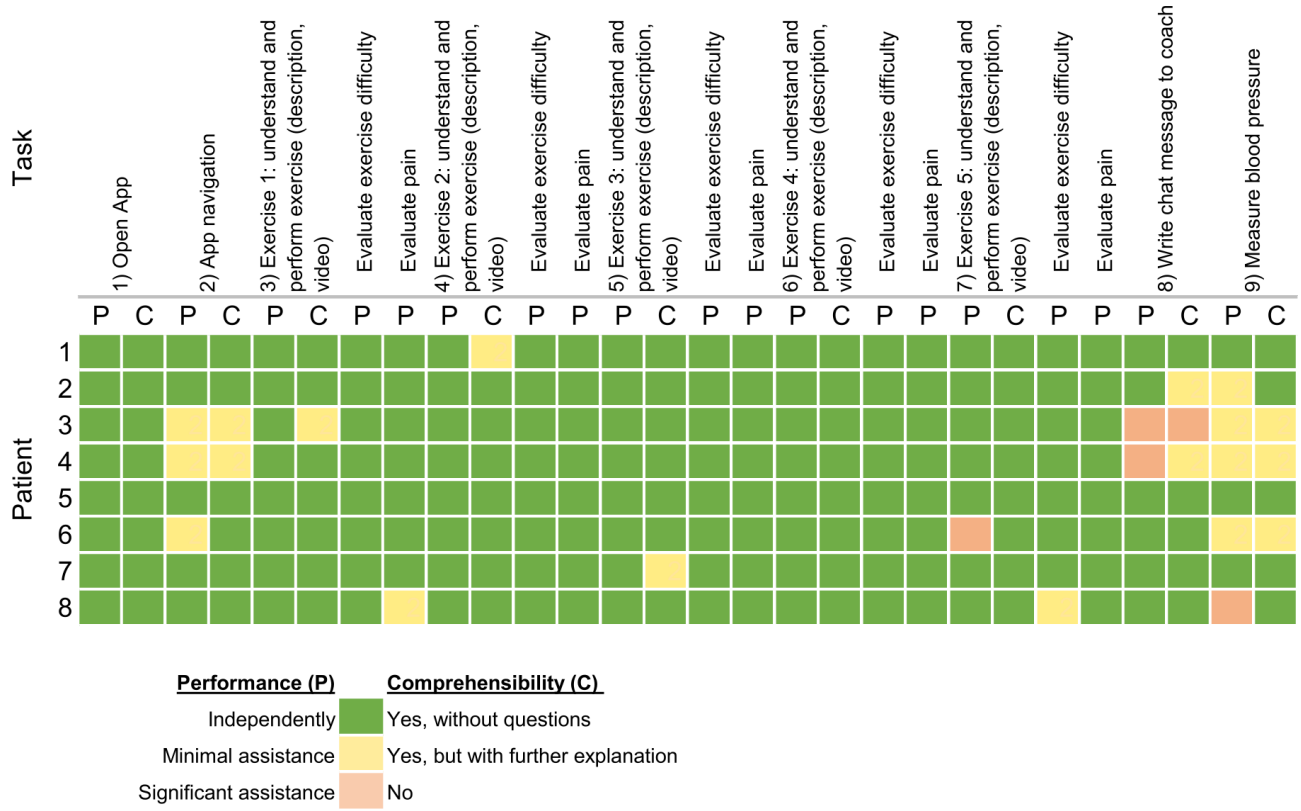
For the MARS-G, both patients and therapists generally rated the user experience and usability of the app as acceptable to good, with the mean scores of Sections A-D being 3.9 for patients and 4.1 for therapists, as well as from the mean scores of the individual sections (Figure 4). The therapists rated no section below 4.0 points, thus categorizing all sections as good. Notably, they tended to rate the app slightly higher than the patients, particularly in the sections “Engagement” and “Aesthetics.” The section on “Functionality” received the highest ratings from patients and therapists. A table with the scores from patients and therapists is provided in the supporting information (Multimedia Appendix 3).

XSL•FO
RenderX

Figure 4. The German version of Mobile App Rating Scale (MARS-G) ratings of patients and therapists. A: engagement; B: functionality; C: esthetics; D information quality; E subjective quality; F: perceived impact; MARS-G: German version of Mobile App Rating Scale; T: therapeutic benefits.

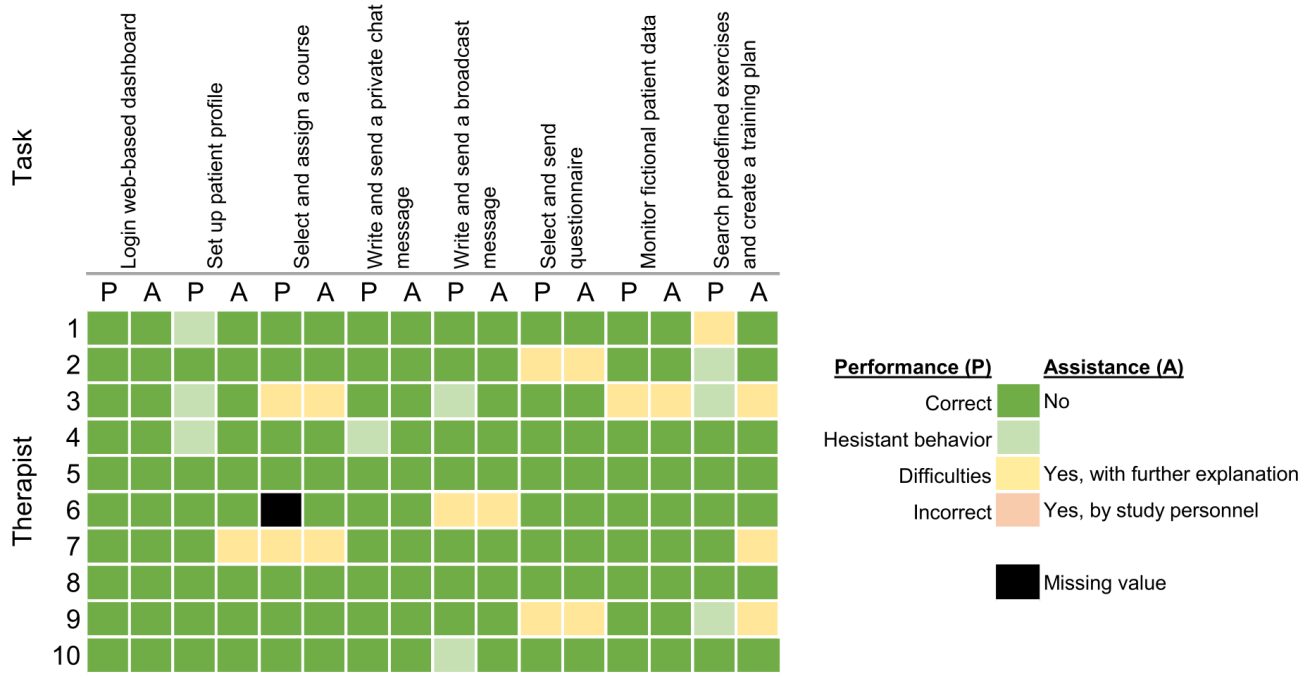
The results of the feedback questionnaire indicated a generally positive perception of the app and the devices. The patients had mixed opinions regarding the handling of the devices in terms of self-monitoring blood pressure and wearing the activity tracker. The latter was partly perceived as somewhat bothersome. The operation of the app on the tablet or smartphone was deemed to be relatively straightforward.



Among the therapists, there was a generally positive evaluation of the system. The question regarding the self-explanatory nature of the web-based dashboard for therapists received the lowest rating, while the question regarding technical functionality received the highest rating (Multimedia Appendix 4 for patients and therapists). Overall, all involved therapists expressed a desire to incorporate the app into their therapy planning.

Observation Protocols

Some patients encountered minor challenges in navigating the app's menus. A few needed substantial assistance in using the chat function to communicate with the coach or had follow-up questions. Patients required the most assistance with blood pressure measurement, with the majority needing at least some help during the measurement process (Figure 5). The emotions of attention, joy, curiosity, and astonishment were repeatedly mentioned. Except for one individual, all patients were engaged and attentive. Two-thirds of the patients exhibited joy throughout the observation. Curiosity and amazement were also noted in approximately half of the patients. In contrast, emotions such as rejection, anger, confusion, and nervousness were rarely observed, with 2 patients exhibiting these feelings.



XSL•FO
RenderX

Figure 5. Evaluation of patients' task performance.

All therapists were able to perform the assigned tasks. Only a few needed some further explanations (Figure 6).

Figure 6. Evaluation of therapists' task performance.

Adherence to the START Program Protocol

Overall, patients' adherence to the protocol varied and was moderate for the test phase between study sessions. Adherence regarding training and monitoring differed distinctively among individual patients (Multimedia Appendix 5). Some patients consistently wore the activity tracker but did not adhere to the planned exercises or blood pressure measurements. There were no adverse events reported during the one-week trial phase.

- Training: adherence to training was low on average. Only one patient trained on most days (≥75% of planned training sessions), while 3 patients showed moderate adherence (between 50% and 74% of the planned sessions). One patient revealed low adherence to the training plan (between

XSL•FO
RenderX

25% and 49%), and 3 had no adherence (<25%). Two patients could not perform exercises on one day or 2 days due to technical problems. Furthermore, some patients skipped part of or all exercises in the app, as noticed by the short time spent on the exercise screens.

- Monitoring:
- Blood pressure measurements: only one patient performed the blood pressure measurement every day. Three patients measured blood pressure on more than half of the planned days.
- Activity tracker: most patients (n=6) showed high adherence (≥75% of planned days) wearing the activity tracker. The adherence of one patient was low (25% - 49%), and one patient did not wear the tracker at all. In the case of this latter patient, however, the reason was a skin allergic reaction. There was no reason for the patients to remove the tracker, whether for charging, sleeping, or bathing, which may have contributed to the generally high adherence regarding the wearing of the trackers.

Discussion

Principal Findings

The aim of this study was to introduce our newly developed START program and initially determine how patients after a stroke and therapists evaluate the usability and functionality of START within the Blended Clinic platform. The following key findings were identified:

- This study demonstrated that both patients and therapists consider the Blended Clinic platform, including the START program, to be user-friendly.
- Regarding the usability of the app for patients after a stroke, the study yielded generally positive results. However, there remains potential for improvement to enhance long-term compliance with the program by patients and to ensure ease of use for therapists in the future.

Usability Evaluation

Evaluating usability is crucial to engage both patients and therapists early in the development process and to incorporate their valuable feedback into ongoing product refinement [36]. The initial insights into the usability of the telerehabilitation platform Blended Clinic in combination with the START program demonstrated good user-friendliness. Most of the given tasks were completed by the patients without assistance, which reassures us that the intended independent use of the Blended Clinic app is achievable. This is supported by the high SUS scores (83.3 among therapists and 87.2 among the participating patients with stroke), indicating the Blended Clinic platform with the START program as user-friendly. In a meta-analysis of digital health apps, the benchmark was a mean score of 68 with an SD of 12.5 [37], which is considerably exceeded in this study.

The evaluation based on the MARS-G allows for the assessment of the overall quality of the app-based training program, as well as the identification of both strengths and weaknesses through the mean scores of the individual sections [30]. In general, both therapists and patients rated the user experience and usability of the app as acceptable to good. Notably, therapists tended to rate the app slightly higher than the patients, particularly in the sections on “Engagement” and “Aesthetics.” Patients appear to be somewhat more critical in their evaluation of the app. This discrepancy may be attributed to the differing requirements and expectations of the 2 groups regarding the app [38].

Although the generalizability and credibility of the results from the feedback questionnaire are limited, it provided valuable insights, for example, concerning the handling of the blood pressure monitor, which can be applied in future studies. The results of the feedback questionnaire also indicated a generally positive perception of the app and the devices by the patients, although several areas for potential improvement have been identified. The technical functionality was regarded as having development potential. However, technical problems are quite common in studies investigating mobile health apps, as described in a scoping review on problems and barriers related to the use of these apps [39].

The therapists’ feedback additionally provided valuable insights into the practical implementation of the app. The therapists expressed a consistently positive response to the question of whether they would like to use the system in their therapy. The ratings indicated a high level of acceptance, overall satisfaction, and the potential of the system as a telerehabilitation option during the rehabilitation process. Our results are consistent with previous research. Physiotherapists are generally open to digital health technologies but frequently emphasize barriers to their implementation. In the study by Martinsen et al [37], therapists expressed concerns particularly about technical aspects, reimbursement issues, and establishing and maintaining a therapeutic relationship with patients [40]. The Blended Clinic platform with the START program is intended to address these issues through a blended care approach, which combines digital elements and personal interaction. The therapists in our study highlighted other important considerations, such as integration into existing therapy workflows, the need for flexibility in scheduling, and potential barriers related to staffing or digital infrastructure.

Patient Adherence to Protocol

The results of the one-week test phase indicated low adherence to the START training exercises among patients, despite the exercises being designed to be manageable and requiring only 10 minutes of daily commitment. Several factors may have contributed to the low adherence rates.

Participation in the study was conducted alongside the patients’ regular therapy regimen, which may have impeded their motivation to fully adhere to the study protocol. In addition, the exercises were rather easy for some patients, which might have influenced their adherence. Exercise difficulty and progression should be evaluated in further investigations.

While the presence of instructional videos and access to a physiotherapist via chat provided valuable resources, patients may still have struggled with their training. It is important to consider that impaired cognitive abilities can hinder protocol adherence. A study involving patients with stroke showed that factors such as age and disarticulation significantly influence

XSL•FO
RenderX

rehabilitation exercise adherence [41]. From our perspective, it would be beneficial to assess and individualize the amount and method of external support and motivation required. Further strategies may have been needed to enhance patient engagement and adherence to the exercise program, for example, family involvement.

Regarding low adherence to blood pressure measurements, patients may have perceived little added value in measuring their blood pressure themselves since these were routinely taken by the care personnel during inpatient stay. Not all patients were equally affected after a stroke, and some may have had further difficulties using the device due to motor function limitations, uncontrolled movements, or even hemiplegia, which could explain the issues encountered during blood pressure measurement.

On the contrary, the adherence to wearing the activity tracker was quite high. Such trackers have high potential to deliver meaningful data for the health care professionals, for example, step counts or time spent on specific activity levels. This activity tracker data could also be included directly in the Blended Clinic platform to increase the motivation and physical activity of patients. Such an approach is described in the pilot study by Paul et al [39], where a gamified approach was used to enhance step count goals [42].

Grau-Pellicer et al [40] conducted a randomized controlled trial using a similar program in conjunction with a smartphone app [43]. The authors could show positive results, for example, an improved activity level in the intervention group, but there was a low adherence to app use. They stressed the importance of developing technologies adapted to patients with stroke that are easy to use in order to increase adherence [43]. In our study, we tested only part of the START program, a one-week period, with a selected patient group (mRS 3 - 5), as usability was of particular importance to us at this stage. In contrast, adherence rates are generally high (≥80%) in telerehabilitation studies for patients with stroke, although this aspect is often underreported [44].

However, a randomized controlled trial by Emmerson et al [42] found no superiority of a home-based exercise program delivered via electronic tablet compared to a paper-based version, underscoring the importance of remote therapeutic support [12]. Consistent with this, promising results have been reported when remote support was provided to enhance adherence to home exercises in individuals with musculoskeletal conditions [45].

Usability evaluations for a wide range of mobile health apps have been conducted across various target populations [46], including patients after a stroke [47], demonstrating beneficial effects for patients. In physical stroke rehabilitation, similar mobile apps were developed and evaluated, for example, ARMStrokes (Towson University) for upper extremity training [48], an app to increase physical activity [42], or a program involving caregivers [49]. These and other technologies show promising results, especially for improving upper extremity function [47].

However, despite the already available apps for patients after stroke, most apps have been developed outside Europe [11]. Furthermore, additional equipment, for example, a balance disc [50] or a virtual reality system [51], is often necessary. With START, we focused on individualized physiotherapeutic exercises that require no special equipment. Notably, our usability study deliberately included patients with moderate to severe disabilities—a group often excluded from similar research—thereby providing valuable insights into the applicability and accessibility of the intervention for a broader spectrum of stroke survivors.

Limitations

Our usability study has several limitations that should be considered when interpreting the results. The sample size was small; however, we could include the planned patients after a stroke and therapists to evaluate the START program.

Furthermore, the intervention period for patients was only one week, which may not have been sufficient to draw conclusions about long-term adherence for the holistic START program. Extended usage periods are warranted to gain a deeper understanding of the factors influencing adherence to digital home-based exercise programs.

We also lack more detailed information about the patients, such as cognitive function or digital literacy. In our study, patients and therapists were asked to engage with a technical system and evaluate its usability and user experience. For study participation, patients were required to own a smartphone or tablet. Therefore, we assume that patients possess at least basic technical knowledge and feel confident in their ability to operate the technology. On the other hand, these requirements proved to be a challenge, as we experienced in a prolonged recruitment phase. However, the proportion of older individuals who own a smartphone is expected to rise [52], ensuring that access to mobile apps will be available for the majority of patients after a stroke. It can therefore be assumed that in the future, a significant proportion of patients after stroke will possess the necessary prerequisites to use these digital opportunities.

The feedback collected from patients and therapists was quite positive, but we cannot exclude the possibility of socially desired responses when interpreting the subjective outcomes. Ried et al [51] propose 8 preventive measures to address this issue; one of them is indirect questioning. Future studies should consider such measures to minimize this bias.

These limitations underscore the need for further research. Based on the findings from our study, we have designed a feasibility study aimed at a more comprehensive evaluation of the entire START program with a larger sample size. This evaluation will encompass the transition between inpatient and outpatient care, as well as the holistic content of the program covering all mRS levels. Additionally, we have established other focal points concerning the outcome measures, such as performance-based outcome measures.

Conclusions

In summary, the Blended Clinic platform, including the START program, was initially considered user-friendly, with good

XSL•FO
RenderX

usability ratings from both patients with stroke and therapists. The available data provide an insight into patient adherence and the underlying challenges. Future efforts should focus on optimizing technical functionality, enhancing user motivation, and integrating training into the daily routines of patients to potentially improve adherence. This study's results and adjustments aimed at enhancing the motivational component and paving the way for a long-term evaluation within a multiweek clinical study, in which the transition between hospital stay and the use of the system in a home setting will be tested.

Acknowledgments

We sincerely thank all the patients and therapists who participated in this study.

Funding

This study is part of the "TeleRehaStroke" project funded by the Canton Aargau, Department of Health and Social Care, Division of Health. There is no reference number available.

Data Availability

Data collected during the usability study can be made available by the first author upon reasonable request.

Conflicts of Interest

BC is the lead developer and founder of the software application used in this study. LHB received a grant from the Canton of Aargau, Switzerland, for the conduct of the present study.

Abstract

Background: Peripheral facial nerve palsy is a debilitating condition that may necessitate surgical intervention. Although motor rehabilitation is considered essential, the most effective approach has not yet been determined.

Objective: This study aimed to evaluate the feasibility and effectiveness of emotional training, a novel telerehabilitation-based treatment, on motor, functional, and psychological outcomes in patients with unilateral facial palsy following triple innervation surgery.

Methods: A prospective, assessor-blinded, 2-arm pilot cohort study was conducted at the rehabilitation unit at University Hospital San Paolo, Milan, Italy, from January to October 2024. Participants (N=16) received 1 treatment session every 2 weeks over 20 weeks, each lasting 45 minutes, according to standard clinical procedures in place at the rehabilitation unit. Participants were nonrandomly assigned to either an in-person group (n=8) or an online group (ie, telerehabilitation; n=8) based on their ability to attend in-person sessions. The primary outcomes assessed at baseline (T0) and after treatment (T1) included facial symmetry (Sunnybrook Facial Grading System; SFGS), facial disability (Facial Disability Index; FDI), and anxiety levels (Beck Anxiety Inventory).

Results: Statistical analysis revealed significant improvements at T1 for both groups in the FDI social and well-being function subscale, Beck Anxiety Inventory, SFGS resting symmetry score, SFGS symmetry of voluntary movement score, SFGS composite score, SFGS with bilateral masseter contraction symmetry of voluntary movement score, and SFGS with bilateral masseter contraction composite score (P<.001 for all). Only the FDI physical function subscale showed a differential improvement at T1 for the in-person group treatment (ANOVA for time × treatment: F_1=14.356; P=.002; Holm-Bonferroni post hoc test: P<.001). Finally, a strong positive correlation was observed between the time elapsed from surgery to rehabilitation and SFGS composite score improvement at T1 (r=0.94; P=.005).

Conclusions: These results suggest that the online emotional training protocol is as feasible and effective as the in-person emotional training protocol in improving facial motor function, reducing anxiety, and enhancing facial expression spontaneity in patients who had undergone surgery for peripheral facial palsy. These findings support the validity of telerehabilitation approaches as a feasible, accessible, and sustainable alternative to conventional in-person therapy for facial nerve recovery.

KEYWORDS

peripheral facial nerve palsy; physiotherapy; motor rehabilitation; telerehabilitation; Sunnybrook Facial Grading System

Introduction

Peripheral facial nerve palsy (FNP) is a neurological disorder that affects the muscles of one side of the face [1], leading to facial asymmetry; synkinesis; hemifacial spasm [2]; impaired eye and mouth closure; and functional deficits in daily activities, including vision, speech, and eating [3,4]. Peripheral FNP resulting from traumatic events (eg, cranial fractures) [5], oral

XSL•FO
RenderX

and maxillofacial surgery [6], or neoplastic conditions (eg, acoustic neuroma) [6] often presents with a highly variable prognosis [6,7] and may require invasive intervention, such as facial reanimation [8]. Following facial reanimation surgery, physiotherapy (PT) plays a critical role in motor and functional recovery [9]. PT interventions capitalize on principles of neuroplasticity and motor learning to restore facial symmetry [10,11]; preserve proprioception, muscle tone, and trophism [12]; reduce synkinesis; and enhance both spontaneous and voluntary facial movements [13].

Triple innervation is a novel surgical protocol [14,15] that uses 3 distinct neural inputs to restore movements and functions: the masseteric and hypoglossal nerves, which serve as quantitative input (ie, facilitating voluntary facial movements, such as smiling during teeth clenching and maintaining muscle tone), and the facial nerve contralateral to the damaged one, which functions as a qualitative input (ie, supporting spontaneous facial expressions such as smiling and blinking) [14,15]. Several studies suggest that triple innervation surgery is associated with complication rates comparable to those of other established techniques [14] while demonstrating improved outcomes in terms of facial symmetry, voluntary and spontaneous movements, and overall functional recovery both at short- and long-term follow-up [14,16,17]. Given the novelty of the surgical technique, no study has assessed the effect of PT following triple innervation yet. In addition, although several PT protocols, including massage [12,18], electrotherapy [19,20], exercise therapy [10,11], and biofeedback therapy [21,22], have demonstrated beneficial effects, no clear evidence supports the superiority of any of them [13,23]. Compared to other pathologies, facial motor rehabilitation is complicated by the intrinsic link between facial movements and emotional expression. The neural circuits governing facial expressions are closely connected to systems involved in emotion recognition and social communication [24-27], suggesting that interventions targeting both motor and emotional components may be particularly relevant in FNP. Moreover, aesthetic and functional impairments often lead to psychosocial distress, reduced self-esteem, and increased anxiety [28,29], reinforcing the need for rehabilitation approaches that also address emotional and cognitive aspects of facial movement. Within the context of PT interventions, emotional training has recently been proposed as a targeted approach to address these neurophysiological and clinical characteristics and optimize rehabilitation outcomes [30]. Emotional training conceptualizes movement control as a cognitive process involving selective attention to sensory cues and task demands [31,32] and integrates emotional, cognitive, and motor components to facilitate selective muscle recruitment, retraining of emotional expressiveness, and the execution of functional exercises oriented toward daily activities. This approach has been recently introduced as a rehabilitation approach for patients after triple innervation surgery in our center [30].

Recently, telerehabilitation has been proposed as a promising rehabilitation method for patients with neurological disorders, showing results comparable to those of conventional face-to-face rehabilitation [33]. While still promising, evidence remains limited for the motor rehabilitation of peripheral FNP [34,35]. Telerehabilitation represents a hospitalization-avoidant strategy that emphasizes the delivery of home-based rehabilitation, minimizing resource requirements and reducing direct supervision needs [36-38]. This approach may serve as a particularly viable treatment option for patients with FNP [36] as it minimizes the need for social exposure and interpersonal contact, which can be especially beneficial for patients facing psychosocial burden.

In this work, we primarily aimed to assess the feasibility and motor-functional and psychological effects of a telerehabilitation-based emotional training intervention [30] in patients with peripheral FNP who underwent triple innervation surgery and compare the results with those of an in-person emotional training approach.

Methods

Study Design and Setting

This prospective, assessor-blinded, 2-arm pilot cohort study was conducted at the rehabilitation unit at University Hospital San Paolo (Milan, Italy). On the basis of their ability to attend in-person sessions, each participant eligible for enrollment (N=16) engaged in either in-person PT treatment (ie, in-person emotional training; n=8) or in telerehabilitation treatment (ie, online emotional training; n=8). In both groups, treatments were led by trained physiotherapists. Motor outcomes (Sunnybrook Facial Grading System [SFGS] and SFGS with bilateral masseter contraction [SFGS with MassCon]), functional outcomes (Facial Disability Index; FDI), and psychological outcomes (Beck Anxiety Inventory; BAI) were assessed at baseline (T0) and at the completion of treatment (T1). Given the exploratory pilot nature of this study, which aimed primarily to assess feasibility and generate preliminary results to inform future confirmatory trials, and considering the rarity of the medical condition targeted by the inclusion criteria, no formal a priori sample size calculation was performed. However, the final sample (N=16) is consistent with those of previous pilot investigations conducted in comparable clinical populations [39,40]. A convenience sampling strategy was adopted, enrolling all consecutive eligible patients referred to the rehabilitation unit during the predefined recruitment period (November 2023 to November 2024). In addition, a prospective observational design was adopted due to several clinical (eg, emotional training is part of postoperative rehabilitation in our department) and logistical (eg, rarity of the target population and allocation to treatment according to patients' real-world logistical circumstances) reasons.

Ethical Considerations

The study protocol followed the Declaration of Helsinki. Considering that emotional training is common practice for patients undergoing triple innervation surgery at the rehabilitation unit of University Hospital San Paolo, and that patients with peripheral FNP would have been treated with the same protocol after triple innervation surgery despite not participating in the study, the research was considered as an observational study. Ethical approval was obtained from the Milan Area 1 Ethics Committee, protocol number 0048450/2022. All patients gave written informed consent

XSL•FO
RenderX

before participation. All data collected in this study were handled in accordance with strict privacy and confidentiality standards. Records were anonymized through the use of coded identifiers, and no personally identifiable information was retained in either the research database or the investigational application. Hard-copy materials (eg, consent forms) were securely stored in a locked cabinet in a restricted-access laboratory, while electronic data were maintained on protected institutional servers with controlled access. Access to the coded datasets was limited to authorized members of the research team. Participants were not provided with financial compensation for their involvement in the study.

Population

This study was conducted between January and October 2024. Participants were recruited from the hospital community based on the following inclusion criteria: (1) age between 18 and 75 years; (2) presence of unilateral facial palsy, confirmed through clinical history and anamnesis; (3) prior treatment with triple innervation surgery (as described in the work by Biglioli et al [14]); (4) a House-Brackmann scale grade of III or higher; (5) ability to understand and perform the tasks; and (6) capacity to provide informed consent. Exclusion criteria were (1) a diagnosis of major neurological, neuropsychological, or psychiatric disorders, confirmed through clinical history and anamnesis; (2) previous treatments for facial palsy other than triple innervation surgery [14]; and (3) changes in pharmacological therapy within 3 months prior to enrollment. Patients were instructed to maintain stable medication regimens throughout the study period and refrain from participating in additional rehabilitation programs.

Treatments

Overview

All patients received the standard 5-month emotional training rehabilitation program [30]. The treatment sessions lasted 50 minutes and were conducted once every 2 weeks over a 20-week period (total number of sessions=10; see Multimedia Appendix 1 for a structured session plan). The primary objective of both the in-person and online groups was to enhance the quality and symmetry of facial muscle movements, initially facilitated through teeth clenching, and progressively dissociating these movements from masseter activation [41-43]. This approach was chosen because one of the primary rehabilitative goals for patients who have undergone triple innervation surgery is to improve voluntary contraction of the mimic muscles by gradually decoupling them from masseter activation through repeated exercises and the progressive automation of movements [41-43]. According to the principles of triple innervation surgery [14], the masseteric nerve, which stimulates the masseter muscles, serves as the principal donor nerve for activating the facial nerve and, consequently, the facial mimic muscles. Therefore, postsurgical facial muscle contractions activate the masseter muscles. The progress of each patient was closely monitored by physiotherapists, who adjusted the complexity of exercises in response to individual progress. As facial movements improved, progressively more advanced exercises were introduced to stimulate emotional expression and functional facial movements in increasingly complex real-world contexts, providing continuous feedback to optimize movement patterns. Through consistent repetition and progressive automation, the secondary objective was to restore the functionality and spontaneity of facial expressions, enhancing facial perception and promoting cortical reorganization. As suggested by previous research [44], exercises were tailored to each patient's residual motor capabilities, functional limitations, and social challenges. The physiotherapists delivering the treatment underwent extensive training prior to its initiation and had prior experience in the rehabilitation of peripheral FNP.

In-Person Emotional Training Protocol

Before initiating the emotional training protocol, tissue flexibility in the impaired masseter, medial and lateral pterygoid, zygomaticus major, orbicularis oculi, and orbicularis oris muscles was improved using manual therapy techniques [45] such as internal and external stretching techniques and transverse massage [45,46]. This preliminary phase was necessary due to the presentation typically observed in soft tissues following facial palsy surgery [47].

As previously reported [30], emotional training comprises 3 phases. The first phase introduces exercises designed to increase sensory awareness, promote appropriate and selective muscle recruitment, and integrate both sensory perception and motor function [32]. Patients were asked to perform tactile and pressure perception exercises, identifying sensations at key points on the face (eg, the corners of the mouth and the eyebrows) [32]. When movement abilities allowed it, facial exercises were paired with the activation of the masseter muscle focusing on 2 movements of functional importance: eye closure and smiling (with either closed or open lips). Otherwise, patients were asked to perform motor imagery exercises, which have been shown to activate the same cortical and subcortical areas as during actual movement execution [48,49]. Patients mentally simulated facial movements focusing on the simulated sensations and were then asked to perform them and compare the simulated and actual sensations. As facial movements improved, exercises progressively intensified, with patients being asked to close their eyes or smile at different intensities of teeth clenching or to self-correct their movements according to their perceived facial symmetry.

The second phase introduces exercises to improve the spontaneity of emotional expression. Patients were asked to perform facial expressions corresponding to emotions defined by Osgood [50] for nonverbal communication (happiness, sadness, interest, disgust, fear, anger, and surprise) elicited through visual (eg, viewing triggering images or scenarios), taste (eg, tasting sour food), or memory (eg, recalling triggering experiences) stimuli. As facial movements improved, patients were asked to switch between emotional expressions (eg, from fear to anger).

The last phase of the protocol focuses on functional exercises aimed at restoring the ability to perform daily activities (eg, communicating effectively or drinking from a glass) using facial muscles. These exercises included, for example, activities to improve word articulation (eg, reading aloud a text or words with challenging sounds such as labial consonants [eg, "b" and

XSL•FO
RenderX

"p"]) or mastication (eg, chewing inside both cheeks or transferring food or liquid from one side to the other).

Online Emotional Training Protocol

Participants in the online treatment group received the same intervention protocol as those in the in-person treatment group in terms of the type, nature, frequency, and objectives of the exercises; however, the intervention was delivered remotely via video call, enabling the physiotherapist to directly monitor exercise correctness, safety, and adherence; provide immediate feedback; and adjust the intervention as needed. No session was recorded as supervision and feedback were provided live during each video call and adherence was tracked through supervised session attendance as the intervention did not include unsupervised exercises requiring additional logging or diaries. Due to the absence of in-person interaction with the physiotherapist, patients were initially trained during the assessment phase to perform manual relaxation techniques and facial exercises targeting eye closure and smiling with masseter muscle activation. These exercises were performed under the physiotherapist's virtual supervision, where the patient was guided to repeat the maneuvers, ensuring correct execution and understanding. Furthermore, throughout the treatment sessions, exercises were designed to encourage patients to focus attentively on the sensory feedback from their facial movements, with continuous feedback provided to assess progress. No further modifications were made to the in-person emotional training protocol compared to the online emotional training protocol.

Outcomes

SFGS, SFGS with MassCon, FDI, and BAI were administered both at baseline (T0) and the posttreatment time point (T1) by a single trained physiotherapist who was blinded to treatment group allocation but not to time points.

The SFGS is a widely used clinical scale designed to evaluate facial asymmetries and the presence of synkinesis comparing the paretic side of the face with the nonparetic side [51]. The scale consists of 3 components: the first (resting symmetry) involves assessing symmetry at rest, including the eye, cheek (nasolabial fold), and mouth; the second (symmetry of voluntary movement) rates symmetry during facial expressions (ie, during 5 standard facial expressions); and the third (synkinesis) grades the severity of synkinesis during these movements. Each component is assigned a score, and the weighted sum of these components generates a composite score ranging from 0 to 100, with a lower score indicating greater severity of facial palsy [51].

For this study, a modified version of the SFGS was used in which participants were instructed to perform the second component (symmetry of voluntary movement) while clenching their jaw (ie, activating the masseter muscles).

The FDI is a 10-item self-report questionnaire assessing 2 domains of facial disability: physical and psychosocial function [52]. It includes 2 subscales—one for physical function and the other for social and well-being function—each comprising 2 items. The scores for each subscale are converted to a 100-point scale, where a score of 100 denotes no impairment in function [52].

The BAI is a psychometrically validated, self-reported, 21-item scale commonly used to measure symptoms of anxiety [53]. The score for each item is summed, yielding a total score ranging from 0 to 63, categorized as minimal anxiety (0-7), mild anxiety (8-15), moderate anxiety (16-25), and severe anxiety (26-63) [53].

Statistical Analysis

Normal distributions of the dependent variables were assessed using the Shapiro-Wilk test for normality [54]. As all variables passed the test (P>.05), parametric statistical analysis was applied. To evaluate the effects of time, treatment, and the interaction between time and treatment, changes in the outcomes at each time point were examined using a 2-way repeated-measure ANOVA with treatment as the between-subject factor. Post hoc analysis was performed using the Holm-Bonferroni correction. Finally, the Pearson correlation coefficient was calculated to explore relationships among age, time from onset of facial palsy to surgery, time from surgery to rehabilitation, time from onset of facial palsy to rehabilitation, and the change in outcome scores (Δ; calculated as Δ score = T1 score − T0 score). A P value of less than .05 was considered statistically significant for all analyses. Data were analyzed using JASP (version 0.16.3) for Windows (JASP Team).

Results

Baseline characteristics of the sample are shown in Table 1 (see Figure 1 for the CONSORT [Consolidated Standards of Reporting Trials] flow diagram). At baseline, there were no significant differences in demographic variables or clinical assessments between the 2 treatment groups (P>.05 for all the analyses).

Figure 1. Flowchart of the study design. T0: baseline; T1: posttreatment time point.

Two-way ANOVA results are shown in Table 2. The analysis revealed no significant treatment effect for the outcomes considered (P>.05 for all the analyses; Table 2). A time × treatment effect was observed only for the FDI physical function subscale (F_1=14.356; P=.002), with post hoc analysis revealing a significant increase between T0 and T1 in the in-person treatment group (mean difference=–21.25, 95% CI −29.125 to −13.375; P<.001; Holm-Bonferroni post hoc test; Figure 2A). The effect of time was found for all the outcome variables except for the SFGS synkinesis score (P>.05). Specifically, a significant increase in score for the FDI social and well-being function subscale (mean difference=−11, 95% CI −15.163 to −6.837; F_1=32.114; P<.001) and decrease in the BAI total score (mean difference=5.375, 95% CI 2.357-8.393; F_1=14.592; P=.002; Figures 2B and 2C, respectively) were detected, a significant decrease in the SFGS resting symmetry score (mean difference=6.250, 95% CI 4.354-8.146; F_1=50.00; P<.001) and increase in the SFGS symmetry of voluntary movement score (mean difference=−17.250, 95% CI −21.111 to −13.389; F_1=91.810; P<.001) and SFGS composite score (mean difference=−0.239, 95% CI −0.288 to −0.191; F_1=111.430; P<.001) were observed (Figures 3A-3C, respectively), and a significant increase in the SFGS with MassCon symmetry of voluntary movement score (mean difference=−12.250, 95% CI −15.486 to −9.014; F_1=65.910; P<.001) and SFGS with MassCon composite score (mean difference=−0.196, 95% CI −0.231 to −0.161; F_1=143.499; P<.001) were observed (Figures 4A and 4B, respectively). No dropouts were registered in either treatment group, indicating strong patient engagement and good adherence to the intervention across both delivery modalities.

Discussion

Principal Findings

Despite the pivotal importance of PT, the most effective PT approach after surgically treated peripheral FNP is still unclear, with a telerehabilitation-based emotional training protocol showing promising foundations given the specific characteristics of the facial impairments. In this exploratory pilot study, we confirmed the feasibility and potential clinical value of a telerehabilitation-based emotional training protocol in improving motor symptoms, facial disability, and anxiety in patients with peripheral FNP treated with triple innervation surgery also when compared with an in-person approach. However, these findings should be considered preliminary.

Emotional training is a novel therapeutic approach based on multiple phases that has shown preliminary promising results in the motor rehabilitation of FNP [30]. The first phase comprises a sensory-based intervention in which patients are asked to recognize the sensations induced by external stimuli on the lesioned hemiface (eg, intrinsic characteristics of objects or surfaces and passive movements performed by the physiotherapist) and perform facial movements—or imagine them, given that both motor imagery and actual movements activate the same neural circuits [48,49]. The rationale behind this first phase relies on the theories of motor control [55] that conceptualize the normal control of movement as a cognitive task [32] in which individuals integrate sensory inputs (feedback control), prior knowledge, and volitional intention (feedforward control) to select appropriate motor programs and regulate motor

XSL•FO
RenderX

output [56,57]. As reported by numerous studies, sensory stimulation reshapes cortical motor representations [58] given the interplay between motor (primary motor cortex, supplementary motor area, and premotor cortex) and somatosensory (primary and secondary somatosensory cortices and the sensory thalamus) regions [59,60]. In neurological motor rehabilitation, sensory-based interventions have been shown to enhance adaptive motor cortical plasticity and promote functional recovery [61-63]. Nevertheless, cognitive processes (eg, information perception and the elaboration, selection, and execution of motor plans) [31,64] play a critical role in mediating these mechanisms, supporting functional interactions between the body and the environment [65,66]. In addition, combining different types of sensory information stimulates the activity of associative brain areas that are important for learning, neuronal plasticity, and recovery [67]. Although evidence remains limited [64,68-71], promising findings suggest that sensory-based interventions can significantly improve the ability to perform activities of daily living and enhance quality of life [71] even for people with peripheral FNP [72,73].

The second phase aims to restore authentic facial expressions, emotional congruence, emotional symmetry, and spontaneity [74], which is crucial for optimal motor recovery [75]. At the neurophysiological level, facial movements in response to emotions are mediated by a widespread neural network involving various cortical regions that project to the facial nucleus, integrating motor planning, somatosensory feedback, and limbic system activity [76,77]. While corticofacial projections from the lateral frontal lobe contribute to the voluntary control of facial movements [24], the cingulate cortex plays a pivotal role in emotional expression through facial mimics, with projections from the amygdala providing the necessary emotional context [24]. For example, among the 2 different neural pathways controlling laughter [25], one, which involves primarily the frontal operculum [78,79] and the primary motor cortex, represents the neural basis of voluntary, nonemotional, conversational laughter; the other, which includes the pregenual anterior cingulate [80,81], ventral striatum and nucleus accumbens, amygdala, and hypothalamus [82], is involved in the production of emotional laughter, with the supplementary motor area likely modulating the production of both [27]. Notably, training voluntary movements to express different emotions helps reconnect the limbic-motor pathways [24], supporting the synergy between voluntary and emotional facial movements [24]. This is particularly important for facial nerve lesions, where voluntary movement and emotional expression are often dissociated [83]. The final phase of rehabilitation focuses on functional exercises designed to restore the ability to perform essential daily activities. These functional tasks, such as eating, speaking clearly, or demonstrating facial expressiveness during conversations, involve complex and coordinated facial muscle activity [84]—which is why these exercises are included as the final part of the treatment. By training patients in real-life contexts, they are engaged in meaningful activities that mirror their daily life. This approach has been shown to enhance neuroplasticity and functional recovery through task-specific repetition [85]—a principle known as “use-dependent cortical reorganization” [86]. In addition, focusing on real-world tasks aligns rehabilitation with the patient’s meaningful goals, improving motivation and adherence to the treatment protocol [87-89].

Taken together, our findings reinforce the conclusions of several systematic reviews on the feasibility of telerehabilitation in neurological conditions [33,90]. Recently, a randomized controlled trial investigated the effectiveness of video exercise–based telerehabilitation on motor and psychological symptoms in patients with peripheral FNP [35]. Patients in the telerehabilitation group not only found the treatment satisfactory and accessible but also demonstrated a significant improvement in FDI scores comparable to those receiving routine in-person care. Furthermore, both groups exhibited similar improvements in anxiety after treatment [35]. Despite the limitations of our study design, our findings are consistent with this evidence, suggesting the need to expand upon the value of telerehabilitation services for peripheral FNP, also considering that both patients and therapists generally have a positive attitude toward the integration of digital technologies [91,92]. Following the telerehabilitation-based emotional training, our patients reported improvements comparable to those of the face-to-face treatment in facial nerve function and facial symmetries (both at rest and during voluntary movement) even when considering the modified version of the SFGS (SFGS with MassCon). This is consistent with the only study assessing the effectiveness of emotional training in peripheral FNP, although the latter was performed in an in-person fashion [30]. Indeed, the authors reported that 50 patients who underwent face-to-face emotional training had improved House-Brackmann scale scores and symmetry of the face both at rest and during movements. In addition, in contrast to our study, only patients with iatrogenic peripheral FNP but not those who underwent surgery had gains in social function and subjectively perceived well-being. In our study, all patients experienced significant improvements in social and well-being function at the end of the treatment both in the in-person and online groups. This result was further confirmed by improved anxiety assessments. This is of particular importance given the substantial psychosocial burden that patients with facial impairments experience [93]. Nevertheless, the nonrandomized allocation and limited sample size warrant a cautious interpretation of these positive findings. Moreover, comparisons should be interpreted cautiously as the aforementioned study [30] was a retrospective analysis with no control group and the authors performed an in-person treatment protocol. However, in this study, self-reported physical function was greater at the end of the in-person treatment when compared to telerehabilitation treatment. At least for physical functioning, the therapeutic alliance and the therapist-patient relationship, which are strengthened by the direct, in-person interaction, and the emotional bond inherent to in-person rehabilitation may have had a positive effect, as previously suggested [33,94].

This study has some limitations. First, the small sample size may have underpowered the study and increased the risk of inflated effect estimates (eg, from correlations), whereas the use of subjective and operator-dependent assessments might have affected the results and interpretation. The nonrandomized allocation could have affected the internal validity of the study, whereas the absence of a follow-up assessment prevents conclusions regarding the durability of the observed

XSL•FO
RenderX

improvements. In addition, our neurophysiological hypotheses should be confirmed through neuroimaging studies, which were not feasible at this time. Second, although our patients were asked to maintain a stable pharmacological treatment throughout the study, the pharmacological therapies of the patients were not documented. The different biochemical effects induced by the medications could have influenced motor recovery, as previously suggested [95,96]. Similarly, we included surgically treated patients with peripheral FNP with multiple palsy etiologies (eg, neurinoma and trauma). The different underlying mechanisms of facial dysfunction might have affected the results and reduced the external validity of our findings.

Clinical Implications

The findings of this pilot study indicate that emotional training could be integrated into routine postoperative care for patients with peripheral FNP after triple innervation surgery, offering measurable benefits in facial symmetry, voluntary motor performance, social functioning, and anxiety reduction. The intervention's emphasis on both motor and psychosocial domains aligns well with the complex functional demands of patients undergoing facial reanimation, who often experience challenges that extend beyond motor impairment alone. Interestingly, the comparable improvements observed with the in-person protocol and telerehabilitation delivery suggest that emotional training can be implemented flexibly without compromising clinical outcomes, providing a viable option for individuals with mobility limitations, work constraints, or psychosocial discomfort associated with facial impairment. The structured nature of emotional training, centered on restoring selective motor control, improving emotional expression, and reducing maladaptive compensatory patterns, offers clinicians a reproducible framework that can be tailored to individual patient needs. Clinicians may consider telerehabilitation as a practical strategy to maintain continuity of care and reduce barriers to treatment access.

Conclusions

In conclusion, this exploratory pilot study provides preliminary evidence that telerehabilitation-based emotional training may have beneficial effects on motor, physical, and psychosocial functioning, as well as on anxiety, in surgically treated patients with peripheral FNP. Given the study's observational design and limited sample size, these findings should be interpreted cautiously and considered hypothesis generating rather than confirmatory. Further studies with optimized designs (eg, double-blind, parallel-group trials), larger sample sizes, and more objective and informative assessments (such as neurophysiological or neuroimaging evaluations) are warranted to confirm and extend these findings.

Abstract

Background: Telerehabilitation expanded rapidly during the COVID-19 pandemic and is increasingly used alongside, or as an alternative to, in-person rehabilitation. Goal setting is a core component of client-centered rehabilitation; however, how therapists conduct goal setting remotely remains poorly understood, particularly in East Asian contexts. To our knowledge, no qualitative study has specifically examined remote goal setting in telerehabilitation in Japan, where remote delivery was not yet routine when these data were collected.

Objective: This qualitative study aimed to explore how Japanese occupational therapists and physical therapists experienced negotiating and adapting rehabilitation goals during telerehabilitation, including how remote delivery shaped assessment, collaboration, and the purposes assigned to goals.

Methods: Individual semistructured interviews (18 - 51 minutes; mean 32 minutes) were conducted via Zoom (Zoom Communications, Inc) in Japanese with 9 therapists (7 occupational therapists and 2 physical therapists; 7 male and 2 female; aged 29 - 43 years) who had direct experience of remote goal setting. Participants were recruited by purposive and snowball sampling from 9 different workplaces across Japan, including metropolitan areas such as Tokyo and regional areas such as Hokkaido and Nagasaki, and worked in hospital, private-practice, community-based, and academic settings. Data were analyzed using reflexive thematic analysis within a contextualist epistemology, following Braun and Clarke. Trustworthiness was considered using Nowell and colleagues' criteria, and reporting followed the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist.

Results: Four themes were constructed: (1) losing touch: uncertainty in remote assessment and goal setting (9/9 participants); (2) from direct intervention to coaching-oriented goal setting (8/9 participants); (3) at home, at ease: needs that surface in clients' own environments (6/9 participants); and (4) when continuity becomes the goal (6/9 participants). Therapists described remote goal setting as shaped by both constraint and possibility. Partial bodily, nonverbal, and contextual information reduced their confidence in assessment and goal negotiation, and they responded through preparation, visual resources, self-monitoring tools, and collaboration with clients and families. Sessions conducted in clients' own environments appeared to support comfort and sometimes made everyday needs more visible. When in-person care was unavailable or insufficient, therapists sometimes broadened goals from functional improvement alone to include continuity, ongoing monitoring, and prevention of disengagement.

Conclusions: In these therapists' accounts, remote goal setting was not simply a diminished version of in-person practice but a distinct clinical process requiring deliberate preparation, collaborative communication, and management of uncertainty. Hybrid pathways may combine in-person assessment, when hands-on examination is needed, with continued remote negotiation, monitoring, and revision of goals. Further research should incorporate clients' and families' perspectives and evaluate hybrid models of goal setting across diverse rehabilitation populations.

Introduction

Telerehabilitation and Remote Goal Setting

Telerehabilitation, defined as the delivery of rehabilitation services through information and communication technologies, such as videoconferencing, mobile apps, sensors, and telephone-based communication, has expanded rapidly in recent years [1,2]. This growth was particularly accelerated by the COVID-19 pandemic, which increased the uptake of remote health care across rehabilitation settings [3]. This expansion has created new opportunities to improve access to care and support continuity of rehabilitation services, particularly for people who face barriers to attending in-person appointments [4]. In addition to improving accessibility, telerehabilitation can offer other benefits, including greater convenience, reduced travel-related costs, improved adherence, and enhanced continuity of care [5]. Recent evidence indicates that telerehabilitation may have a positive role in supporting physical activity and functional outcomes among older adults. For example, a systematic review and meta-analysis of telerehabilitation-delivered exercise interventions for older adults with frailty, cognitive impairment, or mobility disability reported improvements in mobility, muscle strength, and balance [6]. Similarly, a recent meta-analysis of digital interventions for frail older adults found reductions in frailty scores and improvements in grip strength and health-related quality of life [7]. This evidence suggests that telerehabilitation may be a useful alternative or complement to in-person rehabilitation for diverse populations, including frail older adults and others with limited mobility [1,8]. However, its implementation remains constrained by several challenges, including limited digital literacy, difficulties in conducting physical assessments remotely, and insufficient training opportunities for clinicians [3]. Because telerehabilitation was initially adopted rapidly in response to urgent service needs, evidence regarding how to deliver client-centered rehabilitation in remote contexts remains limited [3].

Among the core processes of client-centered rehabilitation, reaching an agreement on goals and tasks is a central element of the therapeutic alliance that requires complex adaptations during the transition from in-person to remote service delivery [9]. Both client-centeredness and the therapeutic alliance are considered beneficial for rehabilitation: a stronger therapist-patient alliance has been associated with better outcomes in physical rehabilitation settings, including greater treatment adherence and satisfaction, improved physical function, and reduced depressive symptoms [10], and goal setting aligned with clients' own priorities may improve engagement, motivation, and psychosocial outcomes such as self-efficacy [11]. Goal setting is widely regarded as essential to client-centered practice [11]. It helps establish priorities, guide intervention, and align rehabilitation efforts with what matters most to clients in their everyday lives [12,13]. In principle, rehabilitation goal setting should be client-centered and involve shared decision-making; however, previous research suggests that this is not always achieved consistently in routine practice [13,14]. When therapists and clients meet in person, goal setting is typically informed by clinical observation, physical assessment, and nonverbal communication [15], and is supported by embodied interaction where meaning and goals are often co-constructed and confirmed through physical guidance and felt bodily changes [16]. In telerehabilitation, these elements are constrained, as physical distance and technology alter nonverbal communication and eliminate hands-on interaction. Although technology may support goal setting through functions such as monitoring, feedback, and communication, this does not in itself explain how goal setting is actually carried out in remote rehabilitation encounters [12,17]. A recent scoping review identified a range of goal-setting tools used in adult rehabilitation, yet highlighted limited evidence regarding their design or validation for remote use [12]. Another scoping review focusing specifically on telerehabilitation and goal setting identified 68 studies, but none were conducted in East Asian countries, including Japan [17]. Goal setting and shared decision-making within remotely delivered rehabilitation have begun to attract attention elsewhere, for example, among older adults starting mobile health cardiac rehabilitation in the United States [18] and in a trial of decision aid-supported shared decision-making within hybrid in-person and virtual pulmonary rehabilitation in China [19]; however, no qualitative study has examined therapists' experiences of goal setting in telerehabilitation in East Asia, including Japan. Examining how goal setting is experienced in telerehabilitation is therefore important, particularly in settings where it is not yet routine, as the challenges and adaptations of early implementation can become less visible once remote practice is normalized and embedded within established workflows.

Japanese Rehabilitation Context

In Japan, goal setting in rehabilitation continues to be strongly influenced by traditional medical-model and clinician-led approaches [20]. This has prompted ongoing discussion about how goal-setting practices can become more collaborative and client-centered [14]. A cross-sectional study involving clients and occupational therapists in Japan found that, although both groups reported high levels of client engagement in the goal-setting process, nearly 80% of goal statements were mismatched between occupational therapists and their clients [13]. This finding suggests that even when both parties perceive goal setting as collaborative, their understandings of the goals may not necessarily be aligned, highlighting the need for higher-quality goal-setting practices [13]. This may also reflect culturally specific factors, as rehabilitation in Japan still tends to focus predominantly on functional training rather than activity- and participation-level goals aligned with what is personally meaningful to the individual [21]. Consistent with this, a recent qualitative study on goal setting in home rehabilitation in Japan highlighted the need for more explicit explanation and more collaborative approaches tailored to the Japanese context [21].

Japan's rapidly aging population and geographic challenges point to the potential value of telerehabilitation for improving access to rehabilitation, particularly for people with mobility limitations, including frail older adults [1,22]. Regional disparities in rehabilitation provision continue to create uneven access across the country [23-25], and in this context,

XSL•FO
RenderX

telerehabilitation may be particularly relevant. Recent studies have reported improvements in balance, gait, and lower-limb strength following remotely delivered exercise programs for pre-frail and frail older adults [26], and a pilot study in Japan found improvements in health-related quality of life after a multiuser telerehabilitation exercise intervention for older adults with frailty [27]. However, the uptake of telerehabilitation in Japan remains limited compared with some other countries, partly because of regulatory and reimbursement constraints, and remote rehabilitation may represent a particularly significant shift in practice for Japanese therapists [20,28,29]. At the time of this study, telerehabilitation in Japan was not yet routine practice: it was typically introduced when in-person care was difficult or impossible, for example, during the COVID-19 pandemic, after hospital discharge, or in geographically underserved areas, and it was largely delivered outside standard reimbursement schemes [28,29]. The experiences examined in this study should therefore be understood against this backdrop of early, often improvised, adoption.

Study Aim

Considering these contextual factors, it is important to understand how therapists in Japan experience the delivery of telerehabilitation, including the goal-setting process. Such knowledge may help identify research priorities, inform clinical training, and support policy discussions on reimbursement and service delivery. Because telerehabilitation was not yet routine in Japan when these data were collected, therapists' accounts of this period can document challenges and adaptations that may become less visible once remote practice is normalized. Therefore, this qualitative study aimed to explore how Japanese occupational therapists and physical therapists experienced negotiating and adapting rehabilitation goals when delivering telerehabilitation across a range of clinical settings in Japan, including how remote delivery shaped assessment, collaboration, and the purposes assigned to goals. Because goal setting is embedded within the broader flow of remote practice, therapists' wider experiences of telerehabilitation were also explored to the extent that they shaped how goals were identified, negotiated, and followed up. To obtain a broad understanding that can inform future research, participants were not limited by practice setting or target population.

Methods

Study Design

This study used a qualitative descriptive design informed by reflexive thematic analysis (RTA), following the 6-phase approach articulated by Braun and Clarke [30,31]. Consistent with RTA, the study was positioned within a contextualist epistemology, which acknowledges that participants' accounts reflect situated experience shaped by cultural, institutional, and interpersonal contexts, and treats the researcher as the analytic instrument through which meaning is constructed rather than discovered [30-32]. Reporting was guided by the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1) [33]. A reflexive thematic approach was selected because the study aimed to explore the experiences, perceptions, and meanings that therapists ascribed to remote goal setting in rehabilitation practice.

Ethical Considerations

Ethical approval for this study was obtained from the Ethics Committee of the Graduate School of Biomedical Sciences (Health Sciences), Nagasaki University (approval number: 22041401). All participants provided written informed consent before participation: each participant received a written information sheet by email as part of the study invitation (see Participants and Recruitment), and signed consent forms were returned by post, with the original forms stored securely at the second author's institution. Participants were informed that participation was entirely voluntary and that consent could be withdrawn at any time without disadvantage. Participants did not receive financial or other compensation for taking part in this study. Interviews were conducted in Japanese and transcribed verbatim. Participant anonymity was protected through the use of identification codes, and all direct identifiers were removed from transcripts. Video recordings and study data were stored securely and will be retained for 5 years in accordance with institutional policy.

Research Team and Reflexivity

The research team comprised 3 authors. The first author (YO) is a male occupational therapist holding BExSc(Hons) and MOT (Master of Occupational Therapy) qualifications at the time of the study, with clinical experience in Australia and formal training in qualitative research through doctoral study; YO conducted all interviews and led the analysis. YO had a research interest in client-centered practice and telerehabilitation prior to the study and approached telerehabilitation as promising but underevidenced in Japanese practice. The second author (KT) is an occupational therapist and university-based researcher with expertise in collaborative goal-setting tools and client-centered practice in Japan; KT contributed to study design, interview guide development, and analytic oversight. The third author (MO) is a physical therapist and university-based researcher with expertise in rehabilitation science in Japan; MO contributed to study design, participant recruitment, and analytic supervision. None of the authors had a prior clinical relationship with the participants at the time of interview; however, several participants were known to the authors through prior professional contact or professional-network introductions, and this was disclosed and discussed in team meetings as part of reflexivity. An audit trail of the sequential analytic process was maintained in a separate document, documenting initial analysis, integration of initial analysis, initial theme generation, and final theme development with illustrative quotes [34]. These materials were shared with all authors for review and discussion [34,35]. Consistent with RTA, interpretation was recognized as shaped by researcher subjectivity and not expected to be identical across researchers; team discussions were used to challenge interpretations, refine thematic boundaries, and strengthen the coherence, credibility, and acceptability of the final thematic structure [35,36].

XSL•FO
RenderX

Participants and Recruitment

Participants were recruited using purposive and snowball sampling to identify therapists with direct experience of remote goal setting in rehabilitation practice [37,38]. For the purposes of this study, remote goal setting was defined broadly to include remote discussions of clients' needs, priorities, and goals that informed rehabilitation planning. Licensed physical therapists and occupational therapists practicing in Japan who had experience with remote goal setting were eligible to participate. No additional exclusion criteria were applied.

Potential participants were identified through the professional networks of the research team and through participant referral. Each potential participant was contacted individually by email with an explanation of the study purpose and an invitation to take part. Each participant worked at a different organization; no two participants were employed at the same workplace at the time of the interview. This was a deliberate consequence of the sampling strategy and reduces the likelihood that the themes constructed reflect a single institutional culture. Participants were drawn from both metropolitan areas (eg, Tokyo) and regional areas of Japan (including Hokkaido and Nagasaki) and worked across a variety of settings, including hospital-based services, private practices, and community-based services. Information on participants' clinical setting and the geographic location of their practice was identified from interview content during the familiarization phase of analysis and recorded in the audit trail; this level of demographic information was not captured in the structured online questionnaire. For one participant (Participant 8), the region of practice could not be confirmed from these sources and is therefore not reported in Table 1.

Table . Participant characteristics (N=9)[a].

ID	Profession; sex; age (years)	Experience, years (remote)	Remote practice context	Region
P1	OT; male; 34	12 (<1)	Adults (19-65 years); hospital; neuromuscular disorders	Kanto
P2	OT; male; 38	16 (1)	Children (0 - 18 years); community; neurodevelopmental disorders	Hokkaido
P3	PT; male; 29	8 (6)	Adults (19-65 years); private practice; musculoskeletal conditions	Kanto
P4	PT; male; 42	21 (1)	Older adults (65+ years); hospital; musculoskeletal conditions	Kyushu
P5	OT; male; 39	17 (7[b])	Adults (19-65 years); community; psychosocial disabilities	Kansai
P6	OT; male; 37	14 (3)	Children (0 - 18 years); academic; neurodevelopmental disorders	Chubu
P7	OT; female; 41	19 (1)	Older adults (65+ years); hospital; musculoskeletal and neuromuscular conditions	Hokkaido
P8	OT; male; 43	19 (1)	Children (0 - 18 years); community; musculoskeletal and neuromuscular conditions	Not reported[c]
P9	OT; female; 31	12 (1)	Children (0 - 18 years); community; neurodevelopmental disorders	Kanto

[a]OT: occupational therapist; PT: physical therapist. Experience is reported as total years of therapist experience, with years of remote service experience in parentheses. Region indicates the broad geographic region of Japan in which the participant practiced, reported at this level to protect participant anonymity: Kanto (eastern Honshu, including the Greater Tokyo area), Chubu (central Honshu), Kansai (western Honshu, including Osaka and Kyoto), Kyushu (the southwestern main island, including Nagasaki), and Hokkaido (the northernmost main island).

[b]Approximately 7 years, with infrequent use.

[c]The region of practice for this participant could not be confirmed from the interview or questionnaire data and is therefore not reported.

Sample size was guided by the concept of information power rather than by a predetermined target or data saturation [39]. Applying Malterud and colleagues' [39] five criteria, we judged that the sample could support the study aim on the basis of (1) a narrow and focused aim (therapists' experiences of remote goal setting); (2) dense specificity of participants (licensed, experienced therapists with direct remote goal-setting experience, drawn from 9 workplaces across metropolitan and regional Japan and a variety of clinical settings); (3) an established conceptual grounding in client-centered goal setting;

XSL•FO
RenderX

(4) focused semistructured interviews conducted by a trained qualitative interviewer using a flexibly applied topic guide (see Data Collection); and (5) a cross-case, theme-oriented analytic strategy. Information power offers a structured basis for judgment rather than a guarantee of completeness, and the uncertainty inherent in this judgment is acknowledged in the Strengths and Limitations section.

Participant Characteristics

Nine therapists participated in the study, including 7 occupational therapists and 2 physical therapists. Of these, 7 were male and 2 were female. Participant ages ranged from 29 to 43 years, and years of therapist experience ranged from 8 to 21 years. Experience with remote service delivery ranged from less than 1 year to approximately 7 years. Participants had experience providing remote services to children, adults, and older adults across a range of clinical areas, including neurodevelopmental disorders in children, musculoskeletal disorders or injuries, neuromuscular disorders, and other conditions. Detailed participant characteristics are presented in Table 1.

Participants delivered remote services mainly by videoconference. Consistent with the early-adoption context described in the Introduction, they had typically introduced remote delivery when in-person care was difficult or impossible, for example, during pandemic-related service disruption, after hospital discharge, or for clients in geographically underserved areas. The frequency and duration of remote sessions were not collected systematically in the questionnaire; the following patterns were identified from interview content during the familiarization phase. Remote service formats were heterogeneous: they ranged from brief, repeated contacts of about 10-30 minutes to sessions of about an hour, delivered at rhythms from weekly to monthly, and several participants combined scheduled video sessions with asynchronous contact between sessions, such as email, messaging applications, activity diaries, and videos recorded and submitted by family members. Examples included weekly 30-40-minute videoconference sessions continuing a hospital program after discharge; a 3-month package of 5 video consultations (an initial 40-minute goal-setting session followed by 20-minute follow-ups) supplemented by unrestricted text chat; and regular 15‐30-minute video calls that complemented, rather than replaced, in-person visits. Because no standardized comparison with usual in-person schedules was collected, the study does not infer that remote delivery itself shortened sessions or changed their frequency.

Data Collection

Semistructured interviews were conducted individually via Zoom videoconference between September and October 2022. Interviews lasted between 18 and 51 minutes, with a mean duration of 32 minutes. Zoom was selected for its ease of use, cost-effectiveness, data management capabilities, and security features, which have been positively appraised in prior qualitative research [40]; known limitations of videoconferencing in qualitative research (eg, technical issues and partial loss of nonverbal cues) were considered acceptable given the nature of the study topic. The interview guide (Multimedia Appendix 1) was developed iteratively by the research team and included open-ended questions about therapists' experiences before, during, and after remote goal-setting encounters, including perceived advantages and barriers, adaptation strategies, and impacts on the therapeutic relationship. The guide was used flexibly rather than as a fixed script: questions served as points of departure for a conversation around each topic, the order of questions varied with the flow of each interview, and follow-up probes were used to invite elaboration, while the interviewer ensured that all topic areas were covered in every interview. The interview guide was not formally pilot tested; however, it was reviewed and refined through team discussion among the coauthors, who have established expertise in qualitative research methods and in rehabilitation goal setting. All interviews were video-recorded with participants' permission. No one other than the interviewer and the participant was present during the interviews, and no repeat interviews were conducted; each participant was interviewed once. Formal field notes were not maintained during or immediately after data collection. Instead, the interviewer (YO) reviewed each video recording in full against the corresponding transcript on multiple occasions during the familiarization phase and recorded reflective observations and interpretive notes in the audit trail. For example, notes made during theme development recorded that therapists repeatedly described relying on partial or secondhand information (eg, answers relayed only as "probably..."), and these notes informed the interpretation, developed in theme 1, that remote delivery reduced therapists' confidence in their clinical judgments.

Transcripts were produced in Japanese using AI-assisted first-pass transcription (Notta), after which YO manually reviewed each recording in full and corrected any errors against the audio and video. Analysis was conducted on the original Japanese transcripts to preserve contextual and cultural meaning. Illustrative quotations presented in this manuscript were translated from Japanese into English with the assistance of generative AI tools as a first-pass aid (see the Acknowledgments section), and were subsequently reviewed and corrected by the corresponding author (YO), a native Japanese speaker fluent in English, against the original Japanese audio and transcripts. Where culturally specific expressions had no direct English equivalent, the translation prioritized conceptual meaning over literal rendering, with the source Japanese preserved in the audit trail for transparency. Demographic and professional background information was collected through a brief online questionnaire covering profession, age, years of therapist experience, years of remote service experience, client age groups served, and broad diagnostic areas served remotely.

Data Analysis

Data were analyzed using RTA as articulated by Braun and Clarke [30,31]. The analysis was primarily inductive and data-driven, and no predetermined coding framework was applied. Coding stayed close to the explicit, semantic content of participants' accounts; more interpretive analysis was introduced in the later phases, for example, when accounts of hesitancy and reduced confidence were interpreted together as a disruption of professional certainty (theme 1). The reflective observations and interpretive notes described above contributed

XSL•FO
RenderX

to this interpretive work. YO led all analytic phases. In phase 1 (familiarization), YO read each transcript repeatedly while checking it against the interview recordings. In phase 2 (initial coding), YO generated codes across the dataset, primarily at the semantic level. In phase 3 (candidate theme generation), codes were grouped to identify broader patterns of meaning and construct candidate themes. In phase 4 (theme review), candidate themes were reviewed against both the coded extracts and the full dataset for internal coherence and external distinctiveness. In phase 5 (theme definition and naming), themes were refined and named to capture the central organizing concept of each. In phase 6 (report production), the analytic narrative was developed by selecting illustrative quotations and relating the final themes back to the study aim [41]. Analytic materials were shared with all authors throughout the process; discussions were used to challenge interpretations and refine thematic boundaries rather than to establish coder agreement, consistent with RTA. Data were managed using Microsoft Excel and Microsoft Word; no dedicated qualitative data analysis software was used, as the dataset comprised 9 transcripts and the audit trail was maintained in a shared spreadsheet that all authors could access directly, preserving the traceability of coding decisions.

Rigor and Trustworthiness

Trustworthiness was addressed through the criteria of credibility, transferability, dependability, and confirmability, following Nowell and colleagues' [42] application of these criteria to thematic analysis. Credibility refers to the confidence that can be placed in the fit between participants' accounts and the researchers' representation of them. Credibility was strengthened through prolonged engagement with the data, including repeated reading of transcripts alongside audio recordings, collaborative analytic discussions among the 3 authors, attention to divergent and less common cases, and retention of the original Japanese data alongside English translations [33,35]. Transferability refers to the extent to which findings may be applicable in other settings, which readers can judge only if the study context is described in sufficient detail. Transferability was supported by detailed reporting of the study setting, participant characteristics, and analytic decisions, as presented in Table 1 and the Methods section [33]. Dependability refers to whether the research process is logical, traceable, and clearly documented. Dependability was enhanced through an audit trail documenting analytic decisions across the 6 phases of analysis, maintained in a shared spreadsheet [34]. Confirmability refers to the demonstration that interpretations are clearly derived from the data rather than from researcher predisposition alone. Confirmability was supported by this audit trail, team review of the links between data extracts and final themes, and reflexive consideration of the research team's positioning, as described in the Research Team and Reflexivity section [34,35]. Participant transcript review, or member checking, was not undertaken. This decision was consistent with the study's contextualist stance, which treats meaning as co-constructed through the analytic process rather than as something to be verified retrospectively by participants [31,35].

Results

Overview

Four themes were constructed that described therapists' experiences of remote goal setting in rehabilitation: (1) losing touch: uncertainty in remote assessment and goal setting; (2) from direct intervention to coaching-oriented goal setting; (3) at home, at ease: needs that surface in clients' own environments; and (4) when continuity becomes the goal. Each theme is described in turn below, and the relationships among the themes are then summarized. Table 2 summarizes each theme and the number of participants whose accounts contributed to it. Within-theme variation was retained in the analysis through close attention to less prominent perspectives and is reflected in the selection of quotations across participants; no minor themes or divergent cases inconsistent with the 4 main themes were identified that warranted construction as a separate theme.

Table . Themes, central organizing concepts, and participant contributions (N=9)[a].

Theme	Central organizing concept	Participants contributing (n/9)
1. Losing touch: uncertainty in remote assessment and goal setting	Loss of embodied and contextual information disrupts clinical certainty.	9/9
2. From direct intervention to coaching-oriented goal setting	Remote constraints prompt a shift from provider to facilitator/coach.	8/9
3. At home, at ease: needs that surface in clients' own environments	Home-based interaction puts clients at ease and discloses context and needs less visibility in clinic settings.	6/9
4. When continuity becomes the goal	Goals are reoriented toward continuity through ongoing monitoring, structured follow-up, and prevention of decline.	6/9

[a]Counts are based on at least one substantive contribution to the theme; counts do not imply quantification of prevalence.

Theme 1: Losing Touch: Uncertainty in Remote Assessment and Goal Setting

The first theme captured therapists' experiences of uncertainty in assessment and goal setting when working remotely. All 9 participants described how the inability to physically touch clients and the reduced access to nonverbal and contextual information limited their confidence in understanding clients' conditions, needs, and priorities. In this study, "reduced visibility" did not mean that clients' homes were invisible;

XSL•FO
RenderX

rather, what therapists could see was restricted to the fragment of the environment and the body captured within the camera frame, shaped by camera angle, device placement, connection quality, and what the client or another person was able or willing to show. Unlike an in-person encounter, in which therapists could walk around, change their vantage point, and observe the whole body and setting, remote observation was partial and fixed. Therapists highlighted limitations in physical assessment and intervention, particularly in situations in which whole-body observation or hands-on assessment would normally inform clinical reasoning. One therapist stated, "It is difficult to understand everyday life scenes remotely...it is hard to picture daily life, or to imagine the actual situation just by listening" [Occupational therapist, participant 9]. Another reflected on the limits of remote postural assessment, explaining that a client's sitting posture might look acceptable during a brief observation on screen but deteriorate over a longer period, something that could be detected only through sustained in-person observation: "With postural adjustment, there are aspects you only understand if you take time. It may seem to be going well in the moment, but posture can collapse over time, so you really need to observe it in person to know" [Occupational therapist, participant 8].

Therapists mentioned difficulty interpreting pauses, atmosphere, and other nonverbal features of interaction that would typically shape in-person communication. In addition, some felt constrained by having to depend on information mediated through third parties. In the Japanese service contexts described by participants, these third parties included, for older clients, care managers (care coordinators who arrange services under Japan's long-term care insurance system) and visiting care staff, and, for children, parents and teachers who acted as the child's spokespersons in remote consultations. Information about the client's wishes then reached the therapist secondhand, already filtered through another person's interpretation. This limited their ability to directly understand clients' perspectives and the reasons underlying their preferences and behaviors. One therapist, who was supporting an older client with Parkinson disease, received information about the client's wishes mainly through the care manager and care staff involved in the client's daily care. She found that these relayed answers were often vague, which made it difficult to identify acceptable alternatives to the client's stated wish. She explained, "I want to know why they want to do it that way, their particular preference, or their true feelings. Without that...it would really have been better if I could have directly asked the person themselves" [Occupational therapist, participant 7].

These accounts described more than practical inconvenience. Without touch and whole-body observation, assessments that would ordinarily feel routine became tentative, therapists made proposals by inference from secondhand information, and one therapist noted that whether a suggestion had worked often became clear only at the following session. In their accounts, information that therapists usually gather through vision, touch, and the atmosphere of an encounter had supported the confidence of their goal setting. Remote goal setting therefore involved interpretive uncertainty: a reduction in therapists' professional certainty that they worked to manage through the adaptations described in the following themes.

Theme 2: From Direct Intervention to Coaching-Oriented Goal Setting

The second theme, reported by 8 of the 9 participants, reflected a shift in therapists' roles from directly intervening in clients' bodies and activities to supporting goal setting through coaching. In this theme, "coaching-oriented" refers to the interactional role therapists adopted: facilitating clients' reflection, self-monitoring, and problem-solving rather than delivering hands-on intervention. It is related to, but not the same as, client-centeredness (see Introduction): client-centeredness concerns whose priorities guide care, whereas coaching describes how therapists worked with clients when hands-on guidance was unavailable. For these therapists, coaching became a principal means of conducting client-centered goal setting remotely. Therapists described compensating for the limitations of remote care by gathering information in advance, using visual materials, and encouraging clients and family members to take a more active role in implementing strategies in daily life. Rather than positioning themselves primarily as direct providers of intervention, therapists described working more as partners who facilitated reflection, supported self-monitoring, and collaboratively developed practical strategies with clients and families.

Several therapists reported using self-monitoring tools, including pedometers and check sheets, to monitor clients' physical activity levels and daily routines between sessions. Remote sessions gave therapists only a brief and delayed view of clients' daily lives, and self-monitoring tools extended assessment and goal setting beyond the session itself: they supported clients' reflection on their activity patterns and gave therapists more structured information about clients' everyday activities, which informed subsequent goal-setting discussions. For example, one hospital-based therapist reviewed a weekly step count from a loaned pedometer with each client and negotiated a graded target for the following week. Notably, several therapists described these strategies not merely as substitutes for in-person methods but as improvements they valued in their own right: one explained that in conventional practice his advice would have ended in the session, whereas the online tools allowed him to follow clients' behavior change between sessions, and another described slide-supported goal setting as something good "in its own way" that was unique to remote delivery.

Others used visual materials, including slide summaries and submitted videos, to overcome what they described as the limitations of verbal communication alone. One therapist, who had noticed in earlier group-based remote sessions that sharing slides on screen helped conversations run smoothly, applied this to individual goal setting with a young school-aged client: rating cards from a goal-setting tool were embedded in the slides, and the client's own words were typed into the slides during the session and summarized visually, so that therapist and client were, in effect, looking at a shared record of the conversation as it developed: "I input the client's narrative directly into the slides and summarised it for them, and by doing that, the conversation became smoother" [Occupational therapist, participant 6]. Physical activities such as skipping rope and using a horizontal bar could not be practiced live through the screen, so the same therapist treated them as a home

program: the online sessions were used to agree on practical strategies the child would try at home, the parent recorded videos of the practice and sent them for monitoring, and the child reported back at the next session on which strategies had worked: "When practising tasks at home on a task-based approach, we discussed online what kinds of strategies could be used" [Occupational therapist, participant 6].

Family members and other supporters occupied a distinctive position in these remote encounters. Particularly for children, a parent or teacher was often physically present with the client while the therapist was not: they operated the device, recorded and sent videos, and carried out with the client the activities that the therapist would ordinarily have demonstrated in person. Therapists therefore had to put into words, and coach others through, actions they would normally have shown directly; as one therapist described, instead of demonstrating a technique and gradually fading support, she had to verbalize it for the mother to understand and carry out, which she found demanding. These arrangements created new demands, but they also distributed ownership of implementation across the therapist, the client, and the people around them. These adaptations nevertheless appeared to support a more collaborative form of goal setting, in which clients and families were encouraged to identify and monitor problems in their own daily lives. One therapist supported a middle-aged client who had returned to work following a neuromuscular condition and who completed an occupational balance check sheet several times a week and emailed it to him between weekly video sessions; the sheet gave the client herself a structured way of noticing and reporting what mattered: "Because they filled in the occupational balance check sheet, they always told me or reported what they, as the person concerned, thought was a problem that week" [Occupational therapist, participant 1].

Theme 3: At Home, at Ease: Needs That Surface in Clients' Own Environments

The third theme, raised by 6 of the 9 participants, described how remote sessions conducted in clients' own living environments changed the goal-setting encounter in 2 intertwined ways: clients often appeared more at ease, and their everyday needs and circumstances became more visible to therapists. Therapists suggested that remote rehabilitation was not only a way of overcoming physical distance, but also a way of shifting the interaction from the clinician's setting to the client's own space. This appeared to allow clients to participate in a more relaxed and natural manner and enabled therapists to observe aspects of clients' everyday environments that were not readily available in clinic-based encounters. Therapists described how being at home could reduce tension and make it easier for clients to disclose concerns and preferences. One therapist, whose clients often joined video consultations while working from home, noted, "Because the user could participate in a relaxed state, I felt as a therapist that it was easier to draw out their needs in a more natural way" [Physical therapist, participant 3]. Everyday remote contact could also create natural openings for goal-related conversation. Another therapist, who kept in regular video contact with a community-dwelling client, described how casual exchanges about the previous evening became shared topics that could be raised naturally in later sessions, weaving needs identification into ordinary conversation rather than formal questioning [Occupational therapist, participant 5].

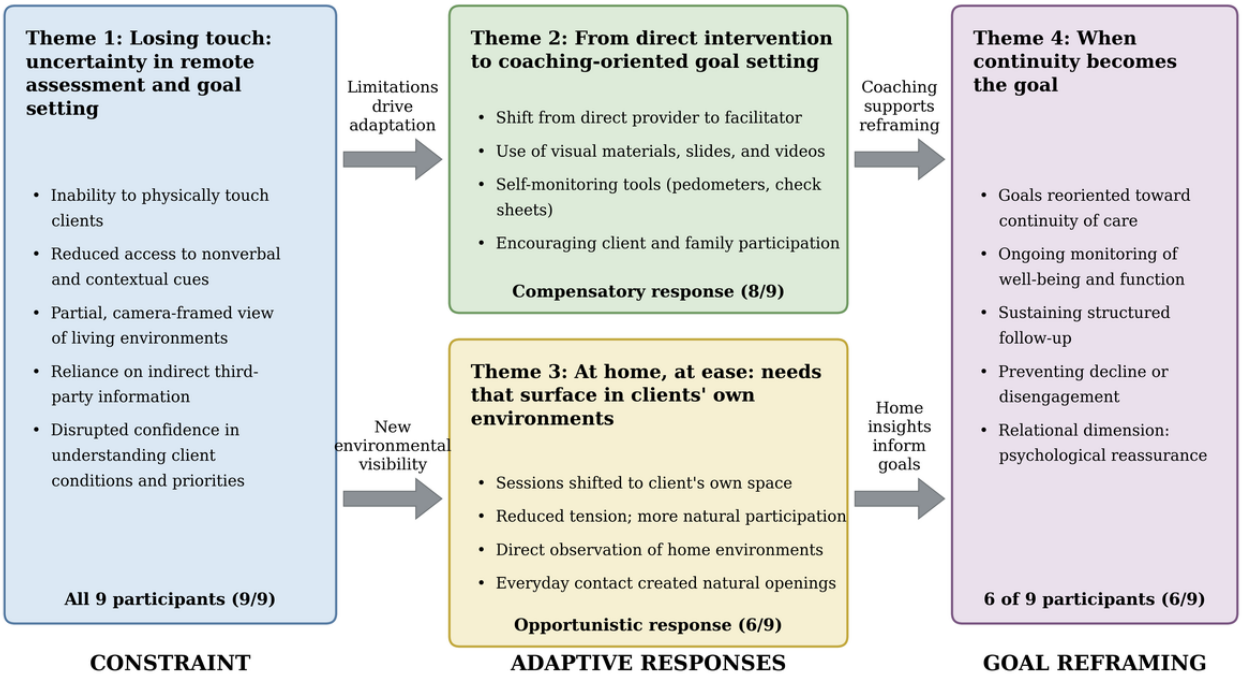
Therapists also reported that remote sessions allowed them to directly observe everyday environments, such as desk setups, room layouts, and family situations, which supported more concrete assessment and goal setting. As one participant stated, "You can also see the desk environment here, and even the family situation is visible, so based on that, we can immediately check things and assess them" [Physical therapist, participant 3]. These accounts suggest that remote care sometimes enabled therapists to identify needs and priorities that may have been less visible in institutional settings. This visibility was of a different kind from the reduced visibility described in theme 1: relative to hands-on, whole-body assessment, remote observation remained partial, but relative to clinic-based encounters, in which the home is available only through the client's description, the video call brought therapists directly into contact with the client's everyday world.

Theme 4: When Continuity Becomes the Goal

The fourth theme, articulated most explicitly by 6 of the 9 participants, concerned a shift in how therapists conceptualized the goals of rehabilitation in remote contexts. Faced with disrupted service access during the pandemic and with ongoing geographical or systemic barriers, therapists described reorienting goals away from functional improvement alone and toward maintaining continuity, ongoing monitoring of well-being, functional status, and daily engagement. Remote rehabilitation was often positioned as a means of sustaining structured follow-up and preventing decline or disengagement from services, rather than as a direct substitute for intensive physical intervention. In some cases, this monitoring function also carried an important relational dimension, as regular remote contact provided psychological reassurance and helped prevent social isolation. Some emphasized the importance of continuity across service transitions and the potential for remote follow-up to support self-management, including pain management. One hospital-based therapist, whose older clients returned to rural areas with limited transport after discharge, continued the hospital's activity program through weekly video sessions and described the rationale for this follow-up: "By continuing the same kind of service remotely even after discharge, [we wondered] whether the onset of chronic pain could be prevented" [Physical therapist, participant 4]. He also noted that clients reported feeling reassured that support did not simply stop at discharge.

Others described the therapeutic value of remaining connected to clients over time. One therapist made regular evening video calls to a client with a psychosocial disability who had recently begun living alone and who was at risk of self-harm driven by loneliness and self-blame. He deliberately avoided making goals explicit with this client, because putting them into words risked drawing the client's attention to questions of life and death; instead, the everyday contact itself carried the therapeutic purpose, oriented toward the client feeling that their life had worth and that tomorrow was worth reaching: "Rather than putting it into words or things like that, what I wanted them to

XSL•FO
RenderX



feel was that it is okay to be alive. That became our goal, or rather our purpose" [Occupational therapist, participant 5]. A further participant, a pediatric therapist practicing in a region with many underserved communities who had heard of families relocating simply to access developmental services, emphasized equity of access, stating, "I wish people could receive services no matter where they live...I want to make sure that is guaranteed for them" [Occupational therapist, participant 2].

This reframing did not appear in therapists' accounts as an abandonment of functional goals. Therapists continued to pursue functional gains where feasible through coached self-management (theme 2), while the immediate purpose of the remote encounter became sustaining engagement, monitoring change, and preserving the therapeutic relationship until more intensive intervention was possible or necessary. Continuity was described as an interim, complementary, or sometimes intrinsically meaningful goal, consistent with a client-centered orientation. The accounts also marked a clinical boundary: goals requiring hands-on assessment or intervention could not be fully pursued remotely and required a hybrid or later in-person response. These accounts indicate that, in remote contexts, therapists sometimes redefined the purpose of goal setting to include ongoing monitoring, sustained support, and continuity of care.

Relationships Among Themes

We interpreted the 4 themes as interconnected rather than independent. In our reading of the data, the constraints described in theme 1 formed the background against which 2 adaptive responses were described: a compensatory shift toward coaching-oriented goal setting (theme 2) and a recognition of needs made visible in clients' home environments (theme 3). These responses, in turn, informed a broader reframing of the purpose of goal setting toward continuity and ongoing monitoring (theme 4). Figure 1 presents this interpretation of the relationships among the themes; it summarizes our analytic account rather than an observed temporal or causal sequence.

Figure 1. The authors' interpretation of the relationships among the four themes: constraint (theme 1), adaptive responses (themes 2 and 3), and goal reframing (theme 4).

Discussion

Principal Findings

In these therapists' accounts, remote goal setting changed both the information available for clinical judgment and the purposes assigned to rehabilitation goals; it was described as a distinct form of practice shaped by constraint and possibility rather than as a diminished copy of in-person goal setting. This study examined the goal-setting experiences of Japanese therapists who practiced telerehabilitation when remote service delivery was not yet routine, frequently under pandemic-related pressure. As summarized in Figure 1, the constraints described in theme 1 were met with 2 adaptive responses, a shift toward coaching-oriented practice (theme 2) and attention to needs visible in clients' home environments (theme 3), and these together informed a reframing of goals toward continuity and ongoing monitoring (theme 4). Reduced visibility and the inability to touch introduced uncertainty into assessment and interpretation, yet remote care also appeared to create opportunities for collaborative and contextually grounded goal setting. Our analysis suggests that the conduct of remote goal setting may depend on how telerehabilitation encounters are prepared, structured, and supported, and not on access to technology alone; this interpretation, derived from the present data, is consistent with the broader telehealth implementation literature [43,44]. This is relevant given the growing recognition of telerehabilitation as a means of supporting physical activity and preventing functional decline among populations with

XSL•FO
RenderX

limited access to conventional rehabilitation, including frail older adults [6,7].

Comparison With Prior Work

The first theme, losing touch, is broadly consistent with previous literature showing that telerehabilitation can limit physical assessment and reduce access to nonverbal and contextual cues [45,46]. However, this study extends that literature by suggesting that these constraints may be experienced not merely as practical barriers but as a disruption to therapists' professional certainty, as described in the final paragraph of theme 1. In other words, remote care appeared to introduce interpretive uncertainty, defined as uncertainty in making clinical sense of partial or mediated information, by reducing the embodied and contextual information on which therapists often rely, sometimes implicitly, to make sense of clients' needs, priorities, and readiness for goal setting [16,47]. In this sample, the challenge of remote goal setting was therefore not simply that it is "harder through a screen," but that it could alter the foundations of clinical reasoning and confidence in goal negotiation.

The second theme, from direct intervention to coaching-oriented goal setting, also aligns with prior work suggesting that telerehabilitation can shift therapists' roles from hands-on intervention toward facilitation, coaching, and collaborative problem-solving [48,49]. In the present study, therapists described using advanced information gathering, visual tools, and self-monitoring resources to compensate for the limits of remote interaction. In particular, pedometers and activity check sheets were used to monitor clients' physical activity between sessions. This aligns with recent evidence suggesting that wearable activity trackers and structured self-monitoring tools may contribute to improvements in physical function among frail older adults, although their effects on overall daily physical activity levels remain inconclusive [50,51]. These adaptations did not appear to function only as substitutes for in-person practice. Rather, they sometimes created a more co-constructed form of goal setting by encouraging clients and families to take a more active role in identifying priorities, monitoring difficulties, and implementing strategies in daily life. This connects directly to the calls, outlined in the Introduction, for more collaborative and client-centered goal setting in Japanese rehabilitation [13,14,21]: coaching, in these accounts, was the interactional form through which client-centered principles were enacted when hands-on guidance was unavailable. Coaching should not, however, be equated with client-centeredness: remote delivery does not automatically make practice client-centered, which continues to depend on clients genuinely owning and negotiating their goals. When adequately supported, the constraints of remote delivery may create opportunities for more participatory and, thereby, more client-centered, goal-setting practices.

The third theme, at home, at ease, highlights a potential advantage of remote care. Previous studies have suggested that, by situating rehabilitation within the client's everyday environment, telerehabilitation can make assessment and goal setting more closely reflect clients' actual daily lives [52,53]. The present findings add that the value of home-based interaction may lie in moving the encounter from the clinician's setting to the client's own space, as well as in observing the physical environment. Therapists perceived that clients were often more relaxed at home, and this appeared to make it easier for some clients to express concerns, preferences, and personally meaningful goals. In this sample, remote goal setting sometimes appeared to make everyday needs more visible both because parts of the home environment could be observed directly and because clients seemed more comfortable in their own surroundings [54].

The fourth theme, when continuity becomes the goal, suggests that the goals of rehabilitation may be repositioned in remote contexts. Rather than focusing solely on functional improvement, therapists described reorienting goals toward maintaining continuity through ongoing monitoring of well-being, functional status, and daily engagement. Remote rehabilitation was often positioned as a means of sustaining structured follow-up and preventing decline or disengagement from services. In some cases, this monitoring function also carried an important relational dimension, as regular remote contact provided psychological reassurance and helped prevent social isolation. This should not be interpreted as a retreat from rehabilitation goals, but rather as a clinically meaningful repositioning of goals under specific service constraints. Such a shift may be particularly relevant in chronic-condition management and longer-term community-based rehabilitation, where self-management, continuity, and therapeutic connection are often central to meaningful care [55,56]. In frailty management, this may be especially important, as sustained physical activity and ongoing monitoring are needed to help prevent further decline. Remote goal setting and digital tracking may provide a practical way to maintain therapeutic engagement and support regular activity beyond scheduled rehabilitation sessions [27,50,51].

Implications for Telerehabilitation Design, Implementation, and Practice

These findings have several implications for the design, implementation, and delivery of telerehabilitation. Remote delivery of rehabilitation, including its goal-setting component, should not be assumed to be suitable for every client, clinical purpose, or stage of care. Rather, decisions about when goal setting is conducted remotely, in person, or in combination need to consider client characteristics, family support, communication needs, home and service environments, and the type of clinical judgment required. The findings also suggest that remote goal setting benefits from structured preparation. Collection of videos, check sheets, or contextual information may help compensate for therapists' reduced access to embodied and situational cues; this implication is consistent with prior work on telehealth-based goal setting and goal management [57]. In this process, families and support persons may need to be positioned not simply as assistants, but as active collaborators whose roles and whose influence on the client's own voice are explicitly negotiated. Visual tools, self-monitoring resources, and shared documentation may also support shared understanding and continuity between sessions. For therapists, this suggests a need for telerehabilitation-specific training that extends beyond technical competence to include rapport-building, verbal coaching, collaborative goal negotiation,

XSL•FO
RenderX

and managing interpretive uncertainty; our findings align here with previous work on remote consultation skills [58].

The findings also support hybrid models in which remote goal setting is used selectively alongside in-person assessment or intervention. In-person review may remain important when hands-on assessment, detailed observation, or risk management is required: initial goal setting and physical assessment might take place in person, with goals then reviewed, monitored, and renegotiated remotely, and needs surfacing during remote sessions might prompt targeted in-person review. Because goal negotiation is an ongoing process embedded in the therapeutic alliance rather than a one-off event, hybrid delivery does not remove the need for remote goal-setting skills; it distributes goal-setting work across delivery modes according to clinical purpose. Organizations may therefore benefit from clear hybrid pathways that identify when remote goal setting is appropriate, what preparation is needed, and when in-person review should be prioritized.

Strengths and Limitations

A strength of this study is that it qualitatively examined remote goal setting from the perspective of rehabilitation therapists practicing in Japan, a context that has received limited attention in the telerehabilitation literature. Participants were recruited from 9 different workplaces across metropolitan and regional areas of Japan, including hospital-based, private-practice, and community-based services. This reduces the likelihood that the patterns identified reflect the practices or culture of a single institution and supports modest transferability to other Japanese rehabilitation settings. Another strength is that the study captured therapists' experiences across the phases before, during, and after remote goal-setting encounters. This enabled a broader understanding of how preparation, interaction, and follow-up shaped remote goal setting in practice. The analysis also identified not only barriers, but also potential advantages of remote goal setting, generating practical implications for service design and implementation.

The study also has limitations. The sample was small, included more occupational therapists (n=7) than physical therapists (n=2), and included more men (n=7) than women (n=2); the perspectives of physical therapists and of female therapists are therefore less fully represented, and the findings should not be read as a balanced account of Japanese rehabilitation practice. Although information power guided our judgment of the dataset, therapists who declined or were not reached may have experienced remote goal setting differently, and a different sample might have led to additional or different themes. The analysis is therefore presented as a contextually situated account of these 9 therapists' experiences rather than an exhaustive description of remote goal setting in Japan. The findings are based on retrospective self-report rather than observation of practice. Session frequency and appointment duration were not collected systematically, which limits comparison with in-person service schedules. Participants represented selected clinical areas and all had some telerehabilitation experience, which may limit transferability to other contexts or to therapists without such experience. The study did not include clients' or families' perspectives and therefore captures only one side of the goal-setting process. Microsoft Excel and Word provided a transparent audit trail but fewer automated retrieval and version-control functions than dedicated qualitative data analysis software. Finally, because the data were collected during the COVID-19 pandemic, some findings may reflect pandemic-related service disruption as well as more enduring features of telerehabilitation.

Future Research

Future research should examine remote goal setting from the perspectives of clients and families to better understand how shared understanding, comfort, participation, and collaboration are experienced across stakeholders. Further research is also needed on tools and supports designed specifically for remote goal setting, such as visual prompts, structured preparation tools, and shared documentation resources. Future studies should also evaluate hybrid models of goal setting that combine remote and in-person elements according to clinical purpose, client preference, and service context. Comparative research across health care systems and cultural contexts may help clarify how institutional, regulatory, and social factors shape remote goal setting in practice. Finally, while some implications of the present findings may be relevant to chronic-condition management and long-term community-based rehabilitation, further research is needed to examine whether similar patterns are observed across other rehabilitation populations and service models.

Conclusions

This qualitative study showed that therapists experienced remote goal setting as both constraining and enabling. Reduced visibility and the inability to touch created uncertainty in assessment and interpretation, yet remote encounters also supported new forms of collaboration, greater visibility of clients' everyday contexts, and a reorientation of goals toward continuity and ongoing monitoring. Remote goal setting should therefore not be viewed simply as a lesser version of in-person rehabilitation. Rather, it represents a distinct form of practice that requires its own clinical reasoning, communication strategies, and implementation supports.

Acknowledgments

The authors thank all participating therapists for their time and candor, and the colleagues in their professional networks who supported recruitment.

AI-assisted transcription tools (Notta) were used for the first-pass transcription of interview audio, after which all transcripts were reviewed and corrected manually by the first author against the original recordings. After the four themes had been constructed by the authors from the Japanese transcripts, generative AI tools (ChatGPT, OpenAI; Claude, Anthropic) were used in three

Abstract

Background: Demographic and epidemiological changes are increasing pressure on health and long-term care systems, underscoring the need for digital innovations. Remote Care Assist is a digital system that enables home care staff to connect with care experts for exchange and support via real-time video calls. Although technology acceptance is crucial for successful implementation, little is known about how care staff's expected benefits for care recipients influence acceptance in professional home care.

Objective: This study examined predictors of user acceptance of the Remote Care Assist among home care staff, with a particular focus on the role of staff's expectations of benefits for home care service users.

Methods: Technology acceptance data were collected from staff in home care organizations in Austria and Luxembourg. Among 337 survey respondents, 139 participants who reported using Remote Care Assist at least once per month over a period of 5-6.5 months were included in the acceptance analysis (45 care experts and 94 on-site care staff). Partial least squares structural equation modeling was used to test a contextualized technology acceptance model.

Results: Technology acceptance was measured by "Behavioral Intention to Use" the Remote Care Assist. "Behavioral Intention to Use" was positively associated with "Expected Benefit for Home Care Service Users" (EBC; β=0.506, 95% CI 0.364 to 0.658; *P*<.001), "Perceived Usefulness (PU)" for care staff (β=0.314, 95% CI 0.151 to 0.460; *P*<.001), and "Perceived Ease of Use" (PEOU; β=0.130, 95% CI 0.038 to 0.231; *P*=.01). "EBC" (β=0.415, 95% CI 0.276 to 0.537; *P*<.001), "Perceived Efficiency" (β=0.396, 95% CI 0.267 to 0.531; *P*<.001), and "PEOU" (β=0.170, 95% CI 0.083 to 0.266; *P*=.001) were positively associated with "PU" for care staff. "PU" also positively mediated the associations of "EBC" (β=0.130, 95% CI 0.061 to 0.194; *P*=.001) and "PEOU" (β=0.053, 95% CI 0.017 to 0.101; *P*=.02) with "Behavioral Intention to Use." "Reliable Functionality" was not significantly associated with "PU."

Conclusions: This study suggests that the technology acceptance of a digital system for enhancing professional exchange between different staff groups in home care is shaped not only by established predictors of acceptance, such as PU and PEOU, but also by a currently neglected predictor, namely care staff's expectations that the technology will benefit home care service users, which plays an important role in technology acceptance. In addition to usability and workflow support, successful implementation strategies for digital technologies should clearly communicate the technology's potential benefits for care staff, care service users, and the broader care ecosystem.

Introduction

Background

The rapid proliferation of digital communication technologies has transformed a number of sectors, with the COVID-19 pandemic accelerating this trend [1]. Although the health care sector is no exception, it has been slower to adopt digital solutions compared to other sectors, such as banking and general insurance [2]. Electronic documentation, for example, has been rolled out later and more slowly [3]. Even within the health care sector, the adoption of digital technologies varies greatly, with long-term care lagging further behind than acute care. In particular, implementing new digital apps in home care settings poses challenges, such as limited time and financial resources [4,5], concerns regarding data security and privacy [6], and resistance or lack of acceptance among care staff. These barriers underscore the importance of designing and evaluating telecare technologies that fit the needs of home care practice.

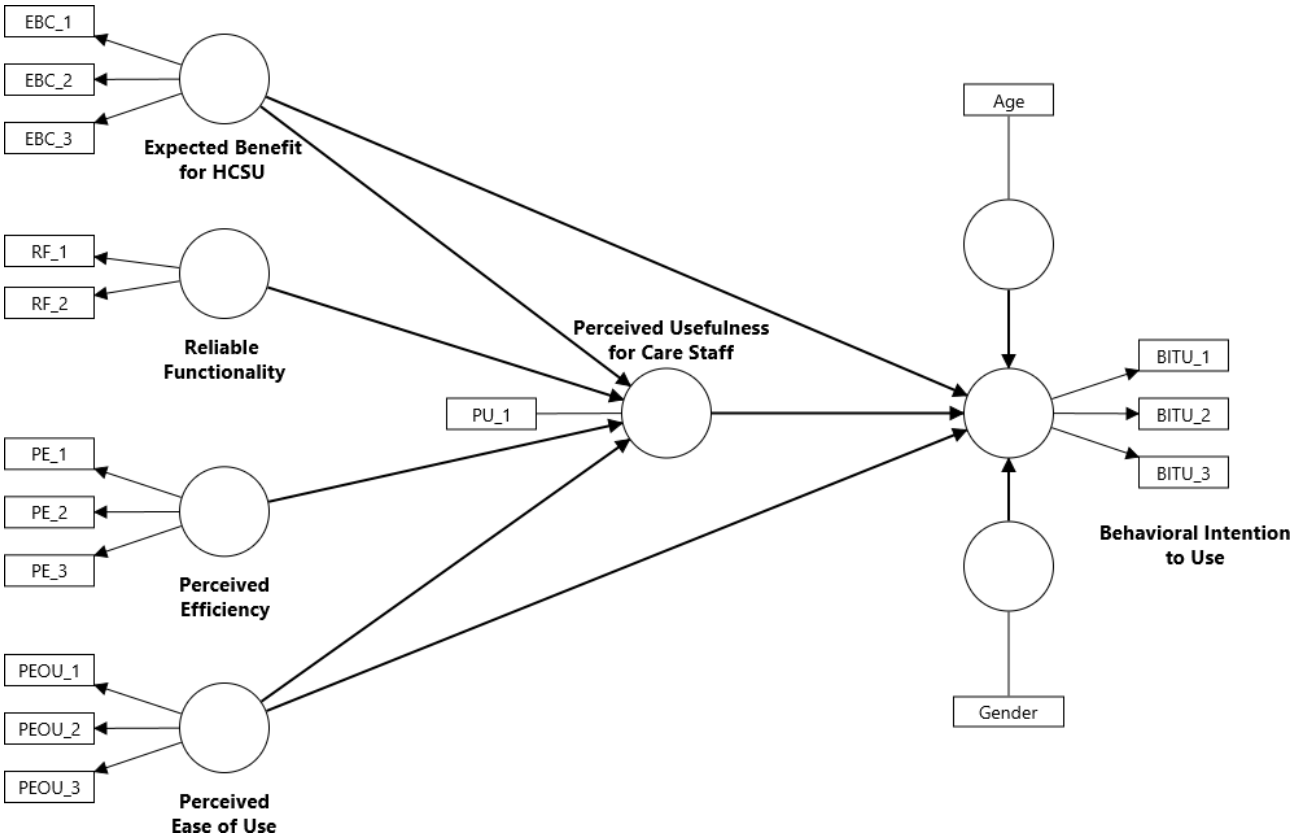
Remote Care Assist

Against this background, research and development projects cofunded by national and European funding agencies aim to develop tailored digital solutions for home care settings. One of these projects, titled "Care about Care," developed and tested a communication system to support care workers in the homes of people receiving care. This so-called "Remote Care Assist" system enabled highly qualified and more experienced care staff (henceforth "care experts") to provide support and advice via video calls [7]. To this end, Remote Care Assist consisted of 2 components. The first component was a "remote support app" on care and nursing staff's Android and iOS company phones to enable video streaming between members of the care team. In addition, care experts also had access to a web app called "the expert center" to receive and make such calls in their offices using laptops or stationary computers. The system enabled care experts to see what their colleagues see in their clients' homes. Different tools supported them in interactive tasks, such as marking and measuring specific wound regions on the screen. In addition, care experts could save screenshots as part of the care documentation. This digital technology thus aimed to facilitate communication and decisions on the appropriate management of wounds, medication, and other care and nursing issues.

Technology Acceptance

For technologies such as Remote Care Assist, successful implementation depends not only on technical performance, but also on end-user acceptance. Acceptance research aims to identify predictors that positively or negatively influence end users' behavioral intention to use a product or service [8]. Because acceptance determinants can vary across contexts, technology acceptance models (TAMs) should be validated for specific contexts, technologies, and end-user groups [9,10]. Established models such as the TAM [11] and the Unified Theory of Acceptance and Use of Technology (UTAUT) [12] are regarded as the gold standard in acceptance research across various apps and industries, including the health care sector [9].

Analytical Model and Hypotheses



TAMs have been widely adopted and further developed in previous studies [13-20]. Building on this body of research, we propose a contextualized model (Figure 1) in which care staff's "Behavioral Intention to Use" Remote Care Assist is associated with "Perceived Usefulness (PU)" and "Perceived Ease of Use (PEOU)." We extend the model by incorporating "Expected Benefit for Home Care Service Users (EBC)" and by modeling "Perceived Efficiency (PE)" and "Reliable Functionality (RF)" as antecedents of "PU."

"PU" has emerged as one of the most influential factors in acceptance research [10,21-23]. The predictor is described as the degree to which an individual believes that using the system will help him or her to attain gains in job performance [12]. We hypothesized a direct association of "PU" for care staff with "Behavioral Intention to Use" Remote Care Assist. Hypothesis 1 was that "PU" for care staff is positively associated with the "Behavioral Intention to Use" Remote Care Assist among care staff.

"EBC" reflects the degree to which care staff believe that home care service users will benefit from the use of the system. We hypothesized a dual motivation for technology acceptance in long-term care settings, which consists of both a direct association of "EBC" with "Behavioral Intention to Use" Remote Care Assist and an indirect mediated relationship through "PU" for care staff. The mediation suggests that care staff who expect digital care technology to be beneficial for their care recipients are more likely to perceive it as useful, which, in turn, enhances their future "Behavioral Intention to Use" the Remote Care Assist. Hypothesis 2a was that "EBC" is positively associated with "Behavioral Intention to Use" Remote Care Assist among care staff, Hypothesis 2b was that "EBC" is positively associated with "PU" for care staff, and Hypothesis 2c was that the relationship between "EBC" and "Behavioral Intention to Use" Remote Care Assist among care staff is positively mediated by "PU" among care staff. While "PU" in acceptance research [12] typically emphasizes efficiency improvement, our study proposed "PU" among care staff as an attitude, with "PE" and "RF" as direct antecedents. "PE" is defined as the degree to which the system will increase the productivity of care staff. "RF" is related to "Output Quality" [8,20]. However, because telecare technologies are not primarily output-oriented, we defined "RF" as the degree to which the system is considered to work consistently and error-free in everyday professional use. Hypothesis 3 was that "PE" is positively associated with "PU" among care staff, and Hypothesis 4 was that "RF" is positively associated with "PU" among care staff.

XSL•FO
RenderX

Figure 1. Proposed technology acceptance model. EBC_1-3: measurement items for "Expected Benefit for HCSU," RF_1-2: measurement items for "Reliable Functionality," PE_1-3: measurement items for "Perceived Efficiency," PEOU_1-3: measurement items for "Perceived Ease of Use," PU_1: measurement item for "Perceived Usefulness for Care Staff," and BITU_1-3: measurement items for "Behavioral Intention to Use." HCSU: home care service user.

Consistent with previous studies [24,25], "PEOU" often emerges as an important predictor of "Behavioral Intention to Use," proposing that end users who perceive information technology as easy to use are more likely to accept it for further use. Therefore, "PEOU" is defined as the degree of ease associated with consumers' use of technology [19]. We hypothesized a direct association of "PEOU" with the "Behavioral Intention to Use" Remote Care Assist and an indirect mediated relationship through "PU" for care staff. The hypothesized mediation suggests that care staff who perceive telecare technology as user-friendly are more likely to perceive it as useful, which in turn enhances their future "Behavioral Intention to Use" Remote Care Assist. Hypothesis 5a was that "PEOU" is positively associated with "Behavioral Intention to Use" Remote Care Assist among care staff, Hypothesis 5b was that "PEOU" is positively associated with "PU" for care staff, and Hypothesis 5c was that the relationship between the "PEOU" and "Behavioral Intention to Use" Remote Care Assist among care staff is positively mediated by "PU."

"Behavioral Intention to Use" Remote Care Assist is defined as the care staff's subjective probability of using the system in the future [26]. In accordance with previous acceptance studies [13-15,27,28], this construct was designated as the principal dependent variable of this study. This choice was justified by the fact that Remote Care Assist was examined in a pilot context and was therefore not available on the open market at the time of the study.

Objective

The objective of this study was to test a contextualized TAM for the "Remote Care Assist" system in professional home care. Specifically, we examined the established associations of "PU" for care staff and "PEOU" with "Behavioral Intention to Use" Remote Care Assist. Additionally, we evaluated "PE" and "RF" as antecedents of "PU." In professional care contexts, however, adoption decisions may also reflect considerations beyond the individual user's own efficiency, including whether a technology is expected to benefit care recipients. While prior research has examined "Perceived Customer Usefulness" in social work contexts [29], little is known about how care staff's expectations of benefits for home care service users influence their intention to use telecare in routine professional practice. This study addresses this gap by extending established acceptance predictors with the EBC and by exploring system- and workflow-related antecedents of the behavioral intention to use a newly developed telecare application.

Methods

Study Design and Participants

The Remote Care Assist was tested in 2 home care organizations in Austria and Luxembourg [30]. Study participants were recruited by the participating care organizations using a 2-stage sampling procedure. First, all care units within each organization were screened for eligibility. Care units were eligible if they did not have major staffing shortages and did not participate in

XSL•FO
RenderX

pretests of the technology. Second, all employees of eligible care units were considered eligible for participation. Participants were classified according to their professional role as care experts (registered nurses or the unit's care managers) or care and nursing staff (nursing assistants and home helpers). All participants were trained in the use of the system (mobile app and expert center) using a peer-to-peer training approach. For more details, refer to the study [30].

Approximately half of the eligible care units were randomly assigned to the test group. Care workers in test-group care units received access to the Remote Care Assist app on their company smartphones. Care experts had access to the web-based care expert center within their assigned units. They did not provide support across units. The acceptance analysis focuses on exposed users rather than on comparisons between randomized groups. Only participants who reported using Remote Care Assist at least once per month were included in the acceptance analyses. To ensure transparency and complete reporting, we followed the CHERRIES (Checklist for Reporting Results of Internet E-Surveys checklist [Checklist 1]).

Sample Size

Sample size considerations were guided by the 10-times rule for partial least squares structural equation modeling (PLS-SEM) based on the maximum number of direct incoming paths to any endogenous construct [31]. In our structural model, "Behavioral Intention to Use" was the endogenous construct with the largest number of direct predictors: "EBC," "PU" for care staff, "PEOU," and the control variables age and gender. Therefore, we determined the minimum required sample size to be 50 valid responses. To assess the adequacy of the achieved sample after the survey, we additionally conducted a PLS-SEM power analysis in line with established recommendations [32].

Data Collection

The acceptance survey was conducted as a special topic survey and as part of the second wave of the study's data collection. The original questionnaire was developed in German and translated into French for French-speaking participants in Luxembourg. Before administration, both language versions were pretested in Austria and Luxembourg. Eligible participants were informed about the project by their colleagues participating in the project consortium. The survey was administered to all eligible care and nursing staff (care workers and nursing assistants) and care experts (registered nurses, wound managers, and care managers). The link provided in a text message directed them to a language-specific LimeSurvey (LimeSurvey GmbH) questionnaire. It comprised modules with questions on potential outcomes of the technology, usability, usage behavior, and technology acceptance. The survey included 65 questions for care staff and 74 questions for care experts. Responses were recorded automatically. Participants could discontinue the survey and resume it at any time using their individual token. Trial periods lasted from March to September 2023, with survey data collection from September 13 to October 15, 2023, in Austria and from May to October 2023, with survey data collection from September 14 to October 30, 2023, in Luxembourg. Differences in the data collection period resulted from a delay in ethical approval in Luxembourg.

Measures

The technology acceptance section of the online survey included 15 items adapted from established acceptance research [11,12] and tailored to the Remote Care Assist context. Construct definitions, item wordings, and variable names were adapted from prior validated instruments, particularly the UTAUT [12], and tailored to the technology used in home care settings (Multimedia Appendix 1).

The outcome variable, "Behavioral Intention to Use" Remote Care Assist, reflected respondents' willingness to use the system in the future and represented technology acceptance. It was assessed using 3 items (BITU_1 to BITU_3). "PU" for care staff, specified as a mediator, captured the perceived benefits for care and nursing staff and was measured using a single global item (PU_1). This was in line with prior research using parsimonious measures [33,34]. The remaining predictors were operationalized as follows: EBC_1 to EBC_3, PE_1 to PE_3, RF_1 to RF_2, and PEOU_1 to PEOU_3. All acceptance items were rated on a 6-point Likert-type agreement scale ranging from 1 ("strongly disagree") to 6 ("strongly agree"). An even-numbered response format was used to reduce midpoint responding, as midpoint selections may indicate forced neutrality [35], serve as a reference point [36], or fail to reflect respondents' true opinions [37].

In addition, consistent with previous studies on technology acceptance [12,25,38,39], age and gender were included as covariates to control for potential differences related to the "Behavioral Intention to Use" the Remote Care Assist. Age was dichotomized using two groups: 20-45 years (lower-age group=0) and 46-60 years (higher-age group=1). Gender was coded as women=0 and men=1.

Statistical Analysis

Descriptive statistics were conducted using R (R Foundation for Statistical Computing). Technology acceptance data were analyzed using SmartPLS (version 4; SmartPLS GmbH). The proposed model was analyzed using PLS-SEM, enabling simultaneous assessment of the measurement model and testing of the hypothesized structural relationships. This approach is particularly suited for exploratory research with small sample sizes [40]. It is a nonparametric method and therefore does not require any distributional assumptions. We used statistical bootstrapping to provide more accurate SEs and CIs and thus reliable parameter estimation [31].

First, we evaluated the measurement models by examining their reliability and validity, with a focus on internal consistency reliability, indicator reliability, convergent validity, and discriminant validity [40]. Internal consistency was evaluated by Cronbach alpha and composite reliability (RhoA and RhoC [41]). Indicator reliability was evaluated based on indicator loadings associated with the underlying constructs. Convergent validity was evaluated using the average variance extracted. Discriminant validity was assessed using the Heterotrait-Monotrait ratio of correlations (HTMT).

After confirming the validity and reliability of the measurement models, we evaluated the hypothesized structural model [40]. This included assessing collinearity among predictor constructs

XSL•FO
RenderX

using variance inflation factors (VIFs), estimating the magnitude and significance of the structural path coefficients, and examining the model's explanatory and predictive power. We applied the PLS-SEM bootstrapping procedure using 10,000 subsamples and assessed directional hypotheses using one-tailed tests at the 5% level. In addition, we report bootstrap CIs. Further, we conducted a mediation analysis to test the hypothesized direct and indirect mediations.

Additionally, we performed an importance-performance map analysis [42] to visualize and classify predictors into 4 quadrants according to their relative importance and performance on "Behavioral intention to Use" Remote Care Assist. The importance threshold was defined as the mean total effect across the key constructs, and the performance threshold was defined as the grand mean of the corresponding construct mean scores. Based on these thresholds, constructs were assigned to 1 of 4 quadrants: low importance and low performance, low importance and high performance, high importance and low performance, and high importance and high performance. The positions of each predictor in the matrix were visualized to identify potential intervention priorities. Highly important constructs were considered priorities, particularly when their performance was low, indicating the greatest room for improvement. In contrast, constructs characterized by low importance, but high performance were considered potential areas from which resources could be reallocated to higher-priority constructs.

Finally, we evaluated the model's in-sample explanatory power using the adjusted coefficient of determination (adjusted R^2). We then assessed its out-of-sample predictive power using the PLSpredict procedure, defined as the model's ability to generate accurate predictions for holdout-sample observations not used in model estimation [43]. Specifically, we applied a 10-fold cross-validation procedure with 10 repetitions [44]. We further compared the root mean square error (RMSE) and mean absolute error (MAE) of the PLS-SEM model with those of the naive linear model benchmark.

Ethical Considerations

The study design was approved by the Ethics Committee of the University of Applied Science Wiener Neustadt (September 2021), the Comité national d'éthique de recherche in Luxembourg (202209/07 version 4.0), and the Ministère de la Santé in Luxembourg (840xe52b7). All participants received written information regarding the purpose, potential benefits, and risks of the study and were assured that all data would remain confidential and processed in line with the General Data Protection Regulation. All participants provided electronic consent based on the information provided and voluntarily agreed to participate in the study. All participants had the option to decline participation or withdraw from the study at any time. Participation was voluntary. No monetary or nonmonetary incentives were provided. However, survey participation was allowed during work hours. Participant information was pseudonymized, and access to the data was restricted to the research team.

Results

Sample Characteristics

In total, 337 care and nursing staff completed the online survey, including 55 care experts. Of these, 139 (41%) reported using Remote Care Assist at least once per month and were therefore included in the technology acceptance analysis. Among these 139 eligible participants, 45 (32%) were care experts (28 from Austria and 17 from Luxembourg) and 94 (68%) were home care staff (75 from Austria and 19 from Luxembourg).

The sample consisted predominantly of women: 123 (89%) were women, 14 (10%) were men, and 2 (1%) did not disclose their gender. The sample reflected the gender composition of the care workforce in typical care settings [45]. About half of the participants (n=75, 54%) were aged 20-45 years, 62 (45%) were aged 46 years or older, and 2 (1%) did not disclose their age.

Behavioral Intention to Use Remote Care Assist

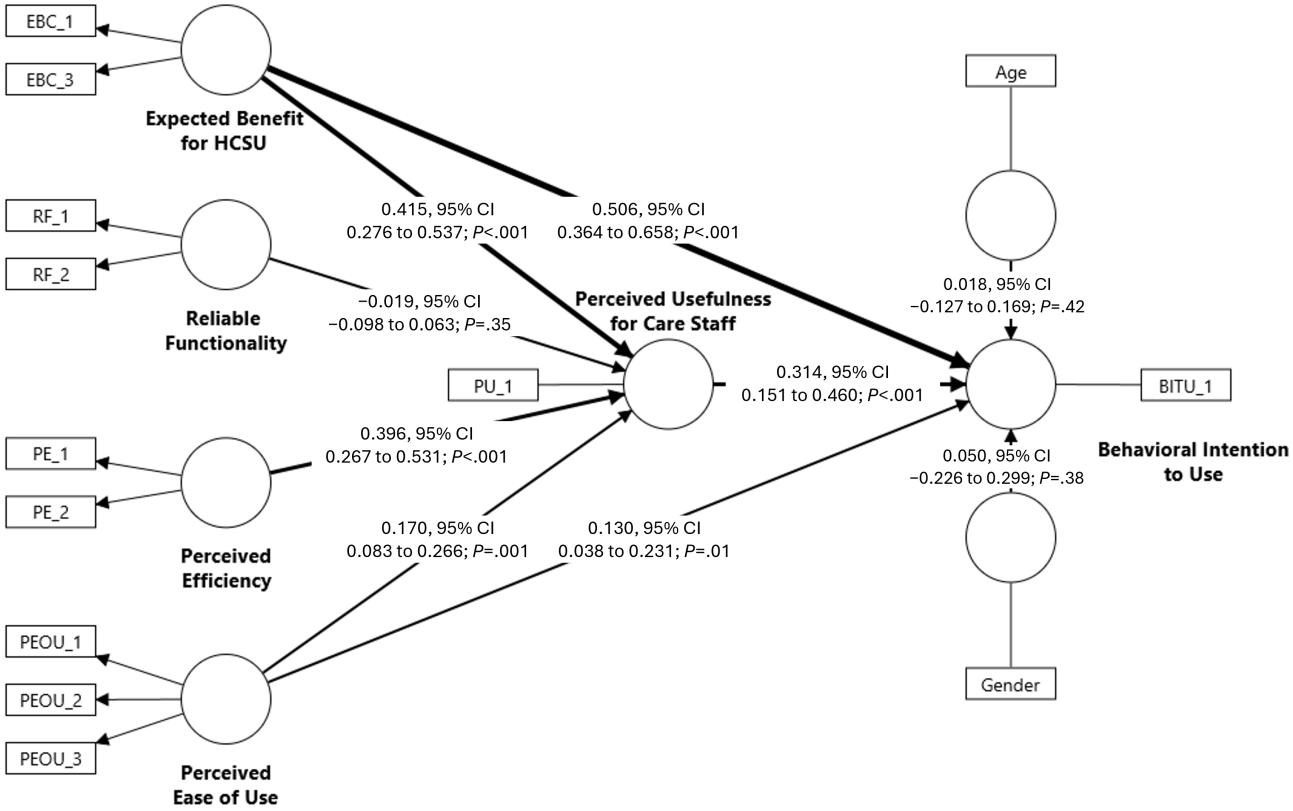
Overall, 113 (81%) participants reported a positive "Behavioral Intention to Use" Remote Care Assist (Likert scores 4 - 6: somewhat agree, mostly agree, and strongly agree). Of these, 44 (32%) selected "somewhat agree," 34 (25%) "mostly agree," and 35 (25%) "strongly agree." In contrast, 26 (19%) participants reported a negative "Behavioral Intention to Use" Remote Care Assist (Likert scores 1 - 3: strongly disagree, mostly disagree, and somewhat disagree). Of these, 6 (4%) selected "strongly disagree," 5 (4%) "mostly disagree," and 15 (11%) "somewhat disagree." The odds of agreement vs disagreement were 4.35:1.

Measurement Model Evaluation

The measurement model was evaluated for indicator reliability, internal consistency reliability, convergent validity, and discriminant validity. We first evaluated the initial measurement model. Due to high internal consistency estimates (Cronbach α and composite reliability values >0.95) and concerns regarding discriminant validity, particularly between "EBC" and "Behavioral Intention to Use" Remote Care Assist (HTMT ratio=0.884), we reassessed redundancy and content validity, resulting in the removal of 4 redundant items: BITU_2, BITU_3, PE_3, and EBC_2. Consistent with prior studies [46-51] and following parsimonious, pilot-oriented item reduction, "Behavioral Intention to Use" was measured as a single-item construct. For a more detailed description of the variable selection, refer to Multimedia Appendix 1.

In the final measurement model, all multi-item constructs showed strong internal consistency, with Cronbach α values ranging from 0.903 to 0.941. All indicator loadings exceeded the recommended threshold of 0.708 and were statistically significant, supporting indicator reliability. Average variance extracted values were above 0.5 for all multi-item constructs, indicating adequate convergent validity. Discriminant validity was also supported, as all HTMT values (Multimedia Appendix 2) were below the conservative threshold of 0.85 [52] and the bootstrapped HTMT upper 95% CI did not include 1 [31]. Thus, all measurement models were found to be reliable and valid.

XSL•FO
RenderX



Multimedia Appendix 3 summarizes the evaluation results for both the proposed model and the final model.

Structural Model Evaluation and Hypothesis Testing

Based on the achieved sample size of 139 participants, the PLS-SEM power analysis (80% power, α=.05) indicated a minimum detectable effect size of 0.211 [32]. VIFs indicated no problematic multicollinearity. All VIFs were below the commonly used threshold of 3, except for the path from "PU" for care staff to "Behavioral Intention to Use" Remote Care Assist (VIF=3.060), which remained below the more liberal threshold of 5 [53] (Multimedia Appendix 4).

Figure 2 presents the structural model results. "Behavioral Intention to Use" the Remote Care Assist was positively associated with "EBC" (β=0.506, 95% CI 0.364 to 0.658; *P*<.001), "PU" for care staff (β=0.314, 95% CI 0.151 to 0.460; *P*<.001), and "PEOU" (β=0.130, 95% CI 0.038 to 0.231; *P*=.01), which supported Hypotheses 1, 2a, and 5a. Among all predictors, "EBC" showed the strongest direct association with "Behavioral Intention to Use."

Figure 2. Structural equation modeling results. EBC_1-3: measurement items for "Expected Benefit for HCSU," RF_1-2: measurement items for "Reliable Functionality," PE_1-2: measurement items for "Perceived Efficiency," "PEOU_1-3: measurement items for "Perceived Ease of Use," PU_1: measurement item for "Perceived Usefulness for Care Staff," and BITU_1: measurement item for "Behavioral Intention to Use." HCSU: home care service user.

According to our expectations, "PU" of the Remote Care Assist for care staff was positively associated with "EBC" (β=0.415, 95% CI 0.276 to 0.537; *P*<.001), "PE" (β=0.396, 95% CI 0.267 to 0.531; *P*<.001), and "PEOU" (β=0.170, 95% CI 0.083 to 0.266; *P*=.001), which confirmed Hypotheses 2b, 3, and 5b. In contrast, we found no evidence for Hypothesis 4, as "RF" was not significantly associated with "PU" for care staff (β=−0.019, 95% CI −0.098 to 0.063; *P*=.35).

In addition to the direct relationship between "EBC" and "Behavioral Intention to Use," the association between "EBC" and "Behavioral Intention to Use" Remote Care Assist among care staff was also positively mediated by "PU" for care staff (β=0.130, 95% CI 0.061 to 0.194; *P*=.001), supporting Hypothesis 2c. These findings support the hypothesized dual role of "EBC" in shaping care staff's "Behavioral Intention to Use" Remote Care Assist. On the one hand, care and nursing staff appeared to be guided by a sense of responsibility toward care recipients, as their expectation that Remote Care Assist would benefit home care service users positively contributed to technology acceptance. On the other hand, higher expected benefits for home care service users were associated with greater PU among care and nursing staff, which in turn was positively associated with technology acceptance.

In addition, the association between "PEOU" and "Behavioral Intention to Use" Remote Care Assist among care staff was positively mediated by "PU" (β=0.053, 95% CI 0.017 to 0.101; *P*=.02), supporting Hypothesis 5c. The result confirms that easy-to-use apps are perceived as more useful, which in turn increases the acceptance of the technology. Because both the direct and indirect associations were statistically significant and pointed in the same direction, both mediation patterns can be interpreted as complementary mediation [33]. Overall, the results supported Hypotheses 1, 2a, 2b, 2c, 3, 5a, 5b, and 5c, whereas Hypothesis 4 was not supported (Table 1).

Finally, age (β=0.018, 95% CI −0.127 to 0.169; *P*=.42) and gender (β=0.050, 95% CI −0.226 to 0.299; *P*=.38) as control

XSL•FO
RenderX

variables showed no statistically significant associations with "Behavioral Intention to Use" Remote Care Assist.

Table . Evaluation of path coefficients from the structural equation model and results from hypothesis testing.

Hypothesis	Path	Estimate β (95% CI)	SE	*P* value	Supported
H1	PU[a] → BITU[b]	0.314 (0.151 to 0.460)	0.094	<.001	Yes
H2a	EBC[c] → BITU	0.506 (0.364 to 0.658)	0.089	<.001	Yes
H2b	EBC → PU	0.415 (0.276 to 0.537)	0.079	<.001	Yes
H2c	EBC → PU → BITU	0.130 (0.061 to 0.194)	0.041	.001	Yes
H3	PE[d] → PU	0.396 (0.267 to 0.531)	0.080	<.001	Yes
H4	RF[e] → PU	–0.019 (–0.098 to 0.063)	0.038	.35	No

H5c	PEOU → PU → BITU	0.053 (0.017 to 0.101)	0.026	.02	Yes

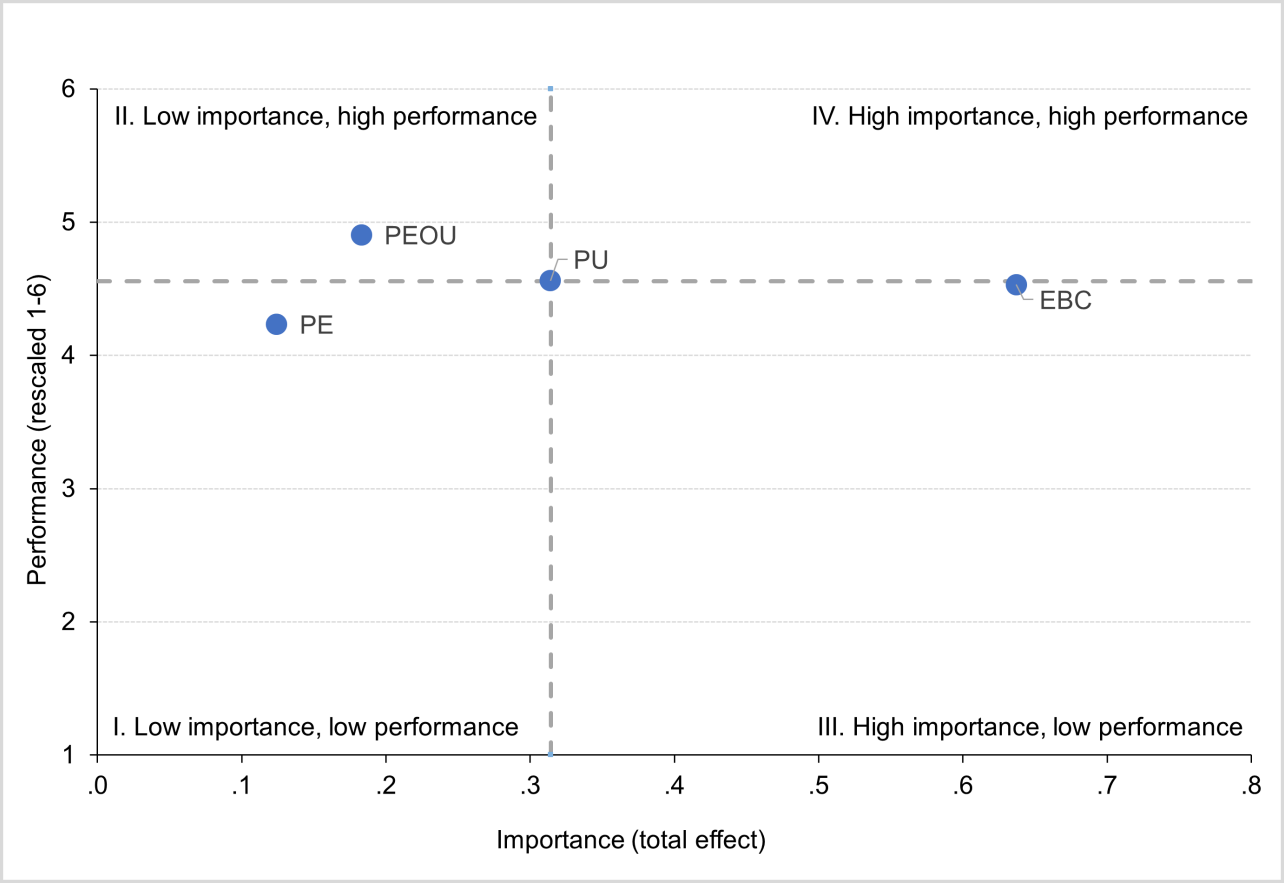
[a]PU: Perceived Usefulness.

[b]BITU: Behavioral Intention to Use.

[c]EBC: Expected Benefit for Home Care Service Users.

[d]PE: Perceived Efficiency.

[e]RF: Reliable Functionality.



[f]PEOU: Perceived Ease of Use.

Importance-Performance Map Analysis

Figure 3 shows the importance-performance map analysis for the predictors of "Behavioral Intention to Use." The mean importance threshold, defined as the average total effect across the key constructs, was 0.315. The mean performance threshold, defined as the grand mean of the latent variable scores, was 4.557. The predictors differed in both importance and performance. "EBC" (importance=0.637; performance=4.531) was positioned in the high-importance/low-performance quadrant and emerged as the strongest predictor overall. "PU" (importance=0.314; performance=4.561) and "PEOU" (importance=0.183; performance=4.904) were in the low-importance/high-performance quadrant, indicating these constructs as secondary targets for further optimization. In contrast, "PE" (importance=0.124; performance=4.233) fell within the low-importance/low-performance quadrant and was the least influential predictor.

XSL•FO
RenderX

Figure 3. Importance-performance map analysis (IPMA) for the predictors of "Behavioral Intention to Use" Remote Care Assist. EBC: Expected Benefit for Home Care Service Users; PE: Perceived Efficiency; PEOU: Perceived Ease of Use; and PU: Perceived Usefulness.

Predictive Performance Assessment

The model showed strong explanatory power. Adjusted R^2 values were 0.724 for "PU" for care staff and 0.726 for "Behavioral Intention to Use" Remote Care Assist. These results were slightly above the coefficient of determination compared to the UTAUT [12]. Out-of-sample predictive performance was also supported [43]. The $Q^2_{predict}$ values were positive for both constructs ("PU": 0.716 and "Behavioral Intention to Use": 0.687), indicating that the PLS-SEM model outperformed the naive indicator-average benchmark [31]. In addition, prediction errors for the PLS-SEM model were lower than those for the naive linear benchmark model. For "PU" and "Behavioral Intention to Use," the PLS-SEM model yielded lower RMSE (ie, 0.664 and 0.736, respectively) than the benchmark model (RMSE=0.671 and RMSE=0.773). The same pattern was observed for MAE=0.486 and MAE=0.507 vs MAE=0.489 and MAE=0.545, respectively. The lower RMSE and MAE values in the PLS-SEM analysis demonstrated that our model provided more accurate predictions than the naive linear benchmark model, confirming its high predictive power. In summary, the final model demonstrated excellent in-sample predictive power and high out-of-sample predictive power, enabling forecasts of the "Behavioral Intention to Use" Remote Care Assist among care staff.

Discussion

Principal Findings

This study tested a contextualized TAM for a newly developed digital communication tool for home care and nursing staff that enabled support and advice via video calls, called Remote Care Assist. Technology acceptance was measured by the "Behavioral Intention to Use" the system among care staff who had already used the system for several months in practice. The most important finding was that a new aspect of technology acceptance, the "EBC," was the strongest predictor of "Behavioral Intention to Use" the Remote Care Assist. This association was observed both directly and indirectly through "PU" for care staff. These findings suggest that technology acceptance in professional home care is shaped not only by care staff's expectations of personal or work-related utility, but also by their expectations of the technology's benefits for home care service users.

The results extend established acceptance theory, building on rational choice [11], by highlighting a relational dimension of technology acceptance in care work. We consider the social influence of home care service users not as a kind of external pressure from other people who want to persuade care staff to perform a behavior, but as an internal perception of care staff that promotes technology acceptance in long-term care settings. In other words, care staff may be more willing to adopt such digital technologies when they believe that they will benefit people receiving care. In addition, this perceived benefit for

XSL•FO
RenderX

home care service users may also strengthen their own perception that the technology is useful in practice. Future research could build on these findings and extend them to focus on whether care staff's emotional attachment to their home care service users or their own standards of professionalism explain why they consider the interests of those in need of care when deciding to accept or reject a particular technology.

Our analysis revealed "PU" as a central and multifaceted predictor and mediator of user acceptance, as supported by previous research [27]. "PU" for care staff was positively associated with care staff's intention to use Remote Care Assist. "PU" for care staff mediated the associations of both "PEOU" and "EBC" with "Behavioral Intention to Use" the Remote Care Assist.

In addition, the study reaffirmed the relevance of "PEOU" as a positive predictor of "Behavioral Intention to Use" [54,55]. "PEOU" was associated with acceptance both directly and indirectly via "PU," consistent with established acceptance theory [8,20,38]. These findings indicate that user-friendly digital technologies are more likely to be perceived as useful because they simplify tasks and workflows, which in turn may increase care staff's willingness to integrate them into daily practice.

Our study confirmed "PE" as an antecedent of "PU" for care staff. The predictor encompasses factors related to improving workflow, speed, and work convenience. By contrast, we found no statistically significant association between "RF" and "PU" for care staff. This nonsignificant result aligns with similar findings in the literature, where the predictor "insecurity," referring to distrust in telehealth systems' ability to function well and properly, also did not significantly affect the outcome [56]. A possible explanation for this result is that the Remote Care Assist technology was tested in an exploratory pilot study. Participants in the trial may have been more tolerant of errors and technological issues. However, once Remote Care Assist technology is fully integrated into routine home care practice, users may be less forgiving of technical problems, which could lead to different acceptance outcomes along the implementation process.

Consistent with previous studies [57,58] and in contrast to others who found age [59] and gender [60] to moderate user acceptance, our findings show that the covariates age [55,60] and gender were not statistically significantly associated with the "Behavioral Intention to Use" Remote Care Assist.

Research on technology acceptance provides valuable insights into the potential predictors of care staff's future intention to use Remote Care Assist or similar digital technologies in care settings. These insights are crucial for management decision-making regarding whether to promote and support technology within a care organization or discontinue its use if it is not well received by end users. For instance, if a predictor of technology acceptance demonstrates low performance but high importance, management should focus on targeted improvements to this predictor. Conversely, if a predictor appears both underperforming and of low importance, it may be appropriate to neglect it and reallocate resources to more promising ones.

Limitations

Several limitations should be considered when interpreting these findings. First, this was an exploratory pilot study, and the analysis was restricted to participants who reported using the Remote Care Assist system at least once per month. As a result, nonusers and less frequent users were not represented, limiting the generalizability of the findings. Second, the role of the "EBC" was examined for the first time in long-term care settings. Although the findings indicate that this construct may be relevant, further research is needed to establish its conceptual and psychometric validity and to clarify its role in TAMs in care settings. Third, the small sample size did not allow for more detailed multigroup analyses by country or professional role, including direct comparisons between Austria and Luxembourg. Moreover, the cross-sectional design precludes causal inference, and the observed associations should not be interpreted as evidence of temporal or causal relationships. Fourth, the analyses were conducted at the individual level and did not account for potential clustering within care units or organizations. If responses were correlated within units, SEs may have been underestimated, leading to overly narrow CIs and optimistic *P* values. Fifth, "PU" and "Behavioral Intention to Use" were modeled as single-item constructs. Although this may be acceptable in parsimonious or pilot research, single-item measures may increase measurement error and may not fully capture the underlying constructs. Sixth, because predictors and outcomes were collected from the same respondents in a single survey, common method bias cannot be excluded. Future research should include nonusers, use larger samples, further validate the newly introduced construct, and, where feasible, apply longitudinal, multi-item, and multilevel designs.

Conclusion

Our findings indicate that care organizations intending to implement digital technologies should prioritize utility for both groups: care and nursing staff and their home care service users. Three factors were positively associated with acceptance of telecare technologies: PU, PEOU, and EBC. In their adoption decisions, care staff appear to consider both their own work-related benefit and the expected benefits for the people receiving care. For applications with a clear EBC, this benefit should be explicitly communicated and clearly justified during the implementation process. In contrast, reliability in the sense of flawless functionality of Remote Care Assist was not statistically significantly associated with user acceptance during the pilot implementation phase. Overall, understanding the antecedents of user acceptance among decision-makers can improve the implementation process and the user acceptance of digital applications in long-term care settings, thereby contributing to a better understanding of crucial factors for a successful digitalization of this field.

Abstract

Background: Rehabilitation frequently extends beyond supervised clinical settings, creating a demand for scalable digital tools to support structured follow-up. We propose a novel open-source telerehabilitation platform.

Objective: We describe the iterative, user-centered development of an open-source rehabilitation follow-up platform and report findings from an initial formative usability evaluation with patients, health care professionals, and additional end users.

Methods: The platform was developed through repeated cycles of stakeholder engagement, prototyping, and evaluation within the rehabilitation department of Insel Group, University of Bern. A formative usability evaluation was conducted with 24 participants (8 health care professionals, 9 patients, and 7 additional participants; mean age 41.1, SD 12.9 y) using a task-based protocol. Perceived usability was assessed with the System Usability Scale (scored 0 - 100) and the Post-Study System Usability Questionnaire (scored 1 - 7; higher is better). Open-ended written responses were processed by one researcher using rapid content analysis.

Results: A web-based telerehabilitation platform enables therapists to manage patient caseloads, assign and track personalized rehabilitation interventions, and monitor patient progress through Fitbit activity data and rehabilitation plan adherence. It supports multiclinic workflows with role-based access, REDCap patient importing (Vanderbilt University), automated background processing via Celery, and multilingual content. Its mean System Usability Scale score was 82.8 (SD 14.1), placing the platform in the “excellent” usability range. The mean Post-Study System Usability Questionnaire overall score was 6.02 (SD 0.77), with all 3 subscales scoring above 5.7. Most participants (20/24, 83%) rated the task set as easy or very easy; no participant rated any task as difficult. Among health care professionals, 7 out of 8 (88%) reported an intention to use the platform in practice. Qualitative themes highlighted the value of a rehabilitation plan overview, structured intervention scheduling, and progress tracking.

Conclusions: The platform, released as open-source (Massachusetts Institute of Technology [MIT] License), demonstrated promising perceived usability across both patient and clinician user groups in a formative evaluation. These findings provide preliminary support for the platform’s perceived usability and justify further evaluation in real-world rehabilitation settings. Future work will evaluate deployment in real-world outpatient settings and assess clinical effectiveness.

Introduction

The aging population is associated with an increase in chronic diseases, and population growth is placing pressure on health care systems [1]. Globally, the need for rehabilitation is increasing and remains substantially unmet, driven in part by population aging, chronic disease, and disability (Checklist 1)[2,3]. Rehabilitation often continues beyond the supervised clinical setting: to maintain functional gains and prevent complications, patients require structured exercise programs, tailored health information, and regular follow-up support after discharge. The resulting mismatch between limited clinical resources and the growing demand for long-term rehabilitation management underscores the need for scalable digital tools that bridge the gap between clinical discharge and sustained recovery at home.

Telerehabilitation has emerged as a promising approach for such tools, using telecommunications technologies to deliver rehabilitation services across geographic distances, supporting patient self-management and reducing travel barriers, particularly in rural or underserved areas [4-6]. Internet-based approaches have also demonstrated potential for cost savings by substituting for services that would otherwise be inaccessible [7]. Evidence from multiple systematic reviews indicates that telerehabilitation can achieve outcomes comparable to in-person rehabilitation across several rehabilitation contexts, including physical therapy broadly, Parkinson disease, and musculoskeletal disorders, and may be more effective than no rehabilitation in settings where face-to-face care is not feasible [5-8].

Well-designed telerehabilitation platforms can offer several advantages for clinical practice: they may enable clinicians to create and schedule individualized rehabilitation plans remotely, allow patients to access structured exercise instructions and educational materials at home, and provide longitudinal data on adherence and health parameters that can inform follow-up decisions [6,8,9]. By integrating wearable device data, patient-reported outcomes, and clinician-defined intervention schedules into a unified workflow, such platforms can support both clinical oversight and patient engagement, which are important for sustained rehabilitation outcomes [9,10].

However, platforms capable of delivering these benefits remain incompletely integrated into routine clinical use. A key barrier in digital health is vendor lock-in: proprietary solutions may create dependency on a single vendor's technology, pricing, and product roadmap, limiting flexibility, portability, interoperability, and reproducibility in research [11]. Reviews of open-source clinical software and open-source electronic health record systems suggest that open-source development can enable local customization, support long-term sustainability, and foster collaborative development. However, adoption remains limited, and reporting is inconsistent [12,13]. More work is needed to translate the open-source paradigm into practical, clinically validated rehabilitation platforms.

To address these gaps, we developed an open-source rehabilitation follow-up platform guided by 3 principles: iterative, user-centered development; open-source transparency and reproducibility; and adaptability across diverse institutional and clinical contexts. The platform supports shared rehabilitation planning and patient self-management after discharge by integrating existing evidence-based rehabilitation content, structuring it into individualized plans, and providing clinicians and patients with a unified workflow for scheduling, monitoring, and feedback. It was developed at the Center for Rehabilitation & Sports Medicine (Inselspital and Berner Reha Zentrum), Bern University Hospital, using an approach that embedded clinical stakeholder input into each development cycle. Existing open-source platforms address related but distinct needs: OpenTera [14] provides a microservice architecture for rapid prototyping of telehealth and robotic applications, primarily in long-term care settings, but it does not focus on structured rehabilitation planning workflows. OpenTeleRehab [15], developed by Humanity & Inclusion and recognized as a Digital Public Good, offers treatment plan templates, an exercise library, and therapist-patient communication features, but it is designed primarily for deployment in low- and middle-income countries with limited digital infrastructure, including offline and SMS text messaging functionality. The proposed platform differs in its focus on integration with existing clinical workflows in high-resource hospital settings, its containerized architecture designed for institutional self-hosting under local data governance frameworks, its integration of wearable device data into structured rehabilitation plans, and its formal usability evaluation using validated instruments. Taken together, these distinctions define the space the platform is designed to fill: a formally evaluated, workflow-oriented, open-source platform for structured rehabilitation follow-up in high-resource hospital settings.

The platform's core features were prioritized to address recognized barriers to rehabilitation follow-up, rather than solely for technical reasons. Limited adherence and engagement after discharge motivated structured scheduling, daily reminders, and visible progress feedback; discontinuity between inpatient and outpatient care motivated shared rehabilitation plans, an intervention library, and a unified clinician-patient workflow; and clinician workload motivated reusable plan templates, role-based caseload management, and consolidated patient overviews. Table 1 summarizes how each platform component is intended to address these barriers.

This paper makes 2 contributions: first, we describe the design and implementation of the platform as an open-source, modular web application; and second, we report findings from an initial formative usability evaluation conducted with patients, health care professionals, and additional end users within the rehabilitation department of the University Hospital of Bern [16].

XSL•FO
RenderX

Table . Conceptual mapping of barriers to rehabilitation follow-up and the platform components intended to address them.

Barrier to follow-up	Platform component intended to address it
Adherence or engagement	Scheduling, daily browser reminders, progress tracking, and "tiny-wins" feedback
Continuity of care	Shared rehabilitation plans, intervention library, and unified clinician-patient workflow
Clinician workload	Reusable plan templates, role-based caseload management, consolidated patient overview, and data export
Patient self-management	Patient dashboard, structured exercise and education content, and wearable-derived activity data

Methods

Design Approach and Iterative Development

We adopted an iterative, user-centered development approach informed by the IDEAS (integrate, design, assess, and share) framework [17]. Rather than following a linear development process, the platform was refined through repeated cycles of stakeholder input, rapid prototyping, implementation, and formative evaluation. In each cycle, feedback from patients, clinicians, and the research team was translated into concrete design requirements, which were implemented in the prototype and subsequently reviewed to identify usability issues, missing features, and opportunities for improvement. This process allowed the platform to evolve progressively in response to user needs and clinical workflow considerations.

Throughout these cycles, an interprofessional team (cardiology and sports medicine, rehabilitation medicine, neurology and neuropsychology, biomedical engineering and gerontechnology, exercise and rehabilitation science, and design research) met regularly to steer development and was supported by 3 structured co-design workshops. In the first workshop (8 team members; August 2024), candidate features were generated through brain-writing and ranked on a relevance-by-feasibility matrix. The priorities carried into development included a structured intervention library with expected benefits, goal-based intervention suggestions, progress tracking with motivating ("tiny wins") feedback, and expert-approved constraints. These priorities shaped the rehabilitation-plan structure and intervention-metadata workflows. A second workshop with 3 patient representatives (October 2024) examined postdischarge needs: participants highlighted the loss of structure, reduced clinical support, and emotional strain, and called for a simple, accessible design with diagnosis-specific guidance and motivating feedback. When shown the team's prioritized ideas, they endorsed them while cautioning that automated suggestions should complement rather than replace human feedback. A third workshop with patient representatives and clinicians (March 2025) compared 2 interaction concepts: a guided flowchart and a structured plan. Participants judged both useful at different recovery stages and stressed the importance of ease of use, web and mobile access, and data protection. These inputs underpin the barrier-to-feature mapping in Table 1 and the prototype evaluated here.

Stakeholder involvement was conducted in hospital clinics within the rehabilitation department of the University Hospital of Bern, engaging patients, clinicians, and researchers to identify needs and priorities for rehabilitation follow-up and digital support. Outputs from these activities informed core platform workflows (eg, rehabilitation plan structure, intervention metadata, and feedback capture) and prioritized features for successive development cycles.

Development proceeded through repeated cycles of (1) requirements elicitation and prioritization, (2) low- and high-fidelity prototyping, (3) implementation of prioritized features, and (4) formative evaluation and refinement. Users participated at each stage, as summarized in Table 2. The formal usability evaluation reported in this paper corresponds to one of these stages and was followed by an expert user experience (UX) review whose recommendations partly informed the current release.

Table . Iterative development phases, user involvement, and outputs[a].

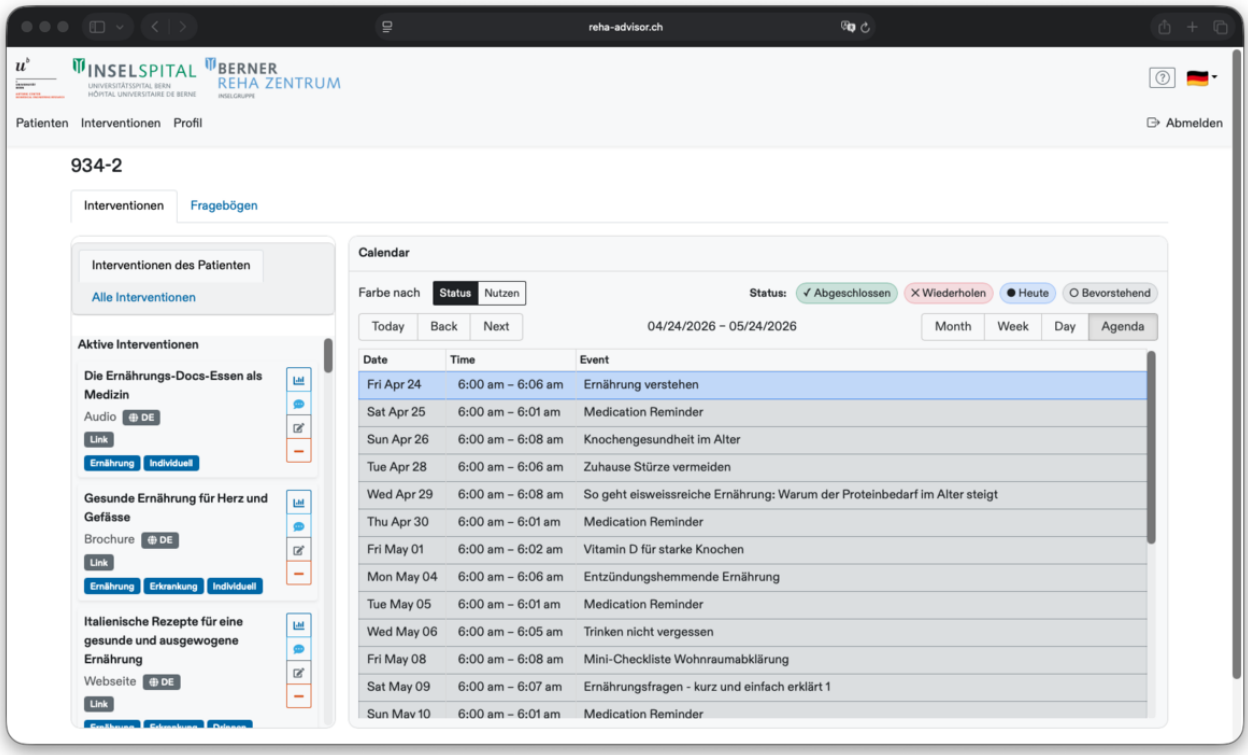
Phase	User involvement	Output
Requirements/needs elicitation	Patients, clinicians, and researchers	Core workflows: plan structure, intervention metadata, and feedback capture
Prototyping (low/high fidelity)	Stakeholder feedback on prototypes	Prioritized feature set and role-based interface designs
Formative usability evaluation (this study)	8 health care professionals, 9 patients, and 7 additional participants	SUS[b]/PSSUQ[c] scores, task completion, and qualitative themes
Expert UX[d] review	UX experts	Refinement priorities (landing page, navigation, dashboards, and motivation)
Postevaluation refinement	Implemented from review	For example, browser-based daily reminders (service worker) added to the current release

[a]The formative usability evaluation reported here represents one stage within this process.

[b]SUS: System Usability Scale.

[c]PSSUQ: Post-Study System Usability Questionnaire.

[d] UX: user experience.



Platform Overview

The proposed platform is a modular web application designed for 2 primary user roles: patients and health care professionals. It provides role-based interfaces: a clinician-facing web portal to manage patients and rehabilitation plans and a patient-facing interface to view assigned interventions, respond to questionnaires, and review relevant health parameters (eg, activity or symptom tracking). Both interfaces are delivered as Progressive Web Apps, allowing them to be installed on mobile and desktop devices without requiring distribution through an app store. For patients, it includes a dashboard for quick status review and a calendar-based view of scheduled rehabilitation activities.

Core functional modules include (1) user and role management; (2) patient administration; (3) an intervention library that supports searching, filtering, and creation of clinic-specific interventions; (4) rehabilitation plan templates and scheduling with calendar-based views; (5) patient feedback capture via questionnaires and postintervention feedback (including optional video feedback with time-limited storage); (6) data export for clinical documentation and research (eg, as PDFs or CSV files); and (7) daily notification reminders to support adherence, configurable through a dedicated settings interface. Figures 1 and 2 illustrate the end-to-end workflow from clinician planning to patient completion and feedback capture.

XSL•FO
RenderX

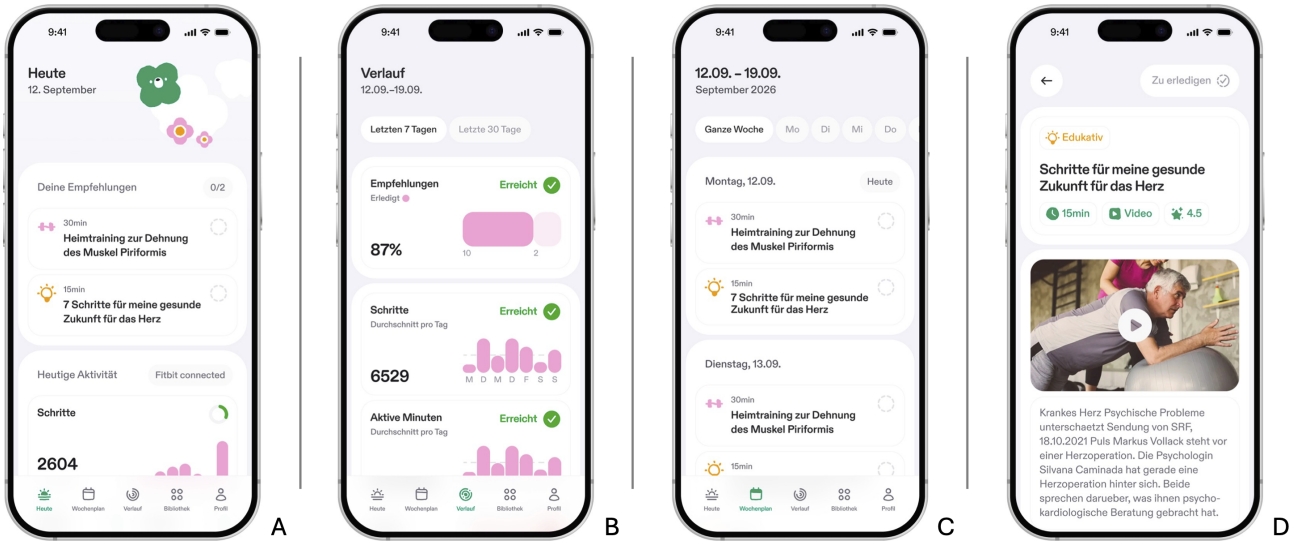


Figure 1. Clinical interface for intervention scheduling and monitoring. Calendar views (month/week/day/agenda) with status-coded interventions and access to the assigned intervention library.

Rather than building all content from scratch, the platform is designed to integrate and curate existing evidence-based educational and rehabilitation resources (eg, publicly available exercise instructions, videos, or rehabilitation applications) and to enable local tailoring to patient needs. This strategy aims to reduce duplication and support the extension to additional rehabilitation contexts.

Rather than building all content from scratch, the platform is designed to integrate and curate existing evidence-based educational and rehabilitation resources (eg, publicly available exercise instructions, videos, or rehabilitation applications) and to enable local tailoring to patient needs. This strategy aims to reduce duplication and support extension to additional rehabilitation contexts.

Figure 2. Patient interface for daily rehabilitation tasks and monitoring, shown across 4 screens of the patient-facing Progressive Web App. (A) Daily home screen ("Heute") showing the current date, the interventions recommended for that day, and today's synced activity data (eg, step count from a connected Fitbit device). (B) Intervention detail view for an individual educational ("Edukativ") intervention, including an embedded instructional video, which the patient can review and mark as completed. (C) Weekly plan view ("Wochenplan") listing the interventions scheduled across the days of the selected week. (D) Progress view ("Verlauf") summarizing longitudinal adherence and activity for a selected period (eg, the last 7 d), including the proportion of recommendations achieved, average daily step count, and active minutes, with status indicators showing which goals were met. Screen content is displayed in German, reflecting the platform's multilingual support.

XSL•FO

Technical Implementation and Architecture

The platform is based on a modular server-client architecture designed to support scalability, maintainability, reproducible deployment, and local adaptation. The front end is built with React 18 (Meta Platforms, Inc) and TypeScript (Microsoft Corp), using Vite for optimized build performance, and is delivered as a Progressive Web App. This enables installation on patients' mobile and desktop devices directly from the browser and ensures the application functions reliably across varying network conditions. A service worker handles browser-based daily reminders that prompt patients to complete their assigned rehabilitation activities, using browser notification mechanisms compatible with the Web Notifications and Push API ecosystems [18]. Notification preferences are managed through a dedicated settings page and are compatible with browsers supporting the Web Notifications API. The back end is implemented with Django 5 (Django Software Foundation) and Django REST Framework (Encode OSS Ltd). Regarding data security, the back end employs token-based authentication, role-based access control, and encrypted data transport, with all data stored within the deploying institution's own infrastructure to support data sovereignty.

For data management, the platform uses MongoDB (version 8.0.3; MongoDB, Inc) for flexible, document-based storage of interventions and patient records, alongside Redis (version 8.4.0; Redis Ltd) for in-memory caching and as a message broker for Celery background tasks. All services are served behind an NGINX (version 1.28.2; F5, Inc) reverse proxy, which handles static file serving, Secure Sockets Layer (SSL) termination, and request routing. The full stack is orchestrated with Docker (version 27.3.1; Docker, Inc), enabling reproducible deployments across different institutional IT infrastructures. The separation between the presentation layer, back-end services, background processing, and data storage allows individual components to be maintained, extended, or replaced independently. To support code quality and deployment confidence, the repository includes comprehensive test suites for both the front end (Jest, version 29.7.0; OpenJS Foundation, and React Testing Library, version 16.3.2) and the back end (Pytest, version 9.0.3), with continuous integration via GitHub Actions and automated coverage reporting.

For data management, the platform uses MongoDB (version 8.0.3) for flexible, document-based storage of interventions and patient records, alongside Redis (version 8.4.0) for in-memory caching and as a message broker for Celery background tasks. All services are served behind an NGINX (version 1.28.2) reverse proxy, which handles static file serving, SSL termination, and request routing. The full stack is orchestrated with Docker (version 27.3.1), enabling reproducible deployments across different institutional IT infrastructures. The separation between the presentation layer, back-end services, background processing, and data storage allows individual components to be maintained, extended, or replaced independently. To support code quality and deployment confidence, the repository includes comprehensive test suites for both the front end (Jest, version 29.7.0 and React Testing Library, version 16.3.2) and the back end (Pytest, version 9.0.3), with continuous integration via GitHub Actions and automated coverage reporting.

Wearable Integration and Data Collection

To support longitudinal monitoring, the platform integrates with the Fitbit web service, which will be updated to the Google Health API due to the deprecation of the Fitbit web service in September 2026, via its publicly available REST API [19], which exposes activity, sleep, and physiological data from Fitbit wearable devices, using an OAuth 2.0 authorization flow [20]. Fitbit devices were selected because they operate independently of the user's smartphone brand, lowering the barrier to access for patients. Once a patient authorizes access, the system performs daily automatic background synchronization.

The platform specifically retrieves and stores the following health metrics in the database:

- Physical activity: daily step counts, distance traveled, and active minutes categorized by heart rate zones
- Physiological data: resting and exercise heart rates
- Sleep metrics: total sleep duration and sleep quality indicators

These passive data streams are complemented by active patient reporting, including the manual entry of vital signs (eg, blood pressure and weight) and responses to structured questionnaires.

Open-Source Strategy and Reproducibility

The software is released as open-source to support transparency, reuse, and reproducible research. The complete source code, documentation, and issue tracker are publicly available on GitHub and are released under the permissive Massachusetts Institute of Technology (MIT) License [16].

The proposed software's open-source strategy is based on several principles: permissive licensing, public access to the codebase, modular software design, reproducible deployment, transparent issue tracking, and documentation for installation and further development. The modular architecture separates the front end, back end, background processing, and data storage components, allowing individual modules to be maintained, extended, or replaced independently. This design supports the platform's adaptation to different rehabilitation contexts without requiring substantial changes to the overall system architecture.

Versioning of software artifacts is implemented using a Git-based repository structure. Source code, deployment files, documentation, and configuration artifacts, such as intervention templates or questionnaire definitions, when stored as repository files, can be tracked through commits, branches, release tags, and documented changes. This enables identifying the software state used in a given evaluation, reproducing deployments from a specific repository version, and tracing modifications over time. User-entered data are not versioned as source artifacts, but they can be exported in structured formats to support reproducibility, secondary analysis, and auditability. Stable software versions are documented using release tags, enabling specific platform versions to be referenced in publications, deployments, and evaluation studies.

XSL•FO
RenderX

To facilitate reuse across institutions, the repository includes developer documentation, deployment guidance, and contribution guidelines. These elements support external review, local adaptation, and collaborative development. Similar open-source strategies have been proposed to avoid reinventing existing components and to focus development efforts on extending capabilities and integrating reusable modules, as demonstrated by open-source telehealth frameworks such as OpenTera [14] and open-source telerehabilitation platforms such as OpenTeleRehab [15].

Usability Evaluation: Participants and Recruitment

Participants were recruited through the rehabilitation department of the University Hospital of Bern (Inselspital) and the Berner Reha Zentrum in Heiligenschwendi, both of which are part of the Insel Group. The recruited sample included health care professionals from the rehabilitation department, patients with rehabilitation experience, and additional healthy participants. Inclusion criteria were (1) aged 18 years or older and (2) the ability to provide written informed consent. Participants were not required to have prior experience with the platform.

The sample size was chosen pragmatically, in line with the evaluation's formative purpose. For early-stage usability testing, small samples are commonly used to identify recurring usability problems and inform iterative refinement. The Nielsen usability testing heuristic suggests that testing approximately 5 users can reveal many major usability issues within a user group, particularly when combined with iterative design cycles [21]. In this study, the inclusion of 24 participants, comprising 8 health care professionals, 9 patients, and 7 additional participants, was therefore considered appropriate for assessing perceived usability and identifying design improvements across the main intended user perspectives. For quantitative usability scoring with the System Usability Scale (SUS), this sample size also provides a pragmatic basis for estimating overall perceived usability, although group-specific estimates remain descriptive because of the limited number of participants per subgroup [22]. The study was not powered to test clinical effectiveness or to conduct inferential comparisons between participant groups.

The evaluation assessed 2 role-specific interfaces. Patients evaluated the patient-facing interface and health care professionals evaluated the clinician-facing interface, reflecting their respective intended uses. The additional participant group evaluated both interfaces, providing cross-interface usability coverage and a larger per-interface denominator (patient interface: n=16; clinician interface: n=15). This approach is appropriate for early-stage formative testing, where the priority is to surface recurring interface-level usability problems efficiently rather than to obtain population-representative estimates. Accordingly, we report SUS and Post-Study System Usability Questionnaire (PSSUQ) outcomes for health care professionals and patients as the primary user populations and present the additional participant group as supplementary, exploratory data.

Formative Usability Protocol

The usability evaluation was conducted on a prototype of the rehabilitation platform that included core workflows for rehabilitation planning, scheduling, patient task completion, and feedback. Features implemented after this evaluation are described separately as subsequent design refinements and were not included in the usability scores reported here. The formative evaluation used a moderated, task-based usability protocol to assess the software's core platform workflows for both user roles. Sessions were conducted in person at the rehabilitation department of the University Hospital of Bern (Inselspital) between August 2025 and December 2025. Before starting the tasks, participants received a short verbal introduction explaining the purpose of the evaluation, the voluntary nature of participation, and that the study aimed to evaluate the platform rather than the participants' performance. Participants were allowed to ask clarification questions before the task session started. During task completion, however, they were asked to work independently and without assistance, unless technical access problems required assistance.

Participants completed the tasks using study-provided hardware or their own devices. The platform was tested on computers and/or smartphones, reflecting the intended use of the clinician-facing and patient-facing interfaces. Clinician tasks were primarily performed on laptop devices, whereas patient-facing tasks were performed on smartphones, depending on participant availability and device preference. No strict maximum time limit was imposed, as the aim was to observe task completion and perceived usability under realistic formative conditions rather than to assess speed under time pressure. Task completion and notable usability issues were observed by the first author and/or the second author using a standardized task checklist.

Participants were asked to complete the following standardized task sets:

- Patient interface tasks: logging in, viewing the interventions scheduled for the current day, marking an intervention as completed, and submitting feedback after it is completed.
- Clinician interface tasks: creating a user account, logging in, assigning a recommendation to a patient with a given diagnosis, creating a new patient profile and a rehabilitation plan with 3 interventions, creating an intervention and assigning it to patient groups, and editing user profile information.

No formal think-aloud protocol was used. Instead, participants were encouraged to report difficulties or uncertainties if they occurred, and the observer documented task completion, usability issues, and spontaneous comments. After completing the tasks and exploring the platform, participants completed standardized usability questionnaires and a written semistructured posttask questionnaire.

The questionnaire combined closed-ended ratings with open-ended questions to capture perceived task difficulty, prior experience with digital technologies, perceived usefulness, barriers to use, and suggestions for improvement. Health care professionals received additional role-specific questions on expected usefulness in rehabilitation workflows, intention to use, perceived effects on time and workload, real-time monitoring, trust in platform-generated recommendations, and willingness to recommend the platform. The complete posttask

XSL•FO
RenderX

questionnaire, including the standardized usability instruments and the role-specific open-ended items, is provided as Multimedia Appendix 1.

The written questionnaire format was used to standardize data collection across participants and to minimize interviewer influence. Responses were entered into a structured electronic case report form. Because the open-ended responses were collected in written form, no audio recording or verbatim transcription was required. The questionnaire guide is provided in Multimedia Appendix 1.

Outcome Measures

Perceived usability was assessed using the SUS (10 items, 1 - 5 response scale, scored 0 - 100) [23] and the PSSUQ (16 items, 1 - 7 response scale) [24]. The SUS was scored according to the standard scoring procedure, with positively worded items scored as the item score minus 1, and negatively worded items scored as 5 minus the item score; the sum was then multiplied by 2.5 to obtain a score from 0 to 100.

For the PSSUQ, the original positively worded item content was retained. However, the response direction was aligned with the SUS and the other agreement-based items administered during the same usability assessment session. Specifically, the electronic questionnaire used a consistent agreement scale in which lower values indicated disagreement and higher values indicated agreement. This was done to reduce the risk of response errors caused by switching between opposite response directions across questionnaires within the same assessment. As a result, PSSUQ scores in this study are reported in a study-specific higher-is-better direction, rather than in the conventional PSSUQ lower-is-better direction. For comparability with conventional PSSUQ reporting, nonmissing item scores can be transformed using $x_{standard}=8 - x_{study}$. Responses coded as 99 were treated as missing. The full mapping is provided in Multimedia Appendix 2.

Additional questions assessed perceived task difficulty (1="very easy" to 5="very difficult"), and among health care professionals, perceived usefulness for follow-up care, intention to use, perceived effect on time and workload, perceived usefulness for real-time monitoring, trust requirements for platform recommendations, and willingness to recommend the platform. Open-ended questions captured positive aspects, barriers, missing functions, and suggested areas for improvement.

Statistical Analysis

We conducted descriptive analyses for SUS and PSSUQ scores overall and by participant group (including health care professionals, patients, and additional participants). Continuous scores are reported as mean and SD. Missing items were treated as missing. SUS scores were calculated only when all 10 items were completed. PSSUQ scale scores were computed as the mean of available items after excluding responses coded as 99 (not applicable). PSSUQ scores are reported in the study-specific direction, where higher values indicate better perceived usability. For transparency and comparability with conventional PSSUQ scoring, the conversion rule to the standard lower-is-better direction is reported in Multimedia Appendix 2. Task completion was summarized as the number and proportion of participants who completed each standardized task, computed separately for the patient-facing and clinician-facing interfaces. Perceived task difficulty was summarized as counts by response category, overall, and by group. The study was not powered for inferential comparisons between groups, and no hypothesis tests were performed.

Qualitative Analysis

Open-ended responses from the written posttask questionnaire were analyzed using rapid content analysis, an approach suited to formative and implementation-oriented evaluations that require timely identification of actionable themes [25]. Responses were exported from REDCap (Vanderbilt University) and organized in a structured matrix by question topic and participant group using Microsoft Excel. One researcher coded the responses, grouping them into recurring categories (perceived strengths, usability issues, missing functions, and improvement suggestions) and consolidating these into overarching themes; representative quotations were then selected to illustrate each theme across participant groups. The analysis focused on identifying actionable findings for the next development iteration rather than on generating a formal qualitative theory, and no formal interrater reliability statistic was computed. The limitation arising from single-researcher coding is addressed in the *Limitations* section.

Ethical Considerations

All procedures performed in the study involving human participants were conducted in accordance with the ethical standards of the institutional and/or national research committee and with the Declaration of Helsinki and its later amendments [26]. Written informed consent was obtained from all participants before study participation. This study was approved by the Bern Cantonal Ethics Committee (KEK Bern: 2025 - 01071).

Results

Participants

In total, 24 participants completed the usability evaluation, including 8 health care professionals, 9 patients, and 7 additional participants. Participant characteristics are summarized in Table 3.

XSL•FO
RenderX

Table . Participant characteristics (N=24).

Characteristic	Overall (N=24)	Health care professionals (n=8)	Patients (n=9)	Other (n=7)
Female, n (%)	10 (41.7)	5 (62.5)	1 (11.1)	4 (57.1)
Male, n (%)	14 (58.3)	3 (37.5)	8 (88.9)	3 (42.9)
Age (y), mean (SD; range)	41.1 (12.9; 25-63)	33.9 (6.7; 27-44)	54.3 (8.5; 36-63)	32.4 (8.1; 25-48)

Usability Outcomes

Overall perceived usability was high. The mean SUS score was 82.8 (SD 14.1). The mean PSSUQ overall score, reported in the study-specific higher-is-better direction, was 6.02 (SD 0.77), corresponding to 1.98 in the conventional lower-is-better PSSUQ direction. Subscale results are shown in Table 4.

Table . Usability outcomes (N=24)[a].

Outcome (scale)	Overall (N=24), mean (SD)	Health care professionals (n=8), mean (SD)	Patients (n=9), mean (SD)	Regular (n=7), mean (SD)
SUS[b] (0 - 100)	82.8 (14.1)	79.4 (13.7)	83.1 (16.3)	86.4 (12.5)
PSSUQ[c] overall (1-7; higher=better, study direction)	6.02 (0.77)	5.74 (0.94)	6.23 (0.76)	6.06 (0.57)
System usefulness (items 1 - 6)	6.12 (0.80)	5.88 (0.92)	6.19 (0.87)	6.31 (0.56)
Information quality (items 7 - 12)	5.92 (0.88)	5.50 (1.17)	6.29 (0.61)	5.94 (0.65)
Interface quality (items 13 - 15)	5.95 (0.74)	5.81 (0.70)	6.15 (0.85)	5.86 (0.69)

[a]PSSUQ scores are reported in the study-specific higher-is-better direction. To convert to the conventional PSSUQ lower-is-better direction, use $x_{standard}=8-x_{study}$ for each nonmissing item.

[b]SUS: System Usability Scale.

[c]PSSUQ: Post-Study System Usability Questionnaire.

Most participants rated the task set as easy or very easy (20/24, 83%); the remaining participants reported neutral difficulty (4/24, 17%). No participant rated the tasks as difficult or very difficult. Perceived difficulty was consistent across groups: 6 out of 8 (75%) health care professionals, 7 out of 9 (78%) patients, and 7 out of 7 (100%) additional participants rated the platform as easy or very easy to use, with the remainder rating it as neutral.

Among 8 health care professionals, 7 (88%) reported that they would use the platform in practice. Six health care professionals reported that they would recommend it to colleagues, one was unsure, and one response was missing. This corresponds to 6 out of 8 (75%) of all health care professionals or 6 out of 7 (86%) of those with valid responses. The perceived impact on workload was mixed: 3 out of 8 reported that the platform would reduce time and workload, 1 out of 8 reported that it would not, 3 out of 8 were unsure, and 1 response was missing. Most health care professionals (6/8, 75%) reported that real-time monitoring features would be helpful. Among patients, 7 out of 9 (78%) found the rehabilitation platform easy or very easy to use, while 2 out of 9 (22%) reported neutral difficulty.

Task Completion

Task completion was high across both interfaces. All participants who attempted a task completed it, and no task failures were recorded against the standardized checklist (Table 5). The 2 patient-interface tasks were completed by all 16 participants (9 patients and 7 additional participants). The 6 clinician-interface tasks were completed by all participants (8 health care professionals and 7 additional participants); for the account-creation task, 1 record was missing, yielding 14 of 15 documented completions. Per-task details are provided in Multimedia Appendix 3. Because the evaluation used realistic, untimed conditions without a think-aloud protocol, time on task, error counts, and help requests were not systematically quantified; observed difficulties were documented descriptively and incorporated into the qualitative themes.

XSL•FO
RenderX

Table . Task completion by interface[a].

Task	Interface	Completed, n/N (%)
Log in and view interventions scheduled for today	Patient	16/16 (100)
Mark an intervention as completed and submit feedback	Patient	16/16 (100)
Create a user account	Clinician	14/14 documented (1 missing)[b]
Log in	Clinician	15/15 (100)
Assign a recommendation to a patient with a given diagnosis	Clinician	15/15 (100)
Create a patient profile and rehabilitation plan with 3 interventions	Clinician	15/15 (100)
Create an intervention and assign it to patient groups	Clinician	15/15 (100)
Edit user profile information	Clinician	15/15 (100)

[a]Patient-interface tasks were performed by patients and additional participants (n=16); clinician-interface tasks were performed by health care professionals and additional participants (n=15).

[b]One clinician-interface participant had no recorded result for this task (treated as missing). No task was recorded as failed.

Qualitative Feedback Analysis

Overview

Overall, the qualitative feedback was consistent with the high-quantitative usability ratings while highlighting specific points of friction. The reported frustrations are therefore interpreted as actionable usability issues identified during formative testing rather than as contradicting the positive usability scores.

Four recurring themes were identified, summarized below; representative quotations and their cross-group distribution are provided in Multimedia Appendix 4.

Value of Overview and Progress Tracking

Participants appreciated having an at-a-glance view of rehabilitation plans and daily activities, as well as the ability to review health and activity data over time, such as steps, sleep, and vital parameters. Several participants requested clearer progress indicators, such as "tiny wins," improved visualization of changes over time, and more actionable interpretation of collected parameters. This was the most frequently raised theme and was expressed across all 3 participant groups. One patient noted that "the overall picture is very useful" [Gesamtbild ist sehr nützlich], while others requested clearer progress feedback, for example, "a weekly overview; e.g. 80% achieved" (German: "Wochenübersicht; bspw. 80% erreicht") and, from an additional participant, "progress for the patients—tiny wins!"

Intervention Library and Structured Planning

Health care professionals valued the ability to create standard plans and templates, search and explore interventions, and schedule activities. Patients valued receiving structured exercise instructions and educational content. Several participants expressed interest in communication features, such as in-app messaging, and in tailoring interventions more explicitly to individual rehabilitation goals. One patient valued that "exercises are provided, and you do not have to assemble a program yourself" (German: "Gut, dass Übungen da sind …"), and an additional participant wished to "chat with my therapist through it."

Interface Simplification and Consistency

Suggested improvements included simplifying screens with many buttons, making views more compact, improving the calendar and navigation, and standardizing terminology and visual design. Some participants reported frustration with error messages and session handling (eg, unexpected logouts). This was the second-most-frequently raised theme. One health care professional observed that there were "currently still very many buttons; the system needs to be faster to operate" (German: "…sehr viele Buttons …"), and friction with error handling and session management was noted directly, for example, "sudden log out" and "bad error messages."

Trust and Clinical Validation

Participants emphasized that trust depends on clinician-validated content, transparent sourcing of educational materials, and clarity about who selected or approved interventions. Health care professionals noted the importance of integrating the platform into established clinical workflows and ensuring that recommendations and content are verified before patient release. This theme was raised predominantly by health care professionals; one emphasized the need for content "always confirmed by a therapist before being released" (German: "…von einem Therapeuten bestätigt …"), and an additional participant valued content that was "[personalised] from my therapist (approved)."

Design Refinements Identified Through UX Review

In parallel with the formative usability testing, an expert UX review workshop was conducted to identify priorities for subsequent design refinement. The usability scores reported in this study, therefore, reflect the prototype version available

XSL•FO
RenderX

during the evaluation, not all the features included in the current open-source release.

During usability testing, the evaluated prototype included the core clinician and patient workflows, including user log in, patient profile creation, intervention library access, rehabilitation plan creation, scheduled intervention assignment, patient-facing daily intervention views, completion marking, and postintervention feedback submission. The expert UX review focused on how these workflows could be improved in subsequent iterations.

Key recommendations included adding a concise landing page that clearly communicates the platform's purpose, streamlining the sitemap and navigation for both user roles, providing dashboards for at-a-glance status information, unifying patient data representations, and improving patient-profile views by combining plan adherence, questionnaire completion, and recent activity. The review also highlighted the potential value of notification support and motivational elements, such as visualization of the rehabilitation journey or gamification, to sustain patient engagement.

Some of these recommendations were implemented after the formative evaluation. In particular, browser-based daily reminders using a service worker were added after usability testing and are therefore part of the current platform version, but they were not reflected in the reported SUS and PSSUQ scores. Other recommendations, such as more advanced motivational elements and extended dashboard visualizations, remain priorities for future development.

Discussion

Principal Findings

This was a formative, single-session usability evaluation. It assessed perceived usability and task completion under short, moderated, task-based conditions and did not assess adherence, workflow burden, long-term engagement, clinical effectiveness, or real-world adoption; the following interpretations are bounded accordingly.

The rehabilitation platform achieved a mean SUS score of 82.8 (SD 14.1), placing it in the "excellent" usability range according to established SUS adjective-rating benchmarks [27]. The mean PSSUQ overall score was 6.02 (SD 0.77) on a 7-point scale, with all 3 subscales (system usefulness, information quality, and interface quality) scoring above 5.7. Scores were consistent across participant groups, with patients rating both instruments marginally higher than health care professionals did, suggesting that the patient-facing interface was particularly well received. Crucially, 20 out of 24 (83%) participants rated the task set as easy or very easy, and no participant rated any task as difficult.

The qualitative findings provide complementary clinical insight. The features participants valued most—at-a-glance rehabilitation plan overview, longitudinal progress tracking, and structured intervention scheduling—map onto broader telerehabilitation implementation priorities, including adherence, engagement, accessibility, satisfaction, and integration into routine workflows [8,10,28]. In our formative data, participants specifically emphasized the importance of visible progress and interpretable feedback. The repeated interest in "tiny wins" and actionable feedback may also be interpreted through self-determination theory, particularly the role of perceived competence in supporting sustained motivation and health behavior change [29]. Together, these themes suggest that the platform's design priorities were appropriate to the clinical context.

Among 8 health care professionals, 7 (88%) reported an intention to use the platform in clinical practice, and 6 out of 8 (75%) would recommend it to colleagues; these are encouraging early signals that require confirmation in deployment studies. The mixed workload impact ratings (3/8 expecting workload reduction and 3/8 uncertain) are expected for a formative prototype and point to specific areas requiring workflow optimization before deployment, particularly plan template creation and assignment workflows. The strong interest in real-time monitoring features (6/8, 75%), combined with the security and content validation concerns raised in qualitative feedback, underscores the importance of clear data governance communication and clinician-controlled content approval workflows in the next development iteration.

Comparison With Prior Work

The usability scores reported here add to an evidence base in which many telerehabilitation studies primarily emphasize clinical, physiological, adherence, or algorithmic outcomes. In contrast, detailed reporting of role-specific UX and formative usability findings is less consistently described [6,8,9,30]. The observed SUS score above 80 and the PSSUQ overall score above 6.0 suggest strong perceived usability at the formative stage. The consistency across patient and health care professional groups further suggests that the role-differentiated interface design did not introduce major usability asymmetries that would complicate deployment. These findings provide early empirical support for the feasibility of a workflow-oriented, open-source approach in this domain. For comparison, we focus on 2 commonly reported strands of digital rehabilitation research: telemonitoring systems and AI-focused rehabilitation tools. These areas were selected because they represent 2 major directions in current rehabilitation technology development, both directly relevant to the platform's intended scope. Telemonitoring systems typically focus on remote observation, physiological data capture, exercise supervision, or adherence monitoring [9,30]. AI-focused rehabilitation tools, in contrast, often emphasize prediction, activity recognition, movement assessment, or decision-support models [31-33]. Both strands are highly relevant to future rehabilitation services, but they often address specific functional components rather than the broader workflow infrastructure needed to plan, assign, monitor, and adapt rehabilitation interventions across patient and clinician roles. To make the platform's intended niche and its contribution relative to the state of the art more explicit, Table 6 contrasts the platform with the open-source systems introduced earlier (OpenTera and OpenTeleRehab) and with these 2 strands across capability, setting, deployment, and evaluation dimensions.

Compared with commonly reported telemonitoring systems and AI-focused rehabilitation tools, the proposed platform emphasizes workflow infrastructure. The platform does not aim

XSL•FO
RenderX

to replace remote monitoring systems or specialized AI models; rather, it provides an extensible environment in which such components can be embedded. Its current contribution lies in supporting intervention libraries, structured rehabilitation planning and scheduling, patient feedback capture, progress documentation, and data export. In this sense, the platform complements existing telemonitoring and AI-oriented approaches by addressing the organizational and interaction layers required to integrate digital rehabilitation tools into clinical workflows.

XSL•FO
RenderX

Table . Structured comparison of the proposed platform with related approaches[a].

Approach	Primary focus	Target setting/context	Rehabilitation workflow support	Data/wearable integration	Openness and deployment model	Evaluation status/evidence base	Relationship to proposed platform
Proposed platform	Open-source infrastructure for structured rehabilitation follow-up: plan management, patient self-management, and clinician-patient workflow support	High-resource hospital and outpatient rehabilitation settings; designed for institutional self-hosting	Intervention library, clinician-assigned plans, scheduling, patient task completion, postintervention feedback, progress documentation, and data export	Integrates Fitbit-derived activity and physiological data; supports manual patient-reported data and questionnaires	Open-source (MIT[b] License); containerized modular architecture for local institutional deployment under local data-governance frameworks	Formative, single-session usability evaluation (n=24; SUS[c], PSSUQ[d], task completion, qualitative feedback); adherence, long-term use, and clinical effectiveness not yet assessed	— (reference point for the comparison)
OpenTera [14]	Microservice architecture for rapid prototyping of telehealth and robotic applications	Care-facility and long-term-care contexts (originally a COVID-19 response)	General telehealth application framework oriented toward flexible prototyping rather than structured rehabilitation-plan management	Extensible architecture; wearable/Fitbit integration is not a described focus	Open-source telehealth framework	Published description of architecture and use cases [14]; not assessed in this study	A broader telehealth/robotics prototyping framework; complementary, as rehabilitation-planning workflows of the type provided here could be built on such an architecture
OpenTeleRehab [15]	Open-source telerehabilitation platform with treatment-plan templates, an exercise library, and therapist-patient communication	Primarily low- and middle-income countries and low-resource settings with limited digital infrastructure	Treatment-plan templates and communication features, with emphasis on low-infrastructure delivery (offline/SMS text messaging)	Optimized for low-infrastructure use (offline/SMS text messaging); wearable integration is not a described focus	Open-source; recognized as a Digital Public Good with documented real-world field deployment	Established field deployment as a Digital Public Good [15]; not assessed in this study	Complementary, with different design priorities: OpenTeleRehab optimizes for low-resource and offline contexts, whereas this platform targets self-hosted integration into high-resource hospital workflows with wearable-supported follow-up
Telemonitoring systems (research category)	Remote observation, physiological-data capture, exercise supervision, and/or adherence monitoring	Often disease- or program-specific remote rehabilitation contexts	Typically monitor activity, symptoms, or adherence; less commonly provide an integrated plan-assign-adapt-document workflow across patient and clinician roles	Frequently sensor-, device-, or physiological-data oriented	Varies across systems; often system-specific or proprietary	Individual systems report clinical, physiological, adherence, or monitoring outcomes (eg, [9,30])	Strong at generating follow-up data; this platform focuses on the organizational workflow layer needed to use such data within rehabilitation planning and could incorporate telemonitoring outputs

XSL•FO
RenderX

Approach	Primary focus	Target setting/context	Rehabilitation workflow support	Data/wearable integration	Openness and deployment model	Evaluation status/evidence base	Relationship to proposed platform
AI-focused rehabilitation tools (research category)	Prediction, activity recognition, movement assessment, or decision-support models	Often research prototypes or specialized digital rehabilitation modules	Usually address specific analytical or decision-support tasks rather than full patient-clinician workflow management	Often use sensor, video, wearable, or task-performance data depending on the model	Varies across tools; may be proprietary, experimental, or model-specific	Individual studies report algorithmic or model-performance outcomes (eg, [31-33])	This platform is not itself primarily an AI system; it provides extensible workflow infrastructure into which such models could be embedded as future modules

[a]OpenTera and OpenTeleRehab are specifically named systems, whereas "telemonitoring systems" and "AI-focused rehabilitation tools" are broad research categories included to situate the platform relative to 2 major directions in rehabilitation technology. For these 2 categories, the cells provide illustrative, nonexhaustive characterizations drawn from the cited examples rather than a systematic survey. Cells describe each approach's primary design orientation; the absence of a feature denotes a different design focus, not a judged deficiency.

[c]SUS: System Usability Scale.

[d]PSSUQ: Post-Study System Usability Questionnaire.

The Value of Open-Source Code in Rehabilitation Technology

A central contribution of this work is to release the software's source code under the permissive MIT License. This directly addresses the widespread issue of vendor lock-in in digital health, which systematic reviews have identified as a barrier to sustainable adoption and cross-institutional collaboration [12,13]. By making the entire codebase publicly available, we enable independent evaluation, adaptation, and extension by other research groups and clinical institutions without licensing constraints.

The containerized, modular architecture enables institutions to host the platform locally, supporting institutional data governance and compliance with applicable national frameworks, such as Swiss human research legislation [34], while contributing improvements to the shared code base. In addition to packaging the software components themselves, container-based deployment supports the explicit management of runtime state through persistent volumes. Volumes can store data generated and used by running services, such as database contents, uploaded media, configuration files, logs, or study-specific artifacts. When appropriately documented, anonymized, and governed, such volumes or volume exports can be archived and shared with a specific software version to reproduce complex study states, for example, a configured study instance, test dataset, or demonstration environment.

This distinction between container images and persistent volumes is relevant for reproducible rehabilitation research. Container images define the executable software environment, whereas volumes preserve selected runtime state across container restarts, updates, or redeployments. In research contexts, it is important to distinguish between sharing the platform implementation, sharing a configured deployment, and sharing study artifacts. Sensitive runtime data, such as patient records or study recordings, should not be included in public releases unless fully anonymized and ethically approved for sharing. Instead, public repositories can provide empty volume definitions, synthetic example data, documented import/export procedures, and where appropriate, restricted-access volume snapshots for reproducibility audits.

This positions the software as an extensible infrastructure rather than a finished product, a distinction that aligns with the iterative development philosophy described in the *Methods* section. Institutions can adopt the platform and adapt it to local clinical workflows, regulatory requirements, and patient populations without dependency on a single vendor's roadmap or pricing decisions.

An open-source release also supports reproducible research: other groups can inspect the implementation, replicate the evaluation, and build on the platform for their own clinical studies. This is particularly important in a field where proprietary systems often prevent independent verification of technical claims and limit cross-site comparability.

Implications of an Open-Source Rehabilitation Platform

Open-source development in digital health enhances transparency, reproducibility, and long-term sustainability by allowing stakeholders to inspect, modify, and extend software independently of vendor constraints. Reviews of open-source clinical software and electronic health record systems emphasize both opportunities and challenges, including variability in project maturity, documentation standards, and governance models [12,13]. Nevertheless, open-source ecosystems can reduce vendor lock-in, foster collaborative development, and support local adaptation, particularly in heterogeneous rehabilitation environments.

Rehabilitation workflows vary substantially across institutions, specialties, and patient populations. Proprietary systems may limit configurability and integration with external tools. A modular open-source platform can mitigate these constraints by enabling shared intervention libraries, standardized data structures, structured feedback capture, and extensible interfaces for integration with external services. In this context, the platform's architecture supports integration with wearable device

XSL•FO
RenderX

ecosystems, including Fitbit-based data exchange, enabling the incorporation of activity, sleep, and physiological metrics into structured rehabilitation follow-up. By separating core infrastructure (eg, user management, scheduling, and documentation export) from optional analytics and wearable integration modules, the proposed platform supports incremental extension without requiring monolithic deployment.

Beyond technical transparency, open-source architectures are intended to facilitate reproducible digital health research by enabling independent verification, replication studies, and cross-institutional reuse—areas that are frequently constrained by proprietary rehabilitation platforms. Cross-institutional reuse was not evaluated in this study.

Limitations and Future Work

This study reflects an early-stage formative usability evaluation and has several limitations.

First, the sample size was modest, and participants were recruited through the rehabilitation department of the University Hospital of Bern and affiliated rehabilitation settings, which may limit generalizability to broader rehabilitation populations and other institutional contexts. Second, participants reported relatively high familiarity with digital technologies, which may have contributed to favorable usability ratings. Third, the evaluation assessed perceived usability during short task-based sessions and did not measure long-term engagement, adherence, clinical outcomes, or integration into routine rehabilitation pathways. Fourth, the qualitative analysis of open-ended responses was conducted by one researcher. Although the analysis was structured around predefined categories and focused on identifying actionable usability issues for iterative development, the absence of independent dual coding or a formal interrater reliability assessment may have introduced interpretive bias. Future evaluations should include independent coding by multiple researchers or consensus-based qualitative analysis to strengthen the credibility of qualitative findings.

Future studies should include longitudinal field trials in real-world outpatient settings, assessment of sustained engagement and adherence, and evaluation of clinical effectiveness and workflow integration. Scalability under real-world load conditions, including concurrent multiuser access and high-volume data synchronization, has not yet been tested and should be evaluated in deployment studies.

Further development will focus on refinement, clinical integration, technical extension of the platform, and incorporation of feedback from the UX workshop. We will prioritize UX improvements, including simplifying navigation, optimizing the calendar, improving onboarding workflows, providing clearer progress summaries, and enhancing error handling, to further improve usability. Browser-based daily notification reminders have already been implemented in the current version.

Additional motivational features are planned to support adherence during longitudinal follow-up. These may include visualization of the rehabilitation journey, progress indicators, goal-setting functions, completion streaks, milestone badges, and feedback on small achievements or “tiny wins.” Such features should be designed carefully to support motivation without creating pressure, guilt, or inappropriate competition among patients. In rehabilitation contexts, gamification may therefore benefit from focusing on self-monitoring, encouragement, and personalized progress feedback rather than on competitive ranking. Future studies should examine whether these motivational components improve adherence, patient engagement, and perceived self-efficacy over time.

Subsequent work will evaluate the platform’s deployment in real-world outpatient rehabilitation workflows, including the assessment of sustained engagement, adherence patterns, and its impact on patient-reported and clinical outcomes. Implementation studies will examine barriers and facilitators to institutional adoption, including training requirements, governance processes, and integration with existing information systems.

From a technical perspective, future extensions will include deeper integration of wearable device ecosystems via standardized interfaces, such as Fitbit, enabling automated import of activity, sleep, and physiological data into structured rehabilitation plans. The platform architecture is designed to support the integration of AI-based motor assessment and decision-support modules while preserving modularity and reproducibility. Interoperability testing with electronic health record systems using standardized data exchange protocols, such as Fast Healthcare Interoperability Resources, will further support clinical integration and scalability [35].

Conclusions

This study describes the iterative development and formative usability evaluation of the platform, an open-source rehabilitation follow-up tool designed to support structured plan management, patient self-management, and clinician-patient workflow integration. In contrast to monitoring-centric telehealth systems and algorithm-focused AI rehabilitation tools, the platform emphasizes reproducible infrastructure, modular extensibility, and structured rehabilitation planning within real-world follow-up contexts.

The high usability scores observed in this formative evaluation suggest that an open-source, workflow-oriented rehabilitation platform can achieve strong perceived usability among both patients and health care professionals. By integrating structured intervention libraries, standardized feedback capture, and extensible interfaces for wearable device ecosystems, the platform is intended to provide a foundation for scalable, interoperable rehabilitation follow-up; this potential remains to be evaluated in deployment studies.

A central contribution of this work is to release the platform source code under the MIT License, directly addressing the widespread issue of vendor lock-in in digital health. By providing a containerized, modular architecture (Django or React or MongoDB), the architecture can help institutions host the platform locally, supporting data sovereignty and long-term research reproducibility. Future work will focus on longitudinal deployment within outpatient rehabilitation workflows and the evaluation of sustained engagement and clinical effectiveness.

Acknowledgments

The authors thank the patients, health care professionals, and other participants who participated in the usability evaluation. The authors used a generative AI assistant, Claude, for language editing to improve the readability of author-written text and to support them in the development of an open-source platform. It was not used to generate scientific content, analyze data, or draw conclusions. All AI-assisted text was reviewed and verified by the authors, who take full responsibility for the content of the manuscript.

Funding

This work was supported by the COPAIN (Co-creation and evaluation of a sensor-based closed-loop telecare program for multimorbid patients after inpatient rehabilitation) project, funded by the SF-Board of the University of Bern and the Insel Group (grant 750,000 CHF).

Data Availability

The software's source code, documentation, and issue tracker are publicly available on GitHub under the permissive

Massachusetts Institute of Technology (MIT) License [16]. Deidentified participant-level data from the usability evaluation are available from the corresponding author upon reasonable request.

Abstract

Background: Age-related macular degeneration (AMD) causes progressive central vision loss in older adults. Low-vision rehabilitation can improve functional vision by training the use of a preferred retinal locus, commonly through clinic-based biofeedback training (BFT). However, repeated supervised rehabilitation is burdensome, and functional gains may be difficult to sustain without home practice. Stand-alone virtual reality (VR) may enable home-based, remotely monitored visual stimulation, but feasibility, safety, and usability in older adults with AMD remain insufficiently characterized.

Objective: This study aimed to evaluate the feasibility and safety of adding home-based VR 3D single-object tracking (3D-SOT-VR) to conventional BFT in older adults with dry AMD in a parallel, randomized, single-blind (to assessors), controlled, formative trial and to generate exploratory functional hypotheses for a future trial.

Methods: Adults with dry AMD were recruited at the Low Vision Clinic, Toronto Western Hospital, University Health Network, Toronto, Ontario, Canada, from September 2021 to October 2023. Participants were randomized to BFT once weekly for 4 weeks (BFT group) or BFT plus home-based 3D-SOT-VR (BFT-VR group) every other day for 4 weeks. Experimental intervention consisted of tracking a single object among distractors moving at different speeds in a 3D virtual space in a VR headset. Primary feasibility and safety outcomes included recruitment, adoption, adherence, compliance, intervention completion, remote data transfer, usability, and VR-induced symptoms and effects. Secondary outcomes included visual acuity, contrast sensitivity, fixation stability, retinal sensitivity, reading speed, and low-vision quality of life. Exploratory outcomes assessed performance at 3D-SOT-VR and usage. Analyses were descriptive and exploratory, with CIs and denominators reported to reflect limited precision and missingness.

Results: Fourteen individuals were randomized (BFT, n=6; BFT-VR, n=8), below the planned sample size of 32. Recruitment was not achieved because of COVID-19–related interruptions and reduced onsite access. Eleven individuals were analyzed for the primary outcome (BFT n=6, BFT-VR n=5). Intervention completion was 100% in the BFT arm and 75% in the BFT-VR arm, below the prespecified BFT-VR threshold. Among participants who used VR, adherence to scheduled home sessions was acceptable, completed VR-session files were transmitted without loss, and no participant met the predefined cybersickness stopping rule. One BFT-VR participant discontinued because headset weight caused neck fatigue. Group-level visual outcomes did not provide significant effectiveness. Reading speed showed a clinically meaningful individual-level improvement in the BFT-VR arm and correlated with VR-task performance. The findings were not clearly durable at follow-up.

Conclusions: This pilot study provides formative evidence that clinic-based BFT combined with home-based, remotely monitored VR visual stimulation can be implemented safely in older adults with dry AMD, while identifying major contextual feasibility barriers. The intervention is innovative because it extends low-vision rehabilitation into the home using a connected device and objective performance monitoring. Recruitment, retention, missing data handling, and sustainability of functional gains must be addressed before effectiveness testing.

KEYWORDS

macular degeneration; low vision; visual rehabilitation; biofeedback training; virtual reality

Introduction

Background

Age-related macular degeneration (AMD) is the main cause of irreversible vision loss in developed countries, responsible for the loss of central, or macular, vision, substantially affecting reading, face recognition, mobility, independence, and quality of life [1,2]. According to BrightFocus Foundation, the number of people living with macular degeneration is expected to reach 196 million worldwide in 2020 and to increase to 288 million by 2040 [3]. There are no treatments available to restore vision and cure the disease; therefore, low-vision rehabilitation remains a central component of supportive care. Contemporary rehabilitation aims not only to prescribe magnification or optical aids, but also to improve the functional use of residual peripheral retina and to reduce the activity limitations caused by central scotoma [4,5]. A core concept in AMD rehabilitation is the preferred retinal locus (PRL), an eccentric retinal area that patients use to substitute for foveal fixation after macular damage [4]. Following the degeneration of the macula and the loss of central vision, patients naturally relocate the fixation point for high visual acuity (VA) peripherally, in an eccentric and healthy part of the retina, to compensate for visual impairments [6]. Relocation to the PRL occurs over time [4,7] but, in more than 25% of cases, the naturally developed PRL lands on a suboptimal retinal area and becomes inefficient, contributing to impaired reading and daily visual tasks [4,6,7]. Modern standard low-vision care for patients with AMD includes biofeedback training (BFT) to relocate the PRL to a healthy retinal patch identified by the health care provider and to acquire better fixation skills [4,7-9]. BFT has been shown to improve distance and near vision, reading speed, contrast sensitivity, retinal sensitivity, and therefore quality of life [4,7,10-12]. However, in clinical practice, it is observed that the patients do not always use the PRL as trained for activities of daily living, losing the benefits of BFT over time, while also highlighting uncertainties regarding optimal training dose, treatment interval, durability, and patient selection [9,13]. The use of the new PRL requires an adjustment of the oculomotor control [4,6,7] and a brain adaptation [14]. In patients with AMD, not only is fixation stability impaired at the PRL [6], negatively affecting VA [15] and making daily tasks such as reading and grooming difficult, but the increased eccentricity of a visual target also extends reaction times and multiplies error rates, deteriorating performance in object detection and recognition tasks [1,2,16]. These observations provide a rationale for combining conventional BFT with repeated attentional and visuomotor training outside the clinic. However, standard BFT is typically delivered under professional supervision in weekly or biweekly sessions, creating access and treatment-burden constraints for older adults. Home-based digital rehabilitation could increase training opportunities, but feasibility must be established before clinical effectiveness can be inferred.

Objective

A new and promising vision rehabilitation technique using binocular 3D single object tracking (3D-SOT) deployed in virtual reality (VR) headsets can provide additional training of the ocular system [17-19]. This innovative technique is particularly well suited for training because the central features of the 3D-SOT closely match attentionally demanding real-life situations [20,21]. Three-dimensional object tracking stimulation programs displayed on monitors or television screens have been shown to increase brain capacity for complex processes such as anticipation, eye-tracking, field of view, and even decision-making in healthy and pathological participants [22-24]. Preliminary observations in low-vision patients with homonymous hemianopsia indicated a beneficial effect on visual perception of an audiovisual 3D object tracking VR stimulation program using stand-alone VR headsets at home [17,18,25]. We hypothesize that the intervention combining BFT and audiovisual 3D-SOT-VR stimulation may have an additive effect in restitution of visual functions and better visual skills resulting in an improved quality of life.

Methods

Study Design

This study was a 4-week, open-label, reference-controlled, randomized, feasibility, and proof-of-concept trial assessing feasibility (recruitment rates, adoption, adherence and compliance, data collection and retrieval, and safety) and potential effectiveness of BFT+3D-SOT-VR (BFT-VR group) versus BFT (BFT group) on visual perception in individuals with AMD and is reported following the CONSORT eHealth statement for pilot and feasibility studies.

Ethical Considerations

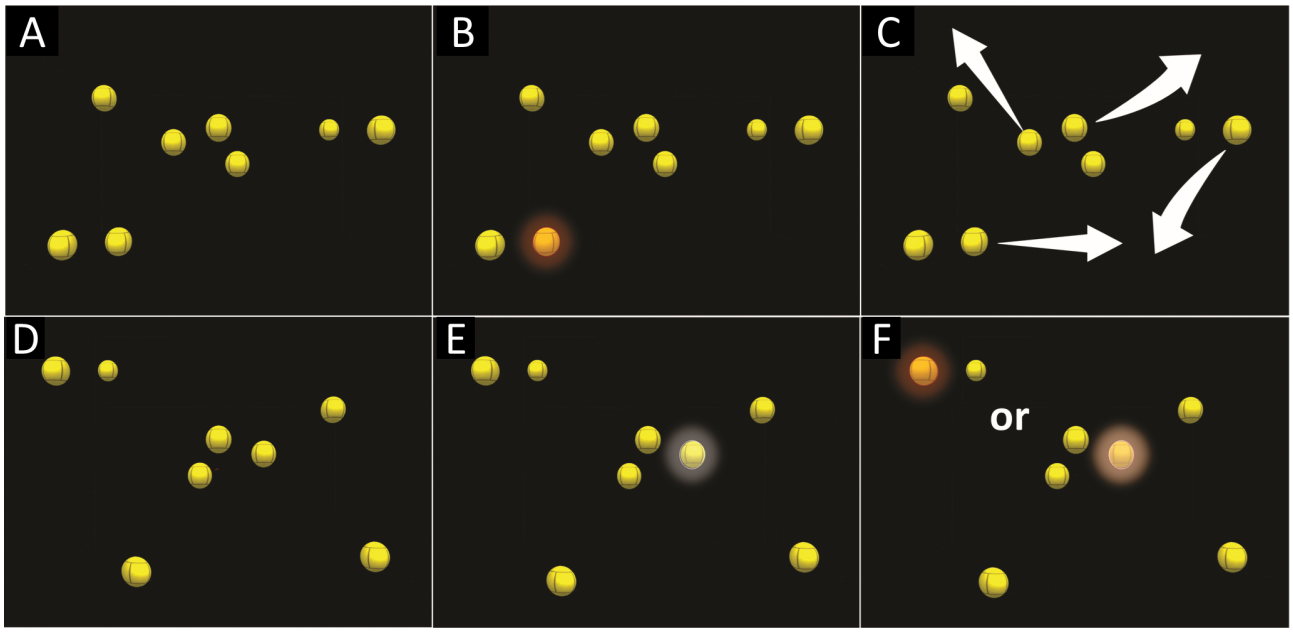
The study protocol has been approved by the Research Ethics Boards at the University Health Network, Toronto, Ontario, Canada (UHN REB# 20‐6143) and registered on ClinicalTrials.gov (NCT04685824; posted on December 28, 2020) following the principles outlined in the World Medical Association Declaration of Helsinki: Research involving human subjects. All participants provided written informed consent before study procedures. The original informed consent allows the secondary analysis without additional consent. Study data were deidentified and pseudonymized for analysis, stored on secure institutional systems, and transmitted through the predefined secure study data management pathway. Participants received US $36 per visit as compensation for commute and parking expenses. No identifiable participant images are included in the paper or multimedia appendices. The study was conducted at the Ophthalmology service, Toronto Western Hospital, University Health Network, Toronto, Ontario, Canada, between September 15, 2021, and October 6, 2023, with multiple interruptions and extensions due to the Ontario Emergency Management and Civil Protection Act related to the COVID-19 pandemic [26].

XSL•FO
RenderX

Participants

The study population included adults with dry AMD from the Toronto Western Hospital pool of patients who were referred by their ophthalmologists. Participants were enrolled by the co-principal investigator ophthalmologist. Inclusion criteria were diagnosed with dry AMD, male and female, VA (best-corrected visual acuity)<0.9 logMAR (logarithm of the minimum angle of resolution), ability to follow the visual and auditory stimuli and training instructions, online auditory test positive (−5 dBHL [decibels hearing level] to 30 dBHL range), home Wi-Fi access. Exclusion criteria were ocular disease not related to AMD physiopathology, wet AMD, both eyes with media opacity that impairs microperimetry testing, inability to perform during testing and training, consumption of psychoactive drugs, three consecutive Virtual Reality-Induced Symptoms and Effects (VRISE) questionnaire scores <25 at inclusion [27], history of vertigo or dizziness, and prior visual rehabilitation interventions.

Randomization and Intervention



Following guidelines for feasibility and pilot studies [28,29], the sample size was determined at 16 participants per arm. The participants were randomized 1:1 (permuted block, block size=2, 4, sealedenveloppe.com generated by the principal investigator) to receive audiovisual monocular (either right -oculus dexter, or left -oculus sinister, eye) BFT for 20 minutes once a week for 4 weeks at Toronto Western Hospital (reference-controlled group, BFT group) as described earlier [7], or audiovisual monocular BFT once a week for 4 weeks and binocular 3D-SOT-VR every other day at home for 4 weeks (interventional group, BFT-VR group), using the stand-alone and remotely controlled head-mounted display Meta Quest 2 (allowing for additional wearing of glasses) provided by our laboratory (Figure 1). Each session of stimulation is composed of three blocks of 15 trials of 20 seconds, equivalent to 3 × 5 minutes of continuous audiovisual stimulation corresponding to 16 sessions for a total time of 3 hours and 15 minutes of stimulation. The audiovisual stimulation task corresponds to the object-tracking paradigm, developed in the 1980s to study visual attention in humans [20,21,30]. The 3D-SOT is composed of eight high-contrast yellow spheres on a black background (luminosity=80 cd/m^2, size=1°-3° of visual angle). After one of the spheres was cued (turning red for 5 s and switching back to yellow; Figure 2), the spheres moved for 20 seconds following random linear paths, bouncing off one another and off the walls of a virtual 3D cube when collisions occurred. The overall span of the movement of the spheres covers 80° and 70° horizontal and vertical visual angles, respectively, as measured using augmented reality and a geometric chart. The initial speed of the spheres was adjustable, from 3 to 240°/second, and determined individually for each participant at inclusion. A spatial sound (125 Hz, 0 - 30 dBHL) is emitted by the cued target and spatially and temporally correlated to its movement. The maximum delay between sound and target is equivalent to the refreshing rate of the headsets, corresponding to 16.6 ms (temporal tolerance), below the 100 ms temporal disparity above which multisensory response enhancement decreases [31]. After 20 seconds, the movement stops and the participants are asked to select, using a virtual laser pointer, the cued sphere (the target) among the other spheres (mark-all procedure) [21]. If the selection is correct (corresponding to the cued target), a positive feedback sound is provided, and the speed of the spheres in the next trial is increased. If the selection is incorrect (corresponding to a distractor), a negative feedback sound is provided, and the speed of the spheres in the next trial is decreased. Speed is modified following an adaptive simple up-down staircase:±0.05 log [32,33]. Participants were allowed to use head and eye movements to track the moving target (overt tracking). During the home-based procedures, head or target position was recorded during the task by the Meta Quest 2 built-in head tracking system (sampling rate 60 Hz) downsampled to 10 Hz for analysis.

Figure 2. Dynamic audiovisual 3D single-object tracking (3D-SOT-VR) stimulation. (A) Eight yellow still spheres are present in a virtual cube. (B) One of these spheres turns red for 15 seconds (cued target) and returns yellow. (C) All spheres randomly move following linear paths across the visual field encompassing the blind field and bouncing off one another and off the walls of the virtual 3D cube when collisions occur. (D) After 30 seconds, spheres stopped moving. (E) The patient had to select the cued target using a hand-guided 32 laser pointer. (F) Correct selection is considered a positive hit.

Outcome Measures

Primary outcomes correspond to feasibility (recruitment rate, dropouts, adoption, adherence, and compliance) and safety (cybersickness). Secondary outcomes correspond to visual function and functional vision measured at the Ophthalmology Low Vision Clinic at the Toronto Western Hospital (University Health Network) following standard procedures in low-vision rehabilitation [5,34]. These visual assessments, blind to the assessor, include VA (best-corrected visual acuity) measured using the Early Treatment Diabetic Retinopathy Study and Colenbrander charts at 4 m; contrast sensitivity measured using the Functional Acuity Contrast Test. Fixation stability (bivariate contour ellipse area 63%) and retinal sensitivity were measured using the Macular Integrity Assessment microperimeter (CentreVue). Reading speed was measured at critical print size using the Minnesota Low Vision Reading test [35]. Quality of vision was measured using the Veterans Affairs–Low-Vision Visual Functioning Questionnaire [36].

Exploratory outcomes in the BFT-VR group corresponded to home-based VR-task performance, including target speed for correct selection, reaction time, head movement, and session time of day. These exploratory variables were collected remotely during the VR task and were used to evaluate operational feasibility and generate mechanistic hypotheses.

Safety, Monitoring, Criteria for Removal, Early Stopping Rules, and Condition of Replacement

Monitoring of the at-home 3D-SOT-VR stimulation program occurred after each 5-minute block when the head-mounted display sent data relative to the participants' adherence and compliance (number of tasks and number of blocks initiated and completed, duration of the blocks or sessions), performance (correct or incorrect selection ratio, reaction time, speed of the target, head movement, and time of day), and safety (VRISE – questionnaire scores before and after intervention) to our secured laboratory computer through Wi-Fi. Criteria for removal and stopping rules were 3 consecutive home-based VRISE scores postintervention ≤25 [27] or no 3D-SOT-VR stimulation reports for 5 consecutive days. There was no replacement for withdrawn participants.

Data and Statistical Analysis

Data analysis of the primary outcomes was performed against predetermined feasibility and safety criteria. Data analysis on secondary outcomes was performed following both intention-to-treat (ITT) and per protocol (PP) methods, based on descriptive statistics including a measure of central tendency (mean) and dispersion (95% CI). Statistical comparisons between groups were performed using the Welch *t* test. Comparisons between pre- and postintervention data were performed using the Wilcoxon signed-rank test. Clinical meaningfulness was determined using the coefficient of repeatability (COR), specific to each test, to compare pre- and postintervention data [37]. The COR, also referred to as the smallest real difference, quantifies absolute reliability in the same unit as the assessment tool. The COR is directly related to the 95% limits of agreement proposed by Bland and Altman [38]. It corresponds to the value below which the absolute differences between two measurements would lie within 95% of probability. Therefore, measurement values strictly different from COR indicate an effect of the intervention [37,39]. Interaction effects were estimated using ANOVA.

Missing Data and Missing Completely At Random Assessment

Missingness was summarized by study arm, visit, and outcome category. Missing data occurred mainly at the participant or visit level because of withdrawal, missed postintervention

XSL•FO
RenderX

assessment, intervention discontinuation, and follow-up loss, rather than as isolated item-level missingness within completed visits. We assessed whether the observed missing data structure was compatible with a Missing Completely At Random (MCAR) mechanism, defined as missingness unrelated to both observed and unobserved data [40]. A formal Little MCAR test was considered [40], but the very small randomized sample, sparse missing data patterns, and number of repeated outcome variables made the test statistically underpowered and not reliably interpretable. Moreover, several missing observations had documented clinical or logistical explanations, making a strict MCAR assumption implausible. Multiple imputation was therefore considered but not implemented because the available sample was too small to support a stable imputation model across multiple outcomes and visits [41]. Analyses were consequently based on available observations, with denominators reported and secondary outcomes interpreted as exploratory.

Results

Feasibility and Safety

Feasibility criteria were defined based on previous studies using VR as an interventional tool [42,43] and CONSORT (Consolidated Standards of Reporting Trials) guidelines for feasibility trials [28]. Of 32 participants determined by power calculation, 18 were screened and 14 randomized in a 1:1 ratio to BFT (n=6) or BFT-VR (n=8; Figure 1 and Table 1).

Table . Participants' demographics.

Group	Sample size, n	Age (years), mean (SD)	Sex ratio	Treatment history
BFT[a]	6	81.5 (5.5)	4F[b], 2M[c]	Last anti-VEGF[d] injection >12 months
BFT-VR[e]	8	83.2 (5.3)	6F, 2M	Last anti-VEGF injection >12 months

[a]BFT: biofeedback training.

[b]F: female.

[c]M: male.

[d]VEGF: vascular endothelial growth factor.

[e]BFT-VR: biofeedback training in immersive virtual reality.

Recruitment rate was below feasibility criteria (≥1.5 participants/week) for both arms, at 0.13 and 0.11 participants/week for BFT-VR and BFT, respectively (Tables 2 and 3). Overall, 6/6 participants (100%) completed the reference-controlled intervention in the BFT arm, and 6/8 participants (75%) completed the investigational intervention in the BFT-VR arm, not reaching feasibility criteria for intervention completion (≥80% of the participants; Table 2). In the BFT-VR arm, 6/8 participants performed 90.6% (87/96) of the home-based scheduled stimulation sessions (45 trials of 20 s), reaching feasibility for adherence and compliance criteria (≥80%). Remote safety and exploratory data collection during the sessions reached the feasibility threshold (≥90%) with 100% of the files collected (96/96) through Wi-Fi, indicating no loss of data. Safety related to the stimulation was assessed using the VRISE questionnaire score, which evaluates cybersickness [27]. VRISE scores post stimulation showed a total average of 33.8 (SD 0.4) out of 35 points, with no scores ≤25 indicating no adverse event (cybersickness symptoms scores criteria ≤3 consecutive VRISE scores ≤25) [27,44] (Table 2). Detailed analysis showed that, for a total of 96 sessions, among the five types of VRISE symptoms (nausea, disorientation, dizziness, fatigue, and instability), fatigue ($\Delta_{post\text{-}pre}$= −0.37, 95% CI −0.46 to −0.28) and dizziness ($\Delta_{post\text{-}pre}$= −0.25, 95% CI −0.16 to −0.34) were the most pronounced symptoms after stimulation, with scores of 6.31 (95% CI 6.11-6.51) and 6.60 (95% CI 6.45-6.75) respectively, although above the cybersickness threshold (Tables 2 and 3).

One drop-out was due to the intervention: the weight of the headset (Meta Quest 2) was reported by the participant as too heavy for the neck muscles, which became sore after the 15-minute session. Usability, measured using a modified version of the virtual reality neuroscience questionnaire [27], showed an overall score >40 above the minimum threshold indicating adequate quality of the software (Table 2). However, three items related to the use of the VR device itself but not to the stimulation, VR device adjustment with straps and pointer use and selection using the remote controller, did not reach the acceptable threshold (Tables 2 and 3), indicating potential interference with the completion of the home-based program.

Preliminary Effect of the Intervention

Effectiveness analyses followed the ITT principle, comprising all 16 randomized participants analyzed as allocated. Because 2 participants in the intervention arm discontinued the program after less than 80% of the sessions and one missed all posttreatment assessments, we prospectively defined a PP set that included participants who attended ≥80% of the sessions and contributed a valid primary-outcome measurement at 4 weeks. Performing both ITT and PP analyses is in line with ICH (International Conference on Harmonisation) E9 guidance (§5.2.3) on assessing the robustness of trial inferences [45], and with CONSORT 2010 recommendations [28] to report numbers analyzed for each set. The PP analysis is reported as a sensitivity check; the ITT analysis remains the primary basis for inference. Clinical relevance was determined using each test's COR; changes exceeding COR are clinically significant [37].

At baseline, groups did not differ in near or distance VA (ITT [Welch t test, 2-tailed]: near VA: $t_{12.1}$=0.75; P=.47; far VA: $t_{15.5}$=0.64; P=.53; PP [Welch t test, 2-tailed]: near VA: $t_{12.9}$=0.80; P=.44; far VA: t_{16}=0.32; P=.75). Post training, no statistically significant group-level gains emerged in either metric, and between-arm (ITT and PP analyses; Tables 4 and

XSL•FO
RenderX

5). Nevertheless, individual COR-positive improvement was observed: 3 of 6 BFT participants improved by ≥0.2 logMAR in near vision and 1 improved for distance; in BFT-VR, 3 of 8 participants showed near-vision gains and 2 showed distance-vision gains. One- and six-month follow-up revealed stable mean acuity but individual fluctuation (Table S1 in Multimedia Appendix 1).

Fixation stability (bivariate contour ellipse area 63%) showed no difference between groups at baseline (ITT: Welsch *t* test: $t_{9.85}$=1.63, *P*=.14; PP: Welsch *t* test: $t_{11.6}$=1.69, *P*=.12). After four weeks, BFT recipients showed no mean change (ITT: Welsch *t* test: $t_{18.1}$=1.37, *P*=.19; PP: Welsch *t* test: $t_{19.5}$=0.86, *P*=.40; Tables 4 and 5) whereas the PP subset of BFT-VR displayed a COR-level worsening (Tables 4 and 5). Individually, two BFT participants worsened (COR>0.61 °^{2}), and one was stable. In the BFT-VR group, three participants had normal fixation stability at baseline and one worsened after intervention (COR>0.61 °^{2}); the others did not show significant changes. Measures at 1- and 6-month post intervention showed no changes (Table S1 in Multimedia Appendix 1).

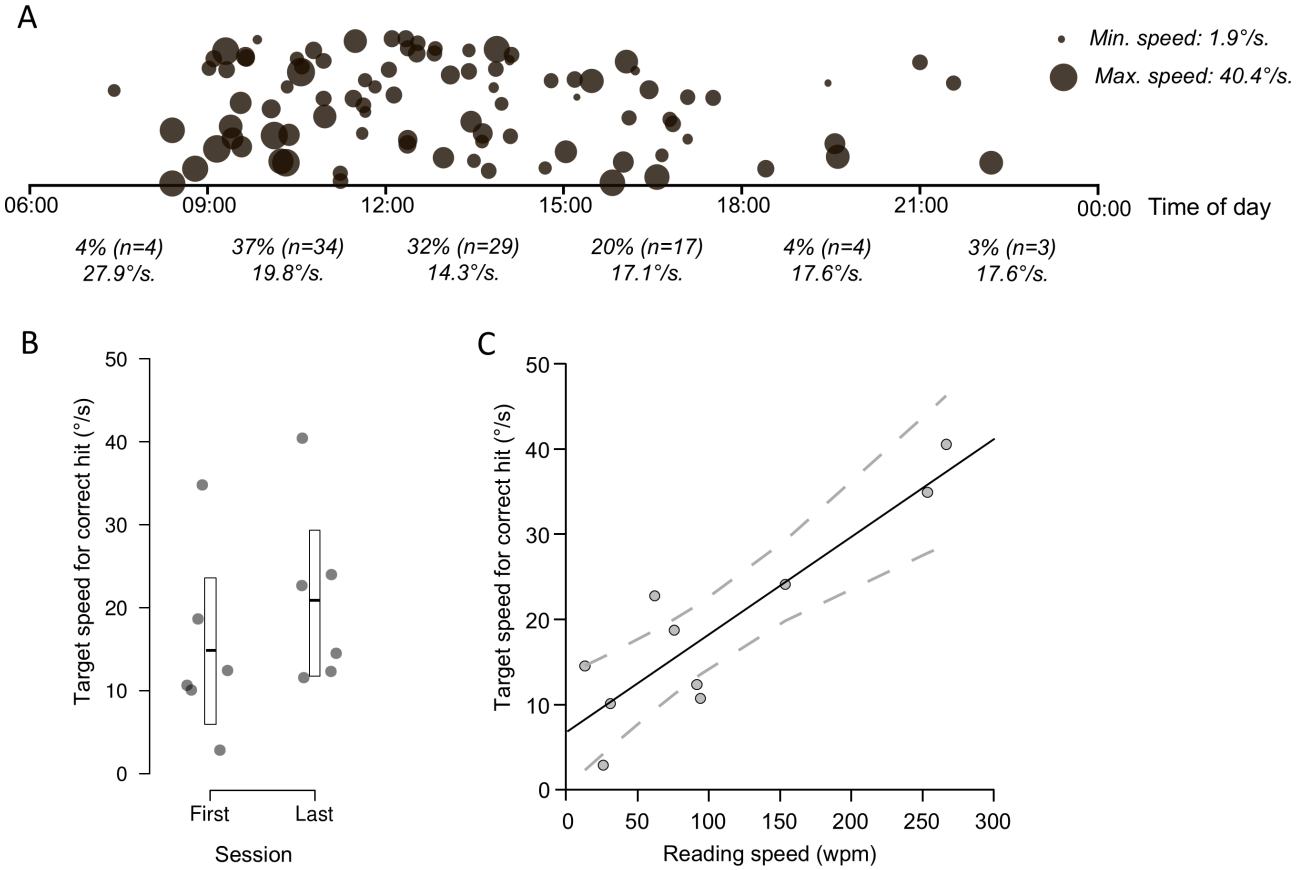
[r]COR: coeficient of repeatability.

Neither baseline group difference (ITT: Welsch *t* test: *t*=1.32, df=19.1, *P*=.19; PP: Welsch *t* test: $t_{19.5}$=1.48, *P*=.17) nor postintervention changes (ITT: Welsch *t* test: $t_{18.5}$=0.87, *P*=.37; PP: Welsch *t* test: $t_{16.1}$=1.50, *P*=.16) reached significance in retinal sensitivity (Tables 4 and 5). Measures at 1- and 6-month post-intervention showed no changes between groups (Table S1 in Multimedia Appendix 1).

Contrast sensitivity was impaired in all participants, across all spatial frequencies at baseline, with no between-group differences (ITT: Welch *t* test, 2-tailed: $t_{12.0}$=0.73, *P*=.48; PP: Welch *t* test: t_9=1.52, *P*=.16). No differences were observed after intervention, nor at 1- and 6-month follow-up (Figure 1 in Multimedia Appendix 2).

Baseline reading speed heterogeneity was large: 2 participants were ≥200 wpm, three ranged 100 - 200 wpm, and the remainder <100 wpm. Group means did not differ initially (ITT: Welch *t* test: $t_{10.6}$=0.42, *P*=.68; PP: Welch *t* test: $t_{7.87}$=0.26, *P*=.79). Data analysis showed no significant difference between BFT and BFT-VR groups in reading speed after intervention (ITT: Welch *t* test: $t_{10.5}$=0.37, *P*=.48; PP: Welch *t* test: $t_{6.12}$=0.84, *P*=.40). Pre- and postintervention analysis showed no statistical difference in the BFT group (ITT and PP analyses; Tables 4 and 5). However, the BFT-VR group showed a clinically significant increase in reading speed after the intervention, above COR (ITT:+13.2, 95% CI −10.8 to 37.3; PP:+21.3, 95% CI −10.1 to 52.6; COR=8.6 wpm). Measures at 1- and 6-month postintervention showed no changes between groups (Table S1 in Multimedia Appendix 1); however, a clinically significant decrease in reading speed was observed between postintervention (117.4, 95% CI 31.7 to 203) and 1-month follow-up (99.2, 95% CI 13.8 to 185; Δ=−18.2, 95% CI -50.7 to 14.3; COR=8.6).



Five domain scores for daily living activities, visual ability, reading, mobility, visual information, and visual motor, and a composite were analyzed. At baseline, no domain differed between arms (Table S1 in Multimedia Appendix 2). After training, both groups exhibited clinically meaningful gains in the reading subscale (BFT:+1.17, 95% CI 0.06 to 2.28; COR>0.44; Table 4) statistically significant for the BFT-VR group (ITT:+0.92, 95% CI 0.17 to 1.66; Wilcoxon ranked test: W=2, n=8, .02<*P*<.05; PP:+0.93, 95% CI −0.20 to 2.07; COR>0.44; Tables 4 and 5). No changes between groups were observed at 1- and 6-month follow-up (Table S1 in Multimedia Appendix 1).

BFT-VR Group: Exploratory Outcomes

The potential use of VR as a home-based interventional tool is very innovative; therefore, data about its use in real-world conditions is lacking. We recorded the time of day when participants who completed the intervention in the BFT-VR group performed the 3D-SOT-VR sessions. Session timestamps revealed that 74% (63/91) were performed between 9 AM and 3 PM (Figure 3A). Average total session duration—pre-VRISE, 3 × 5-min blocks, post-VRISE—was 28 (SD 7) minutes. ANOVA showed no interaction between time of day and tracking performance ($F_{,2}$ =0.38; *P*=.83; Figure 3A).

XSL•FO
RenderX

Figure 3. Exploratory outcomes. (A) Distribution of the session during the day. The size of the circle is correlated to the average speed of the target for a correct answer "ts" during the corresponding session. Percentage and number of sessions during the 3-hour bin are represented with the average speed of the target for a correct answer (=performance). (B) Performance (average speed of the target for a correct answer) at the 3D-SOT-VR (3D single object tracking in immersive virtual reality) stimulation for participants who completed the intervention at the first and last session (n=6). (C) Graph of the correlation between performance (the speed of the target for a correct answer in °/s) as a function of the reading speed (wpm). Pearson R=0.89; P<.001. Max: maximum; Min: minimum; wpm: words per minute.

Participants who completed the intervention (6/8) followed the same 3D-SOT-VR stimulation program for 4 weeks. Aggregate tracking performance increased: mean target speed on correct trials rose from 14.9°/second (95% CI 6.1 to 23.7) at the first session to 20.9°/second (95% CI 12.1 to 29.6) at the final session (Wilcoxon W=1, n=6, .05<P<.10; Figure 3B).

Reading speed was the only functional vision outcome that showed a clinically significant increase in the BFT-VR group, and participants showed variable tracking performance at the 3D-SOT-VR program. We therefore explored whether there is a correlation between the overall tracking performance at the 3D-SOT-VR stimulation and the reading speed. Reading speed correlated strongly with mean 3D-SOT performance (Pearson r=0.89; P<.001) across five participants with complete data (Figure 3C).

Missing Data

Baseline data were complete for the five core clinical outcomes (far VA, near VA, retinal sensitivity, fixation stability, and reading speed). Missingness increased over follow-up, with 5/70 missing data at postintervention, 14/70 at 1-month follow-up, and 25/70 at 6-month follow-up. Little MCAR test on the baseline or postintervention core outcome matrix did not provide statistical evidence against the MCAR assumption (χ^2_5=5.8; P=.33). However, because of the very small sample size and documented reasons for missingness, including missed visits, withdrawal, and follow-up loss, this result was interpreted cautiously and not used as justification for multiple imputation.

Discussion

Principal Findings

This pilot feasibility study is the first to examine the combined use of clinical-based BFT and a tailored, home-delivered 3D-SOT-VR program for older adults with dry AMD. The main finding is one of partial feasibility rather than global feasibility. Adoption, safety monitoring, remote VR data transfer, and adherence among participants who continued the VR program were encouraging. In contrast, recruitment feasibility was not achieved, intervention completion in the BFT-VR arm did not reach the prespecified threshold, and follow-up attrition limited interpretation of longer-term outcomes. Recurrent suspensions under Ontario's Emergency Management and Civil Protection Act between February 2021 and September 2022 hampered the recruitment rate, limited onsite testing capacity, and increased participants' reluctance to travel and come to the hospital, fearing an increased risk of SARS-CoV-2 contamination. Altogether, this resulted in 10-fold slower enrollment than forecast. Similar setbacks have been reported in clinical trials embedded in health care systems during COVID-19 surges [46,47]. Post restriction, participants prioritized family gatherings and reconnecting with close relatives over the study's

XSL•FO
RenderX

requirements, leading to a loss of follow-up and increased no-shows. Nonetheless, the pandemic catalyzed broader public receptivity to digital and remote care solutions, even among older adults traditionally considered technophobic; our 75% completion rate underscores this shift. Previous studies, involving BFT and VR separately in older adults, have shown acceptable recruitment rates [7,10,48], although we cannot fully exclude that the combination of BFT and the audiovisual stimulation in VR might have increased the burden of the intervention.

Importantly, for participants enrolled during reopening periods and randomized in the BFT-VR group, a majority were able to complete the home-based 3D-SOT-VR intervention, in line with other studies indicating adoption of such technology in the older adult population [48,49]. A key benefit of home-based 3D-SOT-VR stimulation is its seamless integration into daily routines, as shown in other groups of participants [19], offering flexible and user-friendly use with reliable data transfer. Such benefits are even more important in the recent context of the pandemic, with the difficulty of travel, staff shortages, and related restrictions, as patients were unable to receive their treatment without delays. If VR potentially represents an adequate platform to deliver a visual rehabilitation program at home [18,19], it requires some adjustments tailored to the target population, especially older adults. Headset adjustments using straps and remote controllers seem to be troublesome for this population, hampering a full adoption or completion of the VR interventions.

Group-level VA, fixation stability, retinal sensitivity, contrast sensitivity, and quality-of-life estimates were imprecise and showed no consistent between-group benefit. Reading speed showed a clinically and statistically significant increase in the BFT-VR group, whereas no improvement was observed in the BFT, in contrast to previous studies [7,9,50,51]. Correspondingly, meaningful improvements were observed in patient-reported quality of vision questionnaires related to reading abilities in both groups. Individual reading-speed improvement in the BFT-VR group and its association with VR-task performance are potentially informative but should be interpreted as hypothesis-generating. A plausible mechanism is that dynamic target tracking may train visual attention, gaze allocation, head-eye coordination, and use of residual peripheral vision during eccentric viewing. However, the study did not directly measure PRL relocation stability, reading eye movements, cortical plasticity, or neural adaptation; therefore, the mechanism remains speculative. An important variable is the number of sessions of BFT delivered and total time of BFT. There is still no consensus on ideal exposure time for an optimal result [4], and previously we obtained significant improvement in visual functions and quality-of-life questionnaire using this scheme of four weekly sessions of 20 minutes (80 min in total) [7]. However, in a recent study that used two different intervals, 150 minutes in total delivered daily or on alternate days over 15 sessions, a statistically significant improvement was observed in VA, reading speed, fixation stability, and self-referred quality-of-life questionnaire in both groups [13]. The decrease in reading speed between postintervention and 1-month follow-up suggests that the short 4-week VR program may not be sufficient to induce sustained functional gains. This finding is compatible with clinical observations that patients may revert to less efficient viewing strategies after supervised rehabilitation if the trained strategy is not reinforced. It does not prove that indefinite treatment is required. Instead, future studies should test longer initial training, lower-burden maintenance sessions, or scheduled booster periods, while measuring whether PRL use and oculomotor behavior are stabilized over time.

The every-other-day schedule was chosen as a pragmatic compromise between repetition and tolerability. Weekly VR exposure was considered unlikely to add sufficient training beyond conventional weekly BFT, whereas daily exposure could increase fatigue, cybersickness risk, and nonadherence in older participants [48,49]. Future trials should include dose-finding components to compare training frequency, total exposure, and maintenance schedules. Such trials should also predefine whether the intended effect is short-term compensatory improvement, durable functional adaptation, or ongoing supportive therapy.

The ergonomics findings are clinically important. One participant discontinued the intervention because of headset weight and neck fatigue, and usability items related to headset adjustment and pointer selection were below threshold. This indicates that future implementation should prioritize lighter devices, improved weight distribution, simplified straps, larger and more accessible interfaces, gaze-based or controller-free selection, caregiver-assisted onboarding when needed, and remote troubleshooting. These design changes are particularly relevant for older adults with low vision, who may also have reduced manual dexterity, neck discomfort, or lower familiarity with immersive technologies [48,49].

Limitations

The major limitation is the small sample size. Recruitment and study conduct were heavily disrupted by the COVID-19 pandemic and associated restrictions in Ontario, producing a marked reduction in recruitment compared with the prespecified criterion. As a consequence, the planned target of 32 participants was not reached, the precision of all secondary estimates was low, and between-group comparisons should not be interpreted as evidence for or against clinical effectiveness.

Additional limitations include open-label design, possible selection bias toward motivated participants who were willing to use VR at home, incomplete follow-up, and missing data that were not demonstrably MCAR. Because missingness was partly attributable to withdrawal, missed assessments, device burden, and follow-up loss, available-case analyses may be biased. Multiple imputation was not used because the sample size and sparse missing data structure would make imputation unstable and potentially misleading. The trial also did not include mechanistic measures of PRL use during reading, fixation strategy outside microperimetry, or neural adaptation, limiting interpretation of the reading-speed signal.

Taken together, these limitations mean that this study should be viewed as a formative feasibility trial. It identifies safety, remote monitoring, adherence among users, and preliminary functional signals that justify further study, but it also identifies

XSL•FO
RenderX

recruitment, retention, missing data, long-term durability, and device ergonomics as barriers that must be solved before a definitive randomized trial.

Conclusions

In conclusion, home-based VR visual stimulation combined with clinic-based BFT can be deployed safely in selected older adults with dry AMD and can generate objective remote adherence, safety, and performance data. The approach differs from conventional low-vision rehabilitation by moving part of the intervention into the home while retaining clinical supervision and remote monitoring. These results should not be interpreted as evidence of effectiveness; rather, they define the operational requirements for the next phase of research. Future trials should use optimized lightweight hardware, simplified interaction, larger multicenter recruitment, predefined missing-data handling, dose-finding of VR exposure, and mechanistic endpoints such as PRL stability, eye and head tracking, and reading-related oculomotor behavior.

Acknowledgments

We thank the participants for their motivation and commitment. We thank NeuropowerTrain for their help with the initiation of this study. During revision, the authors used a generative AI tool to assist with language editing and clarity of phrasing. All scientific content, interpretation, statistical decisions, and final text were reviewed and approved by the authors. No generative AI tool was used to generate data, perform statistical analyses, or replace scientific judgment.

Funding

This work was supported by the Krembil Collaborative Seed grant at University Health Network (MR and SNM) and by the University Health Network Foundation (MR). The funders had no role in study design, data collection, analysis, interpretation, manuscript preparation, or the decision to submit the manuscript for publication.

Data Availability

Deidentified data generated or analyzed during this study are included in this published article and its supplementary information files.

Authors' Contributions

YP, BZ, MM, MDN, AS, DT, and KC collected the clinical data. BZ, KC, and MR collected and analyzed the exploratory data. MDN, SNM, and MR analyzed the clinical data. MDN, LA, SNM, and MR designed the study. EGG and PN developed remote data collection in VR. MDN, SNM, LA, and MR wrote and edited the manuscript.

Abstract

Background: Telerehabilitation is a safe and effective means of delivering physiotherapy services, but implementation in clinical practice has not been widespread.

Objective: This study aimed to explore the shifts in telerehabilitation use throughout the COVID-19 pandemic and the key factors that influenced telerehabilitation caseload after restrictions were eased.

Methods: Between September and November 2023, physiotherapists practicing in Australian private practice, hospital outpatient, or community settings completed an online survey. Data were collected regarding participants' use of telerehabilitation before, during, and after the COVID-19 pandemic restrictions to in-person physiotherapy. Qualitative content analysis of open-text questions was performed to garner more nuanced information about the use of telerehabilitation in clinical practice, and quantitative data were analyzed descriptively.

Results: The proportion of participants using telerehabilitation rose from 30% (44/148) before the pandemic to 94% (138/147) when restrictions to in-person physiotherapy were in place. Although 82% (118/144) of the sample continued to deliver telerehabilitation after COVID-19 restrictions were eased, telerehabilitation accounted for only 14% of the total caseload. Exploratory analyses suggest that despite increased confidence, satisfaction, and perceptions about the effectiveness of telerehabilitation, reduced patient demand, physiotherapists' perceptions about patient preference for in-person consultations, and the perception that in-person physiotherapy is easier continue to influence the use of telerehabilitation in the post-COVID era.

Conclusions: Despite increased uptake during the pandemic, telerehabilitation caseload after restrictions were eased was low. Physiotherapists' perceptions about telerehabilitation in clinical practice remain a substantial barrier to sustained adoption.

Introduction

Background

Evidence suggests that telerehabilitation is a safe, feasible, and effective means of delivering physiotherapy care that is at least as good as in-person physiotherapy in terms of patient outcomes [1,2]. Despite two decades of evidence supporting the effectiveness of telerehabilitation in the management of musculoskeletal [3], neurological [4], cardiorespiratory [5], and postsurgical rehabilitation [6], clinician acceptance and adoption have been low [7]. While telerehabilitation is a viable alternative to traditional in-person physiotherapy with the potential to overcome geographical barriers, improve access, and facilitate continuity of treatment, integration into routine physiotherapy practice before the COVID-19 pandemic remained limited [8].

Before the COVID-19 pandemic, physiotherapists were slow and reluctant to adopt telerehabilitation as a standard model of care [9,10]. Several barriers contributed to this limited uptake of telerehabilitation in physiotherapy practice, including limited acceptance of and low confidence in using telehealth technology,

XSL•FO
RenderX

perceived limitations in conducting physical assessments remotely, and reduced capacity to deliver hands-on interventions that are central to traditional physiotherapy practice [8,11,12]. Additional challenges included perceptions that telerehabilitation was less effective for certain clinical presentations and concerns about developing rapport and patient engagement [11,12].

The COVID-19 pandemic brought unprecedented challenges to health care systems worldwide, including the delivery of physiotherapy services. In response to the pandemic-related restrictions on in-person consultations, many physiotherapy practices turned to telerehabilitation [13] as an alternative method to continue providing necessary care [14]. Although physiotherapy was recognized as an essential health care service in Australia during the COVID-19 pandemic, practice was still notably restricted. Stringent infection control measures, such as mandatory use of personal protective equipment, rigorous patient screening, physical distancing requirements, density limits within clinical spaces, and group size limitations on group therapy sessions [15], impacted the delivery of care across multiple clinical settings. During initial lockdowns, some states, such as Victoria, further restricted in-person physiotherapy services, permitting face-to-face consultations only for urgent cases [16]. Community and aged care physiotherapy faced further barriers, including restrictions on therapists attending multiple sites and outright bans on external providers entering residential facilities [17]. Consequently, physiotherapy practice during the pandemic was markedly disrupted, forcing providers to rapidly transition to providing telerehabilitation services to adhere to public health guidelines and ensure continuity of care.

With the rapid transition to telerehabilitation in response to the pandemic came changes in regulatory frameworks to fund telerehabilitation [18], position statements advocating for the use of telerehabilitation [19], and increased infrastructure and clinical training to support the integration of telerehabilitation into clinical care [20]. During this period, uptake of telerehabilitation increased substantially, reflecting the necessity to maintain continuity of care. Research conducted at the time suggested that physiotherapists intended to continue offering services via telerehabilitation after the easing of restrictions to in-person physiotherapy [20,21]. However, international evidence suggests that uptake and usage have generally decreased from the pandemic peak [22].

Objectives

With the rapid transition to telerehabilitation in response to the pandemic came changes in regulatory frameworks to fund telerehabilitation [18], position statements advocating for the use of telerehabilitation [19], and increased infrastructure and clinical training to support the integration of telerehabilitation into clinical care [20]. During this period, uptake of telerehabilitation increased substantially, reflecting the necessity to maintain continuity of care. Research conducted at the time suggested that physiotherapists intended to continue offering services via telerehabilitation after the easing of restrictions to in-person physiotherapy [20,21]. However, international evidence suggests that uptake and usage have generally decreased from the pandemic peak [22].

The aim of this study was to investigate the use of telerehabilitation in Australian physiotherapy clinical practice throughout the COVID-19 pandemic, with a focus on telerehabilitation use after restrictions were eased.

The specific research questions for this study were as follows: (1) How did the use of telerehabilitation vary in physiotherapy clinical practice in Australia before, during, and after COVID-19 restrictions to in-person consultations? and (2) What are the key factors that influence physiotherapists' telerehabilitation caseload in the postrestrictions period?

Methods

Design

A descriptive, cross-sectional survey was conducted online with physiotherapists currently practicing in Australia. The study was primarily quantitative, with a small qualitative component to supplement descriptive analyses.

Ethical Considerations

The study was approved by The University of Queensland Human Research Ethics Committee (approval number: 2023/HE001802) and reported following the consensus-based CROSS (Checklist for Reporting of Survey Studies) [23]. Participants provided electronic informed consent after reviewing an information sheet and before completing the survey. Participants were entered into a draw for a AUD $1000 (US $667) gift voucher upon completion of the survey. Participants' privacy and confidentiality were maintained by storing nonidentifiable survey data separately from contact details on the University of Queensland Research Data Management System.

Participants

Participants were physiotherapists recruited from the community via online advertisements on social media (eg, Facebook, X, and LinkedIn), via targeted emails, and through Australian Physiotherapy Association member communications (eg, eComms). Physiotherapists were eligible to participate if they were registered with the Australian Health Practitioner Regulation Agency and currently practicing in an Australian private practice, hospital, or community setting. Participants who had not delivered telerehabilitation services were eligible to complete a short version of the questionnaire to explore reasons for not engaging with telerehabilitation and the circumstances that might influence uptake.

Procedure

An online survey was designed to capture information that was relevant to stakeholders and ensure readability and credibility (Multimedia Appendix 1). The survey was developed by the authors using Bennell [20] as a guide and adapted to capture information relevant to the different phases of the COVID-19 pandemic restrictions. The 3 phases were "Prior to the pandemic restrictions," "During the period of restrictions to in-person physiotherapy" (from the introduction of restrictions in 2020 to 2022), and "After restrictions were eased" (2022 onward). Questions were primarily multiple choice (checkbox questions), numerical rating scales (0 - 10), and 5-point Likert scales.

XSL•FO
RenderX

Respondents were asked to estimate their telerehabilitation caseload (individual video, group video, and telephone) for each phase using a sliding scale (0% - 100%). Free-text responses were sought for some questions to ascertain more nuanced and in-depth information about physiotherapists' perceptions of using telerehabilitation in clinical practice.

The survey was administered via an online secure platform (Qualtrics, LLC) and hosted by The University of Queensland. Participants were first invited to complete the online consent form and screening and, if eligible, proceeded to the survey. Participants were asked to provide demographic information, details of clinical practice, and experience with telerehabilitation. The second primary section of the survey comprised questions pertaining to the use of telerehabilitation during each phase of the COVID-19 pandemic restrictions (before, during, and after). All data were collected between September 15 and November 8, 2023.

Data Analysis

Data were exported from the online platform for analysis in R (version 4.3.3; R Core Team). Descriptive statistics, including frequencies (percentages) and means and standard deviations, were used to summarize the data. All responses (including partial responses) meeting eligibility criteria were included in analyses. When an "other" field was provided for additional response options, 2 researchers reviewed free-text responses and either aligned them with existing response options or designated them as unique responses that were added to the final list of response options. Any discrepancies in coding were resolved via discussion.

Responses to free-text questions were analyzed qualitatively using inductive content analysis in Microsoft Excel [24]. First, 2 researchers (MHR and JS) independently read the entire dataset, conducted open coding, and identified topics and initial patterns. The unit of analysis was meaning units, identified within individual responses. Codes were subsequently categorized and combined to form main categories or themes (abstraction), with both authors returning to the dataset to check that codes made sense in relation to the raw data. The 2 authors then met to compare and discuss their coding frameworks, and discrepancies were resolved through discussion. An audit trail was maintained to document coding decisions and category development. Themes with the highest number of individual data points were identified, reported, and described. To enhance trustworthiness, reflexivity was considered throughout the process, and attention was paid to credibility and transparency in coding and interpretation.

To explore which factors influenced physiotherapists' use of telerehabilitation in the postpandemic restrictions period, the total proportion of videoconferencing telerehabilitation caseload (individual and group consultations) was examined. Specifically, this proportion was plotted against the following five key postpandemic variables: confidence, satisfaction, and perceived effectiveness of telerehabilitation; physiotherapists' perception about how much patients like telerehabilitation; and how often patients are requesting it. Locally estimated scatterplot smoothing curves were fitted using the full span of the data (span=1). These smoothed trends, along with their corresponding 95% CIs, were used to visually explore apparent associations. No statistical correlation or regression analyses were performed on these trends.

Results

Sample Characteristics

A total of 222 physiotherapists responded to the survey, with 152 (68%) meeting eligibility criteria and providing sufficient data to be included in analyses (58/222, 26%, excluded for not being an Australian Health Practitioner Regulation Agency–registered physiotherapist currently practicing in an eligible setting [eg, private practice, hospital outpatient, or community] and 12/222, 5% not providing sufficient data to determine eligibility). Most participants (107/152, 70%) completed the survey in less than 20 minutes.

Respondents were primarily women (87/152, 57%); working in musculoskeletal (105/152, 69%) private practice (84/152, 55%) in Queensland (42/152, 28%), Victoria (42/152, 28%), or New South Wales (38/152, 25%); and held either a Bachelor's (70/152, 46%) or Master's (58/152, 38%) degree in physiotherapy. Physiotherapists primarily used Zoom (66/142, 47%), a telephone (59/142, 42%) or Microsoft Teams (47/142, 33%) to conduct telerehabilitation consultations. Only 40% (n=56) of respondents indicated that they had participated in telerehabilitation training. Additional participant characteristics are provided in Table 1.

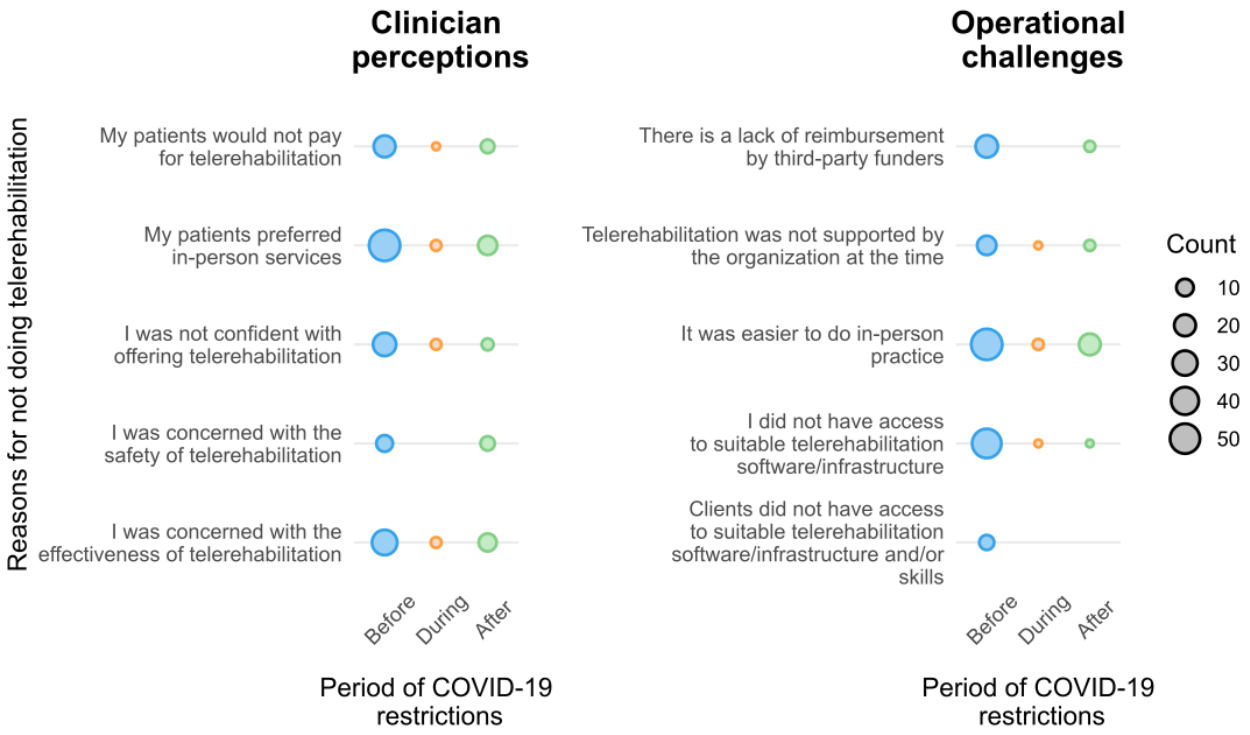
Shifts in Telerehabilitation Use Through the Phases of the COVID-19 Pandemic

Thirty percent (44/148) of respondents indicated that they were using telerehabilitation in clinical practice before the pandemic. This rose to 94% (138/147) during the period of COVID-19 restrictions and reduced to 82% (118/144) after restrictions were lifted. Only 3% (4/152) of the sample indicated that they had never provided telerehabilitation consultations (individual or group videoconferencing, or telephone consultations). Total telerehabilitation caseload rose to account for almost 47% of the total caseload during the period of restrictions but dropped substantially to 14% once restrictions were lifted, but still remained above the prepandemic level of 4% (Figure 1). This pattern was fairly consistent across areas of practice over the COVID-19 pandemic (Figure S1 in Multimedia Appendix 2).

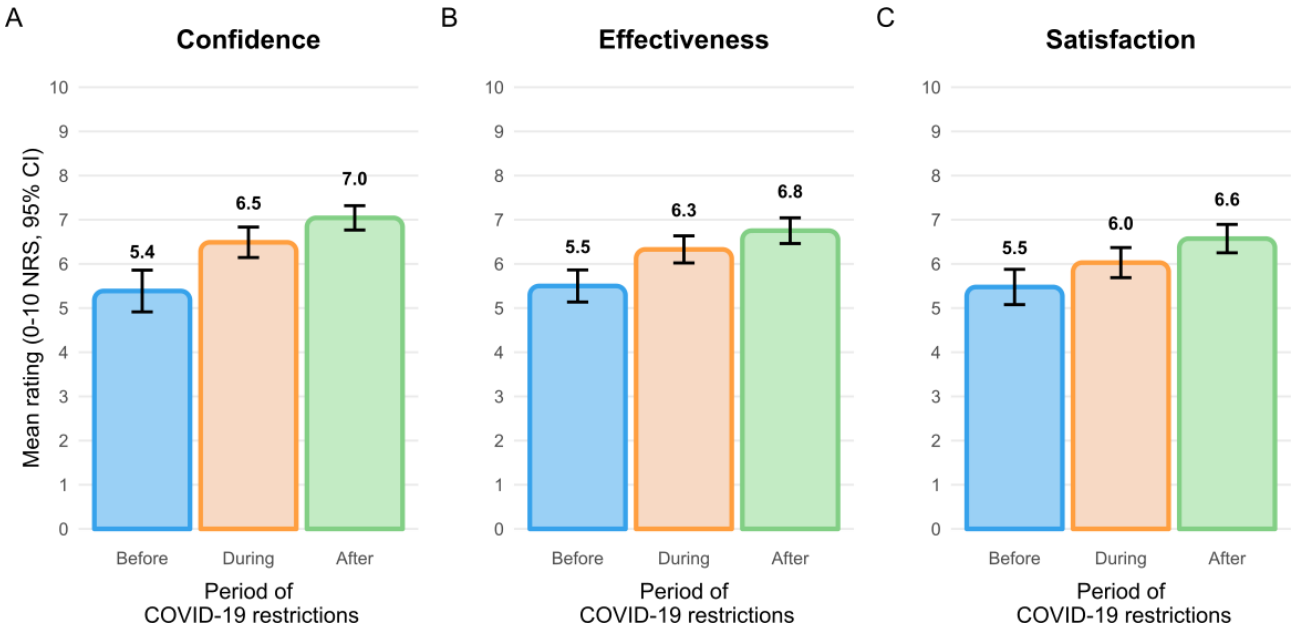


Reasons for not providing telerehabilitation consultations during each phase of the pandemic are provided in Figure 2. Across all 3 phases, the primary reasons were the perception that patients prefer in-person consultations (83/139, 60%) and that it was easier to do in-person consultations (55/139, 55%; Figure 2).

Figure 1. Shift in estimated telerehabilitation caseload before, during, and after the COVID-19 pandemic restrictions (values <2% are plotted without labels).

XSL•FO
RenderX

Figure 2. Reasons for not providing telerehabilitation throughout the phases of the COVID-19 pandemic, grouped by clinician perceptions and operational challenges. The area of circles represents the total count of respondents listing that reason for that point in time.



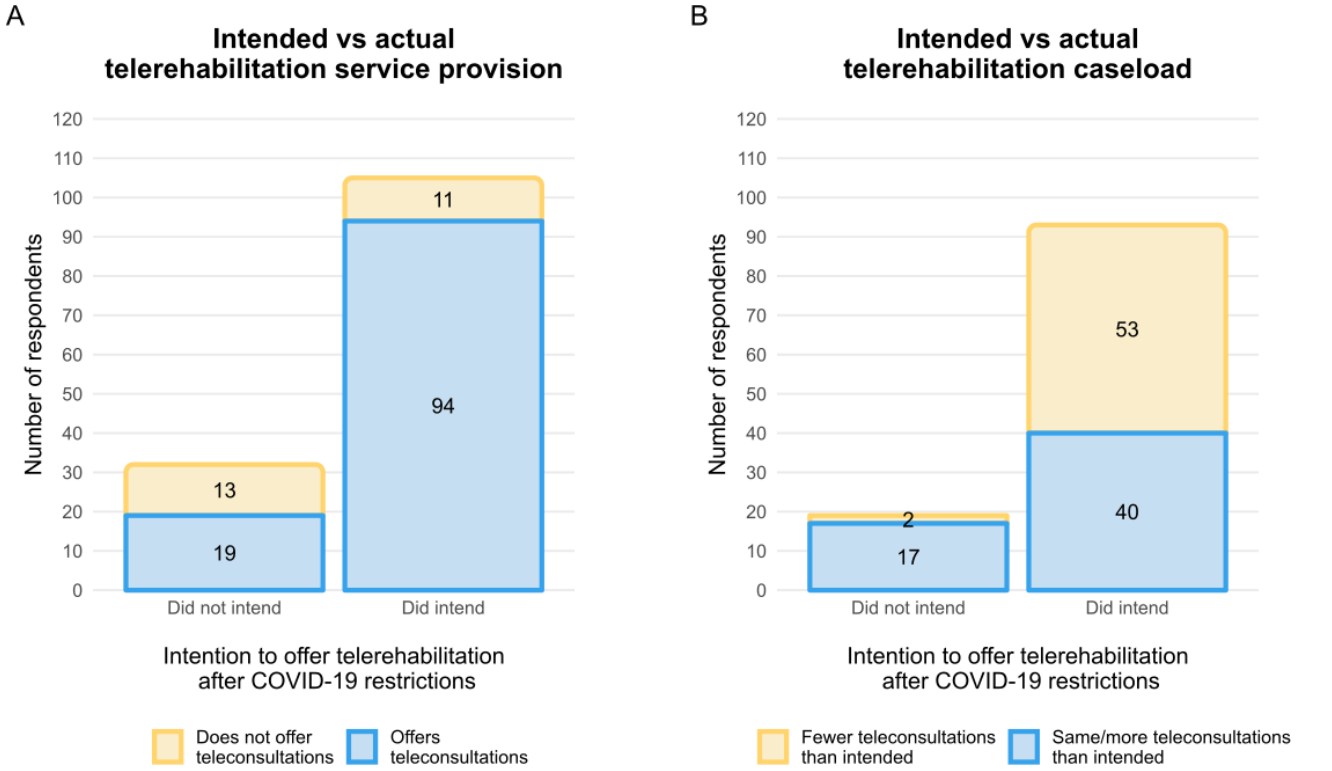
Before the pandemic, additional reasons for not offering telerehabilitation were primarily the perception that there was no need for telerehabilitation (57/104, 55%) or that physiotherapists did not have access to suitable telerehabilitation software or infrastructure (47/104, 45%; Table S1 in Multimedia Appendix 3). After restrictions were eased, the primary reasons for not providing telerehabilitation services were that respondents were concerned about the effectiveness of telerehabilitation (13/26, 50%) and did not like providing care via telerehabilitation (11/26, 42%; Table S1 in Multimedia Appendix 3).

Shifts in Confidence, Effectiveness, and Satisfaction With Telerehabilitation

Physiotherapist ratings of confidence in providing care via telerehabilitation, perceived effectiveness of telerehabilitation, and satisfaction with telerehabilitation progressively increased from before, during, to after restrictions associated with the COVID-19 pandemic (Figure 3). Almost 85% (120/142) of respondents indicated that providing telerehabilitation had become easier over time.

XSL•FO
RenderX

Figure 3. Participant ratings of (A) confidence, (B) perceived effectiveness, and (C) satisfaction with telerehabilitation across the pandemic. NRS: numerical rating scale.



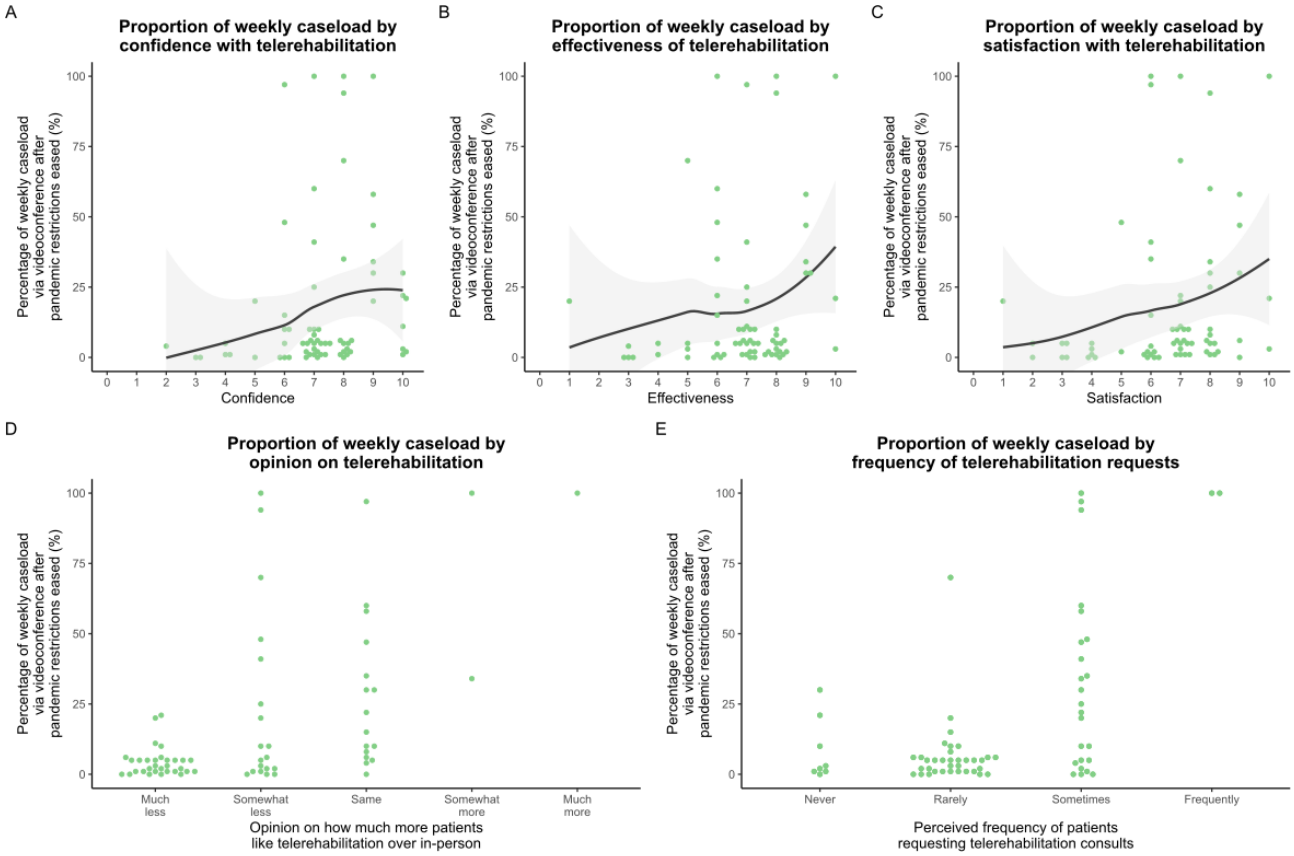
Intended Versus Actual Telerehabilitation Use

Most respondents (105/137, 77%) intended to offer telerehabilitation after the easing of COVID-19 restrictions (Figure 4). Of these, only 10% (11/105) did not offer telerehabilitation despite intending to do so (Figure 4A). Primary reasons for not intending to offer telerehabilitation were because it was "easier to do in-person" (23/32, 72%) and because "patients prefer in-person" (22/32, 69%; Table S2 in Multimedia Appendix 3). Of those who did not intend to, more than half (19/32, 59%) did continue to offer telerehabilitation after restrictions were eased (Figure 4A). Approximately 50% of respondents who intended to continue offering telerehabilitation consultations (53/93) or who actually continued offering them (58/118) after restrictions were eased were providing fewer consultations than initially intended (Figure 4B). Respondents indicated that this was because patients "prefer in-person services" (44/58, 76%), "patient demand reduced more than expected" (32/38, 55%) and because it was "easier to do in-person consultations" (27/38, 47%; Table S3 in Multimedia Appendix 3). Primary reasons for continuing to offer telerehabilitation services included that telerehabilitation allowed physiotherapists to offer services to patients who would not usually be able to attend their clinic (84/118, 71%), that patients like the option of receiving care via telerehabilitation (76/118, 64%), and that patients find telerehabilitation convenient (74/118, 63%; Table S4 in Multimedia Appendix 3).

XSL•FO
RenderX

Figure 4. Intended versus actual telerehabilitation service provision and caseload. (A) Number of respondents who intended to offer telerehabilitation after easing of pandemic restrictions compared to whether they do offer telerehabilitation now. (B) Number of respondents who intended to offer telerehabilitation after easing of pandemic restrictions compared to whether the frequency of telerehabilitation met intentions.

Factors That Influence Telerehabilitation Use Postpandemic Restrictions



Positive correlations were noted between a higher proportion of weekly caseload conducted via telerehabilitation and higher ratings of confidence in using telerehabilitation (Figure 5A), perceived effectiveness of telerehabilitation (Figure 5B), and satisfaction with telerehabilitation (Figure 5C).

Almost half of the respondents (69/142, 49%) indicated that patients were “rarely” requesting telerehabilitation since the easing of restrictions, and in the opinion of approximately half of the respondents (70/142, 49%), patients like telerehabilitation “much less than in-person consultations.” Physiotherapists who believed that patients liked telerehabilitation much less than in-person consultations appeared to have a lower proportion of their weekly caseload conducted via telerehabilitation (Figure 5D). Similarly, physiotherapists who reported that their patients requested telerehabilitation at least sometimes seemed more likely to have a higher proportion of weekly cases conducted via telehealth (Figure 5E).

The median (IQR) percentage of patients considered unsuitable for telerehabilitation by the respondents was 50.5% (50). Patient complexity and conditions requiring hands-on treatment were the primary reasons that patients were “often” considered unsuitable (Figure S2 in Multimedia Appendix 4 and Table S5 in Multimedia Appendix 3). Additional reasons respondents provided for deeming patients unsuitable are provided in Table S6 in Multimedia Appendix 3, with the largest proportion being patient preference for in-person consultations (6/30, 20%), physical examination being indicated (4/30, 13%), and complex patient presentations (6/30, 14%).

XSL•FO
RenderX

Figure 5. noTotal weekly telerehabilitation caseload versus (A) confidence, (B) effectiveness, (C) satisfaction, (D) patient liking for telerehabilitation, and (E) patient requests for telerehabilitation. Dark gray lines represent locally estimated scatterplot smoothing fits (using the whole span of the data) with 95% CIs (light gray shading).

Telerehabilitation Clinical Practice Considerations

Although only 5% (8/142) of respondents reported never experiencing technical issues themselves, most (120/142, 84%) indicated encountering these issues rarely or sometimes, and just 9% (14/142) experienced them often. Likewise, only one respondent (1/142, 1%) reported that their patients had never encountered technical issues, whereas the majority (112/142, 79%) reported that patients experienced technical issues rarely or sometimes, and 19% (29/142) reported that patients often experienced technical issues. When technical issues were encountered, 74% (105/142) reported only moderate or less disruption to the consultation. Only 5% (7/142) reported that technical issues were extremely disruptive, and just 4% (6/142) reported often having to cancel or reschedule appointments due to technical issues (Figure S3 in Multimedia Appendix 5). To support the delivery of telerehabilitation consultations, physiotherapists used text message reminders (109/142, 77%); written or digital educational material about the condition (67/142, 47%); and written instructions, diagrams, or booklets (63/142, 44%; Table S7 in Multimedia Appendix 3).

Almost three-quarters (104/142, 73%) of respondents indicated that they used similar parameters of care for telerehabilitation as for in-person consultations (eg, similar consultation frequency, duration, and similar content). For the respondents indicating that parameters of care were different (38/142, 27%), the primary reasons were that physical assessment or treatment was limited via telerehabilitation (15/38, 39%), consultations were shorter (10/38, 26%), and consultations were more focused on exercise or education (8/38, 21%). Additional reasons are provided in Table S8 in Multimedia Appendix 3. Similarly, most respondents (128/142, 90%) indicated that telerehabilitation consultations were about the same duration or shorter than in-person consultations (Table S9 in Multimedia Appendix 3) and that consultation frequency was "about the same" as in person (72/142, 51%) or less often than in person (53/142, 37%; Table S9 in Multimedia Appendix 3).

Considering the cost of telerehabilitation consultations, almost three-quarters of physiotherapists indicated that they charged "about the same" as an in-person consultation (104/142, 73%), with very few respondents (5/142, 4%) charging more than in-person consultations. Responses about the cost to the business of providing telerehabilitation were similar, with 50% (71/142) of respondents considering telerehabilitation to cost about the same and 36% (51/142) indicating that telerehabilitation consultations cost the business less than in-person consultations (Table S9 in Multimedia Appendix 3).

The median proportion of patients offered hybrid care in a current weekly caseload was 5% (minimum=0, Q1=1, Q3=20, maximum=100). In hybrid models of care, 42% (48/113) of physiotherapists indicated that patients typically receive many more in-person than telerehabilitation consultations, 27% (30/113) receive the same, and 18% (21/113) receive fewer in-person visits compared to telerehabilitation consultations (Table S9 in Multimedia Appendix 3). Other ways in which telerehabilitation models of care differ from in-person models were coded qualitatively and provided in Table S10 in

XSL•FO
RenderX

Multimedia Appendix 3. When respondents used a hybrid model, 27% (8/27) offered telerehabilitation only after an initial in-person consult, 15% (4/27) described limiting the physical assessment or treatment component of consultations, and 11% (3/27) said telerehabilitation consultations in hybrid models had a greater case management focus (3/27, 11%).

Inductive content analysis of free-text responses identified four key themes that reflected respondents' perspectives on using telerehabilitation in clinical practice postpandemic (Table S11 in Multimedia Appendix 3): (1) concerns about telerehabilitation, (2) perceived benefits of telerehabilitation, (3) how telerehabilitation is used in practice, and (4) physiotherapists' willingness to provide telerehabilitation services.

Theme 1: Concerns About Telerehabilitation (n=28)

Physiotherapists expressed a range of concerns about the suitability and practicality of telerehabilitation in postpandemic physiotherapy care. The most commonly reported issue was that clients prefer or actively seek in-person consultations (n=12, 43%). For example, one participant said that despite telerehabilitation remaining available for their patients, they "*often prefer face-to-face*" and that "*people wanted to revert back to the 'usual' ways and leave the changes of COVID behind them moving forward once restrictions eased*" (musculoskeletal physiotherapist). Some respondents (n=4, 14%) emphasized that telerehabilitation is not suitable for all clients, particularly those with complex conditions, communication difficulties, or low digital literacy, and that they were selecting suitable clients for telerehabilitation, and "*not offering [it] for those not 'tech-savvy'*" (neurological physiotherapist). Concerns were also raised about the limitations of assessment via videoconference (n=2, 7%) and challenges related to internet connectivity and software reliability (n=3, 11%). Additional issues included payment and reimbursement barriers (n=2, 7%), difficulties building rapport remotely (n=2, 7%), and reduced referrals and attendance for telerehabilitation compared to in-person care.

Theme 2: Perceived Benefits of Telerehabilitation (n=20)

Despite concerns, respondents acknowledged several advantages of using telerehabilitation in their clinical practice postpandemic restrictions. The most frequently cited benefit was that telerehabilitation improved patient access to care, particularly for those in rural or remote areas or those with difficulties with travel or limited time (n=8, 40%). One musculoskeletal physiotherapist said that telerehabilitation "*has made physiotherapy much more accessible to a wider population and allows people greater flexibility with appointments*." Participants also noted an increased acceptance of telerehabilitation (among patients and providers; n=6, 30%), with some suggesting that it "*has become common practice now*" (musculoskeletal physiotherapist) and that it can be effective for certain presentations (eg, chronic musculoskeletal conditions; n=3, 15%), for supporting patient self-management (n=2, 10%) and providing greater flexibility in service delivery (n=1, 5%).

Theme 3: How Telerehabilitation Is Used in Practice (n=8)

Participants described integrating telerehabilitation into their clinical practice for subsequent consultations following initial in-person visits (n=2, 25%), for triaging (n=1, 12.5%) and case management (n=1, 12.5%), and as a tool for exercise prescription (n=1, 12.5%). Some participants (n=2, 25%) indicated that videoconferencing was preferred over telephone, and 1 (12.5%) participant noted that at times additional support is required at the patient end to effectively deliver telerehabilitation services. One cardiorespiratory, hospital-based physiotherapist described that telerehabilitation "*consultations have been effective in triaging patients and determining the appropriate level of care required*," whereas another described that telerehabilitation "*has been a great option for follow-up appointments, especially when you have already build rapport with patients...[and it]...has been a great way to check in with people who have busy schedules or live far away and find it difficult coming in*" (pelvic health and musculoskeletal physiotherapist).

Theme 4: Physiotherapists' Willingness to Provide Telerehabilitation Services (n=23)

Many participants (n=16, 70%) were willing to continue providing telerehabilitation services, driven by the perceived benefits and uses of telerehabilitation. For example, one private practice, musculoskeletal and mental health physiotherapist said that "*for the provision of exercise and movement based interventions, telerehabilitation has worked better than in-person as it provides easier access to more people given I live in a regional area*." Despite this willingness, some participants expressed low satisfaction with telerehabilitation (n=2, 9%) or a preference for in-person consultations (n=2, 9%). For example, a sports, exercise, and musculoskeletal physiotherapist working in private practice said that despite telerehabilitation "*opening up my practice to lots of different people around Australia and internationally... I still prefer to consult in-person...*" The need for ongoing education about the utility of telerehabilitation in physiotherapy was noted (n=1, 4%), despite the perception that education about how to deliver telerehabilitation had improved during the pandemic (n=1, 4%).

Discussion

Principal Findings

Despite an initial increase due to the COVID-19 pandemic restrictions and physiotherapists' intentions to continue offering telerehabilitation services, many physiotherapists were offering fewer telerehabilitation consultations than anticipated once restrictions were lifted. This was primarily due to a preference for in-person consultations, concerns about the effectiveness of telerehabilitation, and the perception that physiotherapy consultations are easier to conduct in person.

International postpandemic data across both physiotherapy and other health services show a similar "peak-to-plateau" pattern, where telehealth usage increased substantially during restrictions before falling and stabilizing at a lower level rather than returning to prepandemic levels. In a Polish national dataset,

XSL•FO
RenderX

telehealth in both outpatient health and rehabilitation services (excluding mental health) rose from prepandemic levels near zero to peak in 2020 before subsequently stabilizing at approximately one-fifth and one-third of their respective peak volumes [25]. Similarly, musculoskeletal physical therapists in the United States reported reduced telerehabilitation usage postpandemic, albeit at levels higher than prepandemic [22]. Likewise, across the US health system, overall telehealth usage peaked in 2020 and then declined but stabilized by 2023 [26,27]. Notably, however, telehealth usage was better sustained for services less dependent on hands-on care (eg, behavioral health and psychiatry) and in states where policies were put in place to ensure payment parity with comparable in-person services [26].

Although the perceived effectiveness of telerehabilitation had increased over the course of the pandemic, more than half of participants still identified concerns about the effectiveness of telerehabilitation as a primary reason to stop offering telerehabilitation consultations once able to resume in-person services. This is consistent with other studies conducted during the pandemic, where physiotherapists indicated concerns about the effectiveness of telerehabilitation for physiotherapy assessment and/or management [13,28].

Research indicates that outcomes for telerehabilitation are the same, if not better, than in-person physiotherapy for a range of conditions. For example, systematic reviews and randomized controlled trials in musculoskeletal, cardiac, and pulmonary populations demonstrate the noninferiority of telerehabilitation [29] and good validity for assessment conducted via telerehabilitation [30]. Physiotherapists' perceptions may be centered around occupational self-efficacy [31] or their own personal clinical experience of "effectiveness" rather than evidence of effectiveness in the published literature. However, our results suggest that physiotherapists were not concerned about their own ability to deliver services via telerehabilitation. Both perceived satisfaction with telerehabilitation and confidence in delivering telerehabilitation trended upward from the prepandemic to the postpandemic period, and "I was not confident with telerehabilitation" was not a key factor in our findings after restrictions were lifted (3/26, 12%) . However, large proportions of respondents who did not offer telerehabilitation at this stage said it was easier to do in-person consultations instead (20/26, 70%); they were concerned with the effectiveness of telerehabilitation (13/26, 50%), and they did not like providing care via telerehabilitation (11/26, 42%). These findings suggest that there are additional factors influencing physiotherapists' perceptions about the superiority of "hands-on" or "in-person" physiotherapy [32-34] that have not been comprehensively explored, such as the professional identity of a physiotherapist [31,35].

A qualitative study describing a successful, rapid transition to telerehabilitation during the pandemic challenges the perception that physiotherapy requires "hands-on" approaches and needs to be in person [36]. This study identified that physiotherapists' readiness and willingness to modify their approach influenced the success of telerehabilitation. In our study, physiotherapists preferred in-person consultations themselves and perceived that their patients also preferred in-person consultations, which is likely to influence whether they offer telerehabilitation to patients. While systematic reviews suggest that patient satisfaction with telerehabilitation is comparable to and often higher than in-person care [37,38], many patients report a preference for in-person physiotherapy if given a choice [37,39]. Although physiotherapists might have thought during the pandemic that patient demand for telerehabilitation would remain (eg, explaining their intention to offer it), if patient demand for it decreased (as 55% of our sample indicated), physiotherapists would likely perceive that patients prefer in-person care (and indeed 76% of our sample did).

Clinician preferences for providing in-person physiotherapy have also been explored and reported on in the literature. Despite high levels of clinician satisfaction when providing telerehabilitation in clinical trials [40,41], this does not appear to be the case for *in-practice* preference for, or satisfaction with, telerehabilitation [21,22,28]. Although satisfaction and confidence with telerehabilitation increased over time, participants in this study still perceived in-person physiotherapy to be easier. The rigorous planning or structured training required for telerehabilitation delivery in a randomized clinical trial, rather than day-to-day clinical practice, may explain this difference in perceptions, highlighting a need for training specific to the clinical implementation of telerehabilitation. Studies examining barriers to implementing telerehabilitation in routine physiotherapy practice consistently identify insufficient training for conducting telerehabilitation consultations as a primary concern [42]. To address these challenges, international clinical practice guidelines provide evidence-based recommendations and strategies for overcoming barriers, guiding the training of clinicians and facilitating effective implementation of telerehabilitation into physiotherapy practice [43].

Clinicians have long identified the technological illiteracy of clients as a barrier to the adoption of telerehabilitation in physiotherapy [42]. Despite advances in technology infrastructure, when transitioning to telerehabilitation during the COVID-19 pandemic period, clinicians still identified "technology concerns" (including clinician concerns about client ability to use technology) as a barrier to telerehabilitation use in clinical practice [28,34,36,42,44]. In our study, concerns about technical issues or patients being unable to use or access technology were not identified as primary reasons physiotherapists determined patients were unsuitable for telerehabilitation. Additionally, technical issues were only slightly or moderately disruptive to consultations. This is consistent with findings from an evaluation of consultations delivered in a randomized controlled trial, which found that technical issues occurred but were infrequent and minimally disruptive [45]. This could potentially be because, at the time data were collected for this study (2023), physiotherapists and clients had greater experience with and exposure to the technology required for telerehabilitation and had become more comfortable over time [46]. In other studies where data were collected earlier in the pandemic, it is possible that fewer people were familiar with telerehabilitation technology, hence it being a bigger barrier to delivering telerehabilitation services at the time [20,21,36].

Strengths and Limitations

The findings of this study should be interpreted with the following limitations in mind. First, this was a small convenience sample, and findings may have been skewed by self-selection bias (with those with strong opinions, either positive or negative, electing to complete the survey). Second, we asked participants to recall what they were doing before and during the pandemic several years after the fact. Therefore, it should be acknowledged that participants' responses may have been influenced by recall bias. However, our data pertaining to before and during the pandemic were consistent with other studies conducted during the pandemic and their intentions to continue (eg, 69% in our study said that during the pandemic, they intended to offer telerehabilitation after restrictions were eased). In a study by Bennell et al [20], 81% intended to continue offering telerehabilitation consultations after the pandemic, and in a study by Peng et al [28], 55% and 68% intended to continue offering phone and videoconferencing, respectively. If the opportunity arises (ie, another period of restrictions to in-person consultations), researchers should consider using prospective study designs. Moreover, because our survey encompassed both phone calls and videoconferencing, our findings may not reflect modality-specific differences in perceptions reported elsewhere [28]. This survey also only sampled physiotherapists operating within Australia's health care system, so its findings may not fully translate to other countries with different telerehabilitation policies, funding models, or cultural attitudes toward remote care. Finally, due to an error, questions about confidence, satisfaction, and perceived effectiveness after the pandemic restrictions were eased were misworded and instead asked about experiences during the pandemic. It is likely that, given that all questions before this were about easing restrictions, most respondents still answered according to the intention of the question, but we cannot discount that some answered more literally, thereby skewing the data.

Conclusions

Although telerehabilitation use surged with pandemic restrictions, it has subsequently decreased significantly, with telerehabilitation accounting for only a small proportion of the total caseload. Despite increased confidence and satisfaction with telerehabilitation, clinician preference, and physiotherapists' perceptions of patient preference for in-person care, reduced demand and the ease of in-person practice influence the use of telerehabilitation postrestrictions and suggest persistent barriers to frequent use. Addressing these barriers is crucial to enhance the long-term viability and effectiveness of telerehabilitation physiotherapy in Australia.

Abstract

Background: Telerehabilitation has been widely adopted to meet the growing rehabilitation demand, but it is often limited by unstable internet connection, poor audiovisual resolution, and difficult virtual assessment. The Shoulder Telehealth Assessment Tool (STAT), a comprehensive, patient-led, preconsultation shoulder physical examination pictorial guide, was developed to address these limitations by easing the communication of instruction during the consultation and potentially removing the need for video calls.

Objective: This study aimed to develop a linguistically valid and culturally appropriate Filipino version of STAT and to evaluate its content validity, internal consistency, understandability, and ease of use.

Methods: A cross-sectional study on the Filipino STAT was conducted in three phases: (1) linguistic validation by experts, (2) cross-cultural adaptation through pretesting of 12 participants diagnosed with a musculoskeletal shoulder condition at the Philippine General Hospital, and (3) pilot study on 47 participants of the same population.

Results: The Filipino STAT had an excellent content validity (scale validity index=0.80 - 0.97), excellent interrater reliability (κ coefficient=0.82 - 1.00), and good internal consistency (Cronbach α=0.87). Understandability was found to be excellent for pain and activity (98%), good for range of motion and special tests (85%), and poor for strength (37%). However, 24% (11/46) of participants perceived the tool difficult to understand with the use of some Tagalog words as the primary barrier, followed by non-familiarity with the tool and difficulty reading the text.

Conclusions: Development of the Filipino STAT through a rigorous linguistic validation and cultural adaptation has produced a culturally appropriate, valid, and reliable tool. Pain and activity, range of motions, and special test subdomains are suitable for clinical assessment, while strength subdomain needs further improvement in understandability.

KEYWORDS

cross-cultural adaptation; linguistic validation; musculoskeletal rehabilitation; shoulder examination; Shoulder Telehealth Assessment Tool; telerehabilitation; STAT

Introduction

Telemedicine is the use of telecommunication technologies to deliver health care, public health, and health education services remotely [1]. Telerehabilitation is a branch of telemedicine specifically aimed at delivering rehabilitation services. Being an archipelago with limited health care professionals and facilities, the Philippines uses these innovative health care delivery services to improve health access for Filipinos. Telerehabilitation in the Philippines was first adopted in the context of community-based rehabilitation in 2017 [2] and was widely used in 2020 during the COVID-19 pandemic [3]. With the improving COVID-19 situation, telerehabilitation remains a viable solution to delivering rehabilitation services in far-flung areas of the country [4].

XSL•FO
RenderX

However, telerehabilitation is not without limitations, such as unstable internet connection, lack of confidence in establishing clinical diagnosis virtually, limited time allotment per patient, and poor audiovisual resolution [5]. Specifically, in the administration of virtual physical examination, rehabilitation professionals face difficulties in the conduct of special tests, range of motion (ROM) assessment, and strength testing, among others [3]. These challenges have opened opportunities for innovation in telerehabilitation.

One of these innovations was the development of the Shoulder Telehealth Assessment Tool (STAT), which is a comprehensive patient-led shoulder physical examination pictorial guide done prior to the actual teleconsultation, aimed to improve clinical efficiency [6]. It is the first published patient-reported outcome measure to simulate the performance of in-person physical examination, which includes special tests for screening of different shoulder pathologies [7]. A validated visual analog scale (VAS) [8], single assessment numeric evaluation (SANE) [9], and motion analysis and range of motion studies on activities of daily living [10] have also been integrated into the tool. The first subcategory of the STAT is composed of 3 questions for pain and activity. Both VAS and SANE are patient-reported. The VAS ranges from 0=no pain to 10=maximum pain, while the SANE is scored from 0% to 100% of normal. Meanwhile, the current level of daily activity is a nominal score (ie, unaffected sleep, full work, and full recreation or sport). The ROM testing has 9 questions that are answered with either yes (movement completed) or no (movement not completed). There are 5 items for the shoulder special tests answerable by yes or no, and finally 3 items for strength that are answered with either painful, weak, both, or none. Overall, there are a total of 20 questions in the STAT that can be completed in 30 to 45 minutes. In the Philippines and numerous other countries where Filipinos are found, the STAT can potentially improve the accuracy of virtual physical examination techniques for the shoulder, provide better rehabilitation care for patients who do not have stable internet connections or video call capacity, and optimize the delivery of telerehabilitation services. This may also be used by providers from various health care disciplines, such as physiatry, physical therapy, occupational therapy, orthopedics, rheumatology, and pain management, among others, which routinely conduct musculoskeletal examination of the shoulder.

In the Philippines, shoulder conditions have been found to be prevalent among Filipino office workers [11], as well as migrant workers [12]. Currently, the STAT is available in English [6] and has not been translated into any other language. Language and cultural differences call for a careful adaptation of health outcome measures to accurately reflect the cultural nuances and context of the target language version [13]. Hence, this study aimed to develop a linguistically valid and culturally appropriate Filipino version of the STAT and determine its content validity, internal consistency, understandability, and ease of use.

Methods

Study Design

This cross-sectional study used a mixed methods research design on the linguistic validation and cross-cultural adaptation of the Filipino STAT.

Participants

The target population was Filipino adults (aged at least 18 years) with unilateral shoulder pain for at least 6 weeks who consulted in-person or through telemedicine at the Philippine General Hospital (PGH)—Outpatient Department of Rehabilitation Medicine from January 2023 to June 2023. Based on the Department census during that period, there were 304 patients diagnosed with shoulder pathology, such as adhesive capsulitis, rotator cuff injury, and myofascial pain syndrome. The participants should have access to a stable internet and a device with video call capacity and be able to understand written instructions in Filipino or Tagalog, which is the Philippines' most commonly used language. Participants with a history of trauma, suspicion or diagnosis of upper extremity fracture, severe cognitive impairment, known psychiatric comorbidity, cerebrovascular disease, cervical radiculopathy, brachial plexus injury, upper extremity peripheral nerve injury, complex regional pain syndrome, and prior shoulder, neck, and breast surgery were excluded. The participants were allowed to withdraw from the study for any reason.

Sampling

The sample size for the pretest was based on a generally recommended sample size of 12 from the target population based on feasibility and precision of estimates for succeeding studies [14]. The sample size for a pilot study to determine internal consistency through Cronbach α was 46 [15]. Systematic randomized sampling was done where every seventh patient was selected.

Study Procedure

Overview

Adapting the recommendations on linguistic validation and cross-cultural adaptation of self-reported measures, the study procedure was divided into two phases [16,17]: (1) translation of the STAT from the original English to the Filipino version; and (2) cross-cultural adaptation through pretesting. An additional phase was added for internal consistency testing of the final version of the Filipino STAT (Figure 1). Meetings, where necessary, were all done virtually, and permission to record each online meeting was sought from all participants.

XSL•FO
RenderX

Figure 1. This is a flowchart adapted from Lorca et al [17] for linguistic validation and cross-cultural adaptation [6]. STAT: Shoulder Telehealth Assessment Tool.

XSL•FO
RenderX

Phase 1: Linguistic Validation

Step 1: Permission From the Instrument's Authors

Permission for linguistic validation and cross-cultural adaptation into the Filipino language was obtained from the STAT developers prior to initiation of translation.

Step 2: Forward Translation

The forward translation was independently done by 2 bilingual translators. The first forward translator (T1) was a licensed physical therapist with a Master's degree in physical therapy who provided a "reliable equivalence from a clinical perspective," while the second forward translator (T2) was a university instructor and a representative from the *Sentro ng Wikang Filipino* (National Center of the Filipino Language) with no medical background who served to "reflect the language used by the population."

Step 3: Review and Synthesis

The translators, together with a recording observer, convened to synthesize their versions and arrive at a consensus version. Translation and synthesis forms were used throughout the linguistic validation process by the translators and recording observer to document the translated version, rationale for changes, and any disputes or challenges in doing the translation or synthesis.

Step 4: Backward Translation

Backward translation was independently done by another pair of bilingual translators (B1 and B2), who happened to be high school Filipino language teachers and were not familiar with the original version. This step was done to prevent information bias and to detect any errors in the forward translation.

Step 5: Content Validation

The first forward- and backward-translated version of the Filipino STAT was then assessed for content validity independently by clinical experts using a content validation form. The experts were composed of 6 board-certified local physiatrists with expertise in the fields of sports medicine, musculoskeletal ultrasound, interventional physiatry, telerehabilitation, clinical anatomy, and kinesiology. The form was composed of a yes or no scale for clarity, 4-point Likert scale for relevance, and a comment section for each item.

Step 6: Synthesis and Conciliation

All versions of the Filipino STAT available so far and the completed content validation forms (Multimedia Appendix 1) were then reviewed by a consensus committee of experts to arrive at a prefinal version. The consensus committee consisted of all 4 translators (T1, T2, B1, and B2) from the previous steps and the 6 clinical experts who participated in the content validation step. They all met virtually and collectively decided and agreed on each item through the Expert Consensus Committee Guide on Equivalence Form (Multimedia Appendix 2), wherein semantic, idiomatic, experiential, and conceptual equivalence were assessed between the forward- and backward-translated English and Filipino versions. Semantic equivalence pertains to the use of words that have similar, unique meaning in both cultures. Idiomatic equivalence pertains to the use of equivalent colloquialisms and idioms in both cultures. Conceptual equivalence pertains to the use of words or phrases with equivalent conceptual meanings in both cultures, and experiential equivalence pertains to experiences elicited that are consistent or equivalent in both cultures. The form contained a yes or no scale on each type of equivalence, a column for rewording suggestions, and another column for other comments and suggestions to meet cultural equivalence.

Phase 2: Cross-Cultural Adaptation

Step 1: Pretesting

A pretest on 12 adult Filipino patients with shoulder pain was done using the prefinal version of the translated tool through video consultation to simulate the actual STAT procedure and to avoid unnecessary risk of contagion during the pandemic (time of study).

A think-aloud protocol during each video call with the principal investigator or research assistant using an encrypted platform, such as Zoom (Zoom Communications, Inc) or Viber (whichever the participant preferred), was used. The think-aloud protocol entailed each participant to read, perform, and answer the Filipino STAT while verbalizing their thoughts. This was done twice for each question: first without the pictorial guide; and second with the pictorial guide. The trial without the pictorial guide was done to assess the feasibility of the Filipino STAT Text Version for patients with no access to smartphones. An observational checklist (Multimedia Appendix 3) was filled out by the principal investigator to document the participant response, understandability of the tool, and ease and accuracy in performing the Filipino STAT, noting participants' quality of movements and compensatory movements. The principal investigator also asked each participant open-ended interview questions (Multimedia Appendix 4) on their experience (including perceived barriers and facilitators) in using the tool and their suggestions in improving it.

Step 2: Review of Results

General and question-specific errors and suggestions from the pre-test participants were reviewed by the committee in developing the final version of the Filipino STAT.

Step 3: Proofreading

The resulting version was then proofread by a Filipino language teacher to correct any spelling and grammatical errors. All translation forms and STAT versions were sent to the original authors for their review and feedback.

Phase 3: Internal Consistency Testing

Finally, all 46 participants underwent the same process as pretesting using the final version of the Filipino STAT for the pilot study to determine the internal consistency of the tool.

Data Analysis

Content validation was determined through computation of item-level and scale-level content validity indices based on average and universal agreement methods. Sociodemographic data were reported using descriptive statistics. The internal consistency of participant responses was determined through Cronbach α. This was evaluated separately for items in VAS,

XSL•FO
RenderX

SANE, ROM, strength tests, and special tests using STATA 16.1/IC (StataCorp LLC). Considering ≥90% as excellent, 89% to 70% as good, 69% to 50% as fair, and ≤49% as poor, understandability was assessed using the worst-performing item in the observational checklist.

Interview responses were uploaded to NVivo 12 (Lumivero) for organization and thematic analysis of unstructured data pertaining to understandability. An inductive approach was employed where the data content directed the development of themes. The members of the research team were all physiatrists and had broad experience in musculoskeletal evaluation and telerehabilitation in clinical practice and research. JA was a rehabilitation medicine resident trained during the height of telerehabilitation during the COVID-19 pandemic. CFL spearheaded several research endeavors on telerehabilitation in the Philippines. SI and JM were the chairs of the Department of Rehabilitation Medicine with extensive teaching, research, and clinical experiences.

Ethical Considerations

The study was approved by the University of the Philippines Manila Research Ethics Board (UPMREB Code 2022-0516-01). Informed consent was secured through Google Forms, written and explained in Filipino either by the principal investigator or research assistant. Study introduction, objectives, procedure, duration, risks, benefits, incentives, and contact information were discussed with the participants. Participants were also assured of the confidentiality of their information, the voluntary nature of participation, and their right to refuse at any point of the study. The translators, recording observers, and Filipino teacher were appropriately compensated with Philippine 1000 each (US $20). All phase 2 participants were compensated with Philippine 200 (US $4) worth of prepaid load as reimbursement for internet fee for the video call interview and answering of online forms. The clinical experts did not receive remuneration and were acknowledged in this paper.

Results

Forward Translation

Both forward translators had challenges in translating the strength and special tests questions due to absence of direct translation of some English words to Filipino. Hence, both translators resorted to rephrasing some English sentences in Filipino. During synthesis, T1 shared the technical context of the subtests, while T2 suggested the use of understandable albeit literal translations of some words. For item Q9 (ROM) (Table 1), the use of the phrase "*itupi ang siko*" was selected over "*itupi ang braso*" based on T1's input to pertain to the correct anatomical joint that does flexion. On the other hand, for item Q12 (special test), "*idiin ang kamay sa tiyan*" was selected over "*pindutin ang tiyan*" based on T2's input on the context of pressing the belly. Items that resulted in differences between T1 and T2, as well as the final terminology agreed upon during synthesis, are presented in Table 1.

[b] T2: forward translator 2.

[c]STAT: Shoulder Telehealth Assessment Tool.

XSL•FO
RenderX

Backward Translation

Similar to the forward translators, the back translators did not apply word-for-word translation in strength and special test questions to simplify the items and make them easier to understand. The back translation versions were generally consistent with the original English version, with no significant differences, as agreed upon by the consensus committee.

Content Validation of Prefinal STAT

The instructions in all subdomains, except for strength, were clear to the experts. The items on pain and activity (Q1) and range of motion (Q4, Q5, and Q6) were clear to all experts. Content validity through the scale validity index was measured using the item-level content validity index (0.97) and using universal agreement (0.80). κ values across all items ranged from 0.82 to 1.00, indicating excellent inter-rater reliability.

Cultural Equivalence

Pertinent findings from the discussion of the consensus experts on equivalence are summarized in Table 2.

Table . Pertinent results from the expert consensus discussion on equivalence[a].

	SE[b]	IE[c]	CE[d]	EE[e]	Comments
Pain and activity					
Q1	✓	✓	✓	✓	• Inconsistent: not a question
Q2	✓	✓	✓	✓	• Inconsistent: not a question
Q3	✓	✓	✓	X	• Inconsistent: not a question • Vague: choices not in one spectrum • EE: did not include informal work
Range of motion					
Q7	✓	✓	X	✓	• CE: not relatable to everyone
Special test					
Instruction	✓	X	✓	✓	• IE: Test demands active patient response
Q13	✓	✓	✓	✓	• Safety: for severely painful shoulder • Unclear: confusing literal translation
Q17	✓	✓	X	✓	• CE: incomplete instruction for the test

[a]Checks (✓) indicate equivalence, while cross marks (X) indicate non-equivalence.

[b]SE: semantic equivalence.

[c]IE: idiomatic equivalence.

[d]CE: conceptual equivalence.

[e]EE: experiential equivalence.

To facilitate consistency of the translations throughout the tool, items Q1 to Q3 (pain and activity) were converted from declarative statements into questions. Choices for item Q3 (sleep, work, and recreation or sports) were deemed to pertain to different aspects of activities and were thus converted to stand-alone questions for each activity (Q3A, Q3B, and Q3C). To facilitate clarity, the literal translation of item Q13 was rephrased for easier understanding. To ensure patient safety when using the tool, precautions for severely painful shoulders were added to the instructions for the special test subdomain.

XSL•FO
RenderX

To facilitate experiential equivalence, item Q3B's use of the term "*nakakapagtrabaho*" (able to work) was supplemented by the modifier "*gawaing bahay*" (house chores) to be more encompassing of the different types of work in the Filipino culture. To facilitate conceptual equivalence, item Q7's (ROM) use of "*bulsa sa likod ng apektadong balikat*" (back pocket on the affected side) was changed to "*pigi*" (buttock) as it pertains to the same area and is more relatable and easily understandable. Likewise, item Q17 was clarified with the phrase "*paharap sa lebel ng braso*" (forward raising to arm level) to demonstrate shoulder flexion to 90 degrees as in the Speed test. To facilitate idiomatic equivalence, instruction for the special test subdomain was improved from "*na makakapagsabi sa amin*" (that may tell us) to "*upang malaman namin*" (so that we will know) as the test demands active patient response. Finally, the expert committee all suggested taking new pictures for the tool with a Filipino-looking model for the pictorial guide for it to be more relatable and also to facilitate minor improvements in the angle of the shots and designation of the task of each arm.

Pretest

There were 12 participants in the pretest, with the majority being females (10/12, 83%), aged 50 - 59 years (5/12, 42%) with a mean age of 53 (SD 12) years, married or cohabiting (5/12, 42%), and having finished tertiary education (8/12, 67%; Table 3). Most were unemployed (6/12, 50%), while those employed were engaged in nonhealth-related work (8/12, 67%). The monthly family income of participants was positively skewed, with the majority (7/12, 58%) earning Philippine 5000 to 10,000 (US $100 - $200).

XSL•FO

Separated or divorced	1 (8)	2 (4)
Widowed	2 (17)	6 (13)
Educational status, n (%)		
Primary	0 (0)	4 (9)
Secondary	4 (33)	15 (32)
Tertiary	8 (67)	26 (55)
Postgraduate	0 (0)	2 (4)
Employment, n (%)		
Student	0 (0)	2 (4)
Employed	4 (33)	15 (32)
Unemployed	6 (50)	23 (49)
Retired	2 (17)	7 (15)
Type of work, n (%)		
Health-related work	4 (33)	7 (15)
Nonhealth-related work	8 (67)	40 (85)
Family monthly income (Philippine [US $]), n (%)		
<5000 (<100)	2 (17)	21 (45)
5000-10,000 (100 - 200)	7 (58)	9 (19)
10,001-20,000 (201 - 400)	2 (18)	8 (17)
20,001-50,000 (401 - 1000)	1 (8)	6 (13)
>50,000 (>1000)	0 (0)	3 (6)

Items on pain and activity (Q1 and Q3A-Q3C), ROM (Q2-Q6), and special tests (Q15) were performed correctly by at least 75% (9/12) of the participants independently. Up to 25% (3/12) of the participants needed cueing in the whole pain and activity subdomain and special tests (Q14). Less than 25% of the participants were able to perform ROM items Q8 and Q9, all strength items, and half of the items in the special test subdomain.

Six out of 12 (50%) participants reported an increase in pain upon performance of certain maneuvers (eg, items Q4, Q5, Q7, Q9, and Q14), although all were still able to complete the tasks. They were advised to seek outpatient consultation at the Rehabilitation Medicine Outpatient Clinic if the pain persisted.

Six (50%) participants found the tool easy to follow, while 5 (42%) found it difficult. Visual aids in the form of pictures and arrows were most helpful in making the tool easily

XSL•FO
RenderX

understandable. The presence of a caregiver was helpful for two of the participants.

The use of some Tagalog words (such as *pigi* or buttocks in English) was the primary barrier for understanding the tool (Table 4). Five (42%) participants were content with the prefinal version of the tool and had no suggested changes. One (8%) participant suggested that the presence of a physician or a caregiver (at the least) was still necessary to guide patients and ensure accuracy and safety in following the tool. Finally, 6 (50%) participants reiterated the need for pictures, and 1 (8%) participant suggested improvement in the portrayal of movement in the pictures.

Table . Results from the thematic analysis related to understandability of the Filipino Shoulder Telehealth Assessment Tool (STAT) and factors that make it easy or difficult to understand.

	Pretest (n=12), n (%)	Pilot (n=46), n (%)
Ease of understanding

Lessons From the Pretest and Development of the Final Filipino STAT

Difficulty reading the text of the tool and tendency to skip a specific question (Q3A) in a predominantly older adult population suggested inappropriate user interface design to the study team. While readers with advancing age have varying levels of possible age-related cognitive and visual decline, inclusivity was ensured in redesigning the tool [18]. These lessons were applied to the final version of the Filipino STAT (Multimedia Appendix 5) as follows: breaking down chunks of texts into bullet points, using Sans Serif typefaces with at least a 16-point font size, and providing white spaces and appropriate contrasts [18,19].

The conduct of special tests revealed an average of 73% (SD 14%) positive test findings (painful) that might have contributed to the increase in shoulder pain among pretest participants. This was addressed in the final version by placing the special test subdomain last as in clinical examination so any pain would not get in the way of the conduct of the other parts of the assessment.

Specific pretest errors could be classified as (1) misinterpretations observed in the subdomains of pain and activity (items Q2 and Q3C) and ROM (Q8); (2) differences in the semantic understanding of specific body parts, evident in ROM items Q1, Q4, Q5, Q7, and Q8; (3) difficulty understanding long instructions, which were evident in ROM item Q9 and all strength and special test items; and (4) inconsistent experiential equivalence in special test item Q17. Text qualifiers were added to misinterpreted items such as Q2, labeling 0=“normal” and 100=“hindi normal” (not normal), to avoid reversal of the scale. Items with different potential semantic meanings were significantly improved when pictorial guides were provided. Long, unclear instructions were broken down into short, step-by-step instructions with pictorial guides in each step. Finally, in item Q17 (Speed test), instead of holding a plate forward, most participants held a plate on the side, as a waiter would. The phrase was therefore changed from “*parang may hawak na plato*” (like holding a plate) to “*parang nanghihingi habang nakaunat ang siko*” (like reaching out or asking for something with an outstretched arm) to improve participants’ accuracy in performing the task and the relatability of the task in Filipino culture.

Final Filipino STAT Pilot Study

There were 47 participants in the pilot study; one of them did not complete the video consultation and withdrew due to technical difficulties (ie, unstable internet) on the patient’s end. The majority of the participants were females (35/47, 75%), aged 50 - 59 years (21/47, 45%) with a mean age of 55 (SD 14) years, married or cohabiting (29/47, 62%), and finished tertiary education (26/47, 55%; Table 3). Most were unemployed (23/47, 49%), while those employed were mostly engaged in nonhealth-related work (40/47, 85%). The monthly family income of the participants was positively skewed, with the majority (21/47, 45%) earning less than Philippine 5000 (US $<100).

XSL•FO
RenderX

For each of the items under the pain and activity subdomains, 35 (75%) to 43 (91%) participants were able to perform the tasks correctly. Meanwhile, some needed cueing from their caregiver to perform the tasks correctly, particularly for item Q2, where 11 (23%) participants needed help. With items Q3A and Q3C, 1 out of the 47 (2%) participants was not able to perform the task completely.

The ROM, strength, and special test subdomains were tested both without and with pictorial guides. For ROM-related items, a lot of participants were not able to perform the tasks correctly without a picture (Q2: chin, Q7: back pocket, Q8: lower back, and Q9: wall touching). In contrast, for those items with picture guides, there was a greater number of patients who were able to perform the tasks correctly, with little to no need of cueing from their caregivers. Four (8%) participants showed compensatory movements with some items, yet they answered yes when asked if they could do the tasks. Hence, they were considered incorrect task performances, with item Q8 being the most common item that resulted in compensatory movements.

Without pictorial guides, more than half of the participants were not able to perform all the tasks under the strength subdomain. Slightly more participants correctly performed the tasks for items Q11 and Q12 when shown pictorial guides. Moreover, the same scenario was observed for all items in the special test subdomain—having pictorial guides improved the number of participants able to perform the tasks correctly from 34 (74%) to 39 (87%) participants, while 2 (4%) to 6 (13%) participants needed cueing from their caregivers to be able to perform the tasks correctly.

Among the 46 participants who shared their experience with the final Filipino STAT, 13 (28%) found the tool easy to understand, while 11 (24%) found it difficult. The pictures and arrows were found to be most helpful for participants. Participant 47 remarked, "*maayos po binigay ang panuto at dahil sa larawan ay naintindihan po nang mabuti*" (the instructions were given properly, and because of the pictures, they were better understood). The use of some Tagalog words, however, was considered the primary barrier by the majority of the participants, followed by their nonfamiliarity with the tool and difficulty reading the text (Table 4). The same participant also remarked, "*May kahinaan po ako sa Pilipino, tulad po ng pigi po, hindi ko siya naintindihan*" (I have some difficulty in understanding Tagalog, for example, I did not understand the Tagalog word for buttock").

Content Validity and Internal Consistency Testing of the Final Filipino STAT

Content validity through scale validity indices was deemed excellent at 0.97 using the item-level content validity index and 0.80 using the universal agreement. The κ coefficients were excellent across all items, supporting that the degree of agreement among the experts was beyond chance [20]. A Cronbach α score of 0.87 indicated that all test items were unidimensional, or that performance on the items could be explained in terms of a single underlying factor (Multimedia Appendix 6).

Discussion

Principal Findings

The Filipino STAT has an excellent content validity (scale validity index=0.80 - 0.97), excellent interrater reliability (κ coefficient=0.82 - 1.00), and good internal consistency (Cronbach α=0.87). Its understandability is excellent for pain and activity (98%), good for ROM and special tests (85%), and poor for strength (37%).

Comparison With Prior Work

The findings of this study are consistent with the existing literature on shoulder teleconsultation psychometric properties. Internet assessment of rehabilitation outcomes such as pain, ROM, muscle strength, and functional assessment had good concurrent validity. There is a strong agreement between virtual and in-person examination for ROM (87.4% agreement; x^2=30.782; P<.001), and diagnosis (85.1% agreement; κ=0.82, 95% CI) [21-23]. Further studies on the Filipino STAT compared against in-person examination or imaging modalities may be done to ascertain concurrent validity of the tool.

Strengths and Limitations

Since a direct translation of a tool from an original English version may not reflect the cultural nuances and context of another culture [13], this study observed a rigorous and standard linguistic validation and cross-cultural adaptation to ensure a culturally appropriate, valid, and reliable translation. Although the original STAT has not been validated as a whole tool, the Filipino-translated tool has been subjected to content validity and internal consistency testing in this study. The collective inputs from the consensus committee of experts, the understandability questionnaire, and qualitative data from the participants ensured that the final tool can be used in the clinical setting.

There are some limitations to this study. First, the assessment of ease of understanding of the tool using the open-ended questionnaire may have been confounded by the consecutive performance of the tool without and with a pictorial guide, as well as the videoconsultation study setup. The test-taking that was twice as long, with no visual aid provided at the start, could have made the consultation more difficult for the participants. The barriers to the videoconsultation study setup were consistent with previous literature, such as unstable internet connection and poor audiovisual resolution [5]. In the envisioned clinical performance of the Filipino STAT, only the pictorial guide will be performed before the actual consultation, thereby eliminating these concerns.

Second, understandability per subdomain was excellent for pain and activity, good for ROM and special tests, and poor for strength. The incidence of compensatory or trick movement was accounted for in this study and was most frequently seen in the ROM subdomain, particularly item Q8 (50 degrees of internal rotation).

Finally, such as in an in-person physical examination, incorrect performance of a virtual test, from poor understandability or compensatory movement, makes its results invalid and

XSL•FO
RenderX

questionable. This shall serve as a reminder that the Filipino STAT is not meant to replace actual in-person consultations and should just aid the clinician in assessing the patient and make clinical work efficient. The clinician must be prudent in confirming the initial Filipino STAT findings during the actual consultation, as necessary. Further studies may consider the use of instructional videos to improve understandability of the tool, especially for the strength subdomain.

Future Directions

Both pretest and pilot study findings reveal significant improvements in the correct performance of the Filipino STAT tasks with pictorial guides, compared to none. The majority of the participants from both phases of the study also shared a positive perception of the use of pictures and arrows and the presence of a caregiver. Thus, it is the study's recommendation to use the Filipino STAT with a pictorial guide, as intended in the original tool [6]. The association of the presence of a caregiver in the successful performance of the Filipino STAT was beyond the scope of this present study. Nonetheless, having a caregiver around may help with the conduct of the Filipino STAT but should not discourage those who do not have an available caregiver.

Conclusions

The development of the Filipino STAT through a rigorous linguistic validation and cultural adaptation ensured a culturally appropriate, valid, and reliable translation. Understandability and ease of understanding by end-users are also critical to assess in patient-reported outcome measures. The pain and activity, ROM, and special test subdomains of the Filipino STAT may be used for clinical assessment, while the strength subdomain needs further improvement on understandability.

Acknowledgments

The authors would like to acknowledge the clinical experts Dorothy Dy Ching Bing-Agsaoay, Monalisa Lim-Dungca, Christopher Constantino, Nathaniel Napa, Mitchelle Gabuya, and Frances Carlos, as well as our Filipino STAT model Nancy Cheng, for their generous contributions to this study. They would also like to acknowledge the STAT original authors, Gregory Sprowls, Jaycen Brown, and Brett Robin, for allowing translation of their tool.

Abstract

Background: Post–COVID-19 condition (PCC) is characterized by persistent symptoms and functional limitations that impair quality of life, and rehabilitation is an important component of its management. Because access to conventional face-to-face rehabilitation may be limited, telerehabilitation has emerged as an accessible alternative. However, the effectiveness of telerehabilitation across clinical outcomes remains uncertain, and the influence of different delivery modes is not well understood.

Objective: This study aimed to evaluate the effects of telerehabilitation on health-related quality of life (HRQoL), physical capacity, and symptom burden in adults with PCC, and to determine whether delivery mode (synchronous, asynchronous, or hybrid) modified these effects.

Methods: Seven databases (PubMed, Cochrane Library, Web of Science, Scopus, Embase, EBSCO, and PEDro) were searched for randomized controlled trials published from January 2020 through December 2025. Eligible trials enrolled adults with PCC and compared telerehabilitation with usual care or another control condition. The primary outcome was HRQoL; secondary outcomes included functional capacity assessed by the 6-minute walk test and sit-to-stand test, dyspnea, fatigue, and symptoms of anxiety and depression. Risk of bias was assessed using the Cochrane Risk of Bias 2 tool. Mean differences or standardized mean differences (SMDs) with 95% CIs were pooled using random-effects models with the Hartung-Knapp-Sidik-Jonkman adjustment. Heterogeneity was quantified using I^2 and τ^2, with 95% prediction intervals reported where estimable. Certainty of evidence was evaluated using the GRADE (Grading of Recommendations Assessment, Development and Evaluation) approach.

Results: A total of 22 randomized controlled trials involving 2294 participants were included. Telerehabilitation was associated with significant improvements in HRQoL (SMD 1.26, 95% CI 0.07-2.45; *P*=.04), dyspnea (SMD 1.95, 95% CI 0.60-3.31; *P*=.005), and functional aerobic capacity (6-minute walk test : mean difference 77.79 meters, 95% CI 30.44-125.14; *P*=.001). Fatigue was also significantly reduced (SMD 0.89, 95% CI 0.16-1.62; *P*=.02), but no significant effects were observed for lower-limb strength (sit-to-stand test: SMD 0.55, 95% CI –0.15 to 1.25; *P*=.12) or symptoms of anxiety and depression (SMD 0.12, 95% CI –0.13 to 0.38; *P*=.36). No significant differences between delivery modes were observed for HRQoL (*P*=.93), functional aerobic capacity (*P*=.29), or dyspnea (*P*=.16). A significant subgroup difference was observed for lower-limb strength (*P*=.02).

Conclusions: Telerehabilitation may improve quality of life, aerobic capacity, and symptom burden in PCC and offer an accessible option for post-COVID rehabilitation, although the certainty of evidence was generally limited. Asynchronous delivery appears feasible for general reconditioning, whereas its benefit for lower-limb strength and the value of synchronous supervision remain uncertain.

KEYWORDS

telerehabilitation; post–COVID-19 condition; health-related quality of life; digital rehabilitation; meta-analysis

Introduction

Post–COVID-19 condition (PCC), also referred to as long COVID, is a common long-term consequence of SARS-CoV-2 infection. The World Health Organization defines it as symptoms occurring about 3 months after probable or confirmed COVID-19. These symptoms last for at least 2 months and cannot be explained by another diagnosis [1,2]. Common manifestations include fatigue, dyspnea, postexertional symptoms, reduced exercise capacity, cognitive difficulties, and psychological symptoms. These problems often coexist and can lead to sustained limitations in daily functioning, participation, and health-related quality of life (HRQoL) [3-6]. Although the acute phase of the pandemic has passed, PCC remains common, and its prolonged course continues to create substantial health care needs for patients and health systems [2,7,8].

Physical rehabilitation, particularly pulmonary and exercise training, is widely recognized as a central component of PCC management [9,10]. Studies have demonstrated that structured rehabilitation can significantly improve exercise capacity and alleviate dyspnea in convalescent patients [11-14]. However, access to conventional face-to-face rehabilitation remains limited due to health care resource constraints, geographic barriers, and workforce shortages [15]. These challenges underscore the need for alternative rehabilitation delivery models that are both effective and scalable within existing health care systems.

Telerehabilitation, defined as the delivery of rehabilitation services through information and communication technologies, has emerged as a promising approach to address limited access to conventional rehabilitation in individuals with PCC [16,17]. By reducing travel requirements and allowing treatment to be completed at home, telerehabilitation may support continuity of care, scheduling flexibility, and access for patients who are unable to attend regular facility-based programs [18,19]. However, remote delivery also introduces important challenges. Participation and treatment response may be influenced by access to technology, digital literacy, platform usability, patient engagement, and the availability of timely clinical feedback. Existing digital health studies in PCC have also reported considerable variation in intervention design and limited reporting of implementation and safety outcomes [20,21].

Recent studies generally support the beneficial effects of telerehabilitation on physical function and symptom management in populations with PCC [22-24]. However, interpretation of these findings remains limited by differences in patient characteristics, intervention components, outcome instruments, and follow-up duration. Earlier reviews were also based largely on small or early trials and frequently combined different forms of remote rehabilitation within a single treatment category [23,25-27]. A recent updated meta-analysis expanded the evidence base to 28 randomized controlled trials (RCTs) and reported improvements in physical function and several symptom outcomes, but its primary quantitative synthesis remained focused on physical and symptom-based outcomes [28]. Consequently, uncertainty remains regarding the overall effect of telerehabilitation on HRQoL and the extent to which treatment effects vary across different digital delivery modes.

A further gap concerns the assessment of patient-centered outcomes. Because patients with PCC experience multiple and fluctuating symptoms, the overall impact of the condition cannot be adequately represented by a single objective test. HRQoL captures how symptoms and functional limitations affect patients' daily lives and was therefore selected as the primary outcome of this review. This emphasis is consistent with rehabilitation frameworks that prioritize functioning and participation [29,30] and with PCC core outcome initiatives calling for standardized, patient-centered assessment [31,32]. Objective measures of aerobic capacity and lower-limb function, including the 6-minute walk test (6MWT) [33] and sit-to-stand test (STS) [34,35], were included as complementary secondary outcomes.

The mode of telerehabilitation delivery represents another important but unresolved issue. Synchronous programs provide real-time supervision, immediate feedback, and opportunities to adjust treatment during a session, but they require greater clinician time and scheduling coordination. Asynchronous programs offer greater flexibility and may reduce resource demands, but they provide less immediate feedback and rely more heavily on patient self-management. Hybrid programs combine elements of both approaches, although their added value has not been clearly established [35,36]. Existing reviews have often pooled these delivery modes or examined telerehabilitation as a single category, making it difficult to determine whether the amount and timing of supervision influence treatment effects. Evidence comparing delivery approaches remains limited, and previous analyses have not consistently examined synchronous, asynchronous, and hybrid interventions across HRQoL, functional, and symptom outcomes [37,38].

This systematic review and meta-analysis evaluated the effects of telerehabilitation on HRQoL as the primary outcome and on functional capacity, dyspnea, fatigue, and symptoms of anxiety and depression as secondary outcomes in adults with PCC, compared with usual care or another control. We further examined whether intervention effects differed across synchronous, asynchronous, and hybrid delivery modes. By synthesizing HRQoL across validated instruments and assessing delivery mode within a single analytical framework, this review provides an updated, patient-centered synthesis of the available randomized evidence.

Methods

Design and Search Strategy

The research adhered to the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) reporting guideline and was registered in PROSPERO (CRD42023490863) (Multimedia Appendix 1) [39]. A comprehensive electronic literature search was conducted from January 2020 to December 2025 in several databases including PubMed, the Cochrane Library, Web of Science, PEDro, Scopus, Embase, and EBSCO. Search terms and synonyms included adults with PCC or long COVID, along with Telerehabilitation, or Remote Rehabilitation, or Digital Rehabilitation, tailored to each search engine (Multimedia Appendix 2). We manually reviewed the reference lists of included studies and pertinent review to find additional papers not included. Study eligibility criteria were defined according to the PICOS (Population, Intervention, Comparison, Outcome, and Study design) framework (Table 1) [40].

Table 1. PICOS (Population, Intervention, Comparison, Outcome, and Study design) model.

Domain	Description
Population	Adults with post–COVID-19 condition or long COVID.
Intervention	Telerehabilitation interventions delivered remotely through digital or telecommunication technologies, including programs conducted in home-based or nonclinical settings.
Comparison	Contrast with usual care, no intervention group or placebo.
Outcomes	Reported data on health-related quality of life, physical capacity, symptom burden (fatigue and dyspnea), or psychological outcomes assessed using validated scales.
Study design	Randomized controlled design.

Study Selection and Data Extraction

We examined only RCTs with full text that compared telerehabilitation therapies with usual care, placebo, or control in adults (older than 18 years) with PCC. Telerehabilitation was defined as rehabilitation delivered remotely through digital or telecommunication technologies, allowing patients to perform rehabilitation in home-based or nonclinical settings, with guidance, feedback, monitoring, or education provided by health professionals or structured digital systems and without in-person contact [16]. Home-based programs that lacked ongoing remote supervision or interactive support were not classified as telerehabilitation. Based on the mode of delivery, interventions were classified into 3 categories: synchronous, delivered in real time with live, therapist-supervised interaction (eg, videoconferencing or live online sessions); asynchronous, delivered without real-time interaction through self-paced tools (eg, mobile apps, web platforms, prerecorded modules, or remote monitoring); and hybrid, combining real-time and self-paced components within the same program [41]. The delivery mode of each included study is shown in Table 2. We did not impose any limitations regarding comorbidities or medication usage during the rehabilitation procedure. Excluded were studies without sufficient statistical data for extraction, reviews, case reports, observational studies, and any other type of publications (eg, guidelines, protocols, comments, conference abstracts, and editorials). Two reviewers (XH and YT) conducted independent searches of papers in each database. Disagreements were resolved by consensus or by involving a third reviewer. We collected information on authors, publication year, participants, intervention details, and outcome data.

Outcome Measures

The primary outcome was HRQoL. Because HRQoL was assessed using multiple instruments, we included generic measures where available, including the 36-Item Short Form Health Survey (SF-36), the 12-Item Short Form, the EQ-5D, the World Health Organization Quality of Life Brief, and the PROMIS Preference score, as well as respiratory

XSL•FO
RenderX

disease–specific measures such as the St George Respiratory Questionnaire and the King Brief Interstitial Lung Disease questionnaire. Secondary outcomes included functional aerobic capacity (6MWT), lower-limb function (STS), dyspnea (modified Medical Research Council scale), Dyspnea-12, Transition Dyspnea Index, and Barthel Dyspnea Index, fatigue (Chalder Fatigue Scale, Fatigue Assessment Scale, and Fatigue Severity Scale), and anxiety and depression (Hospital Anxiety and Depression Scale [HADS]). When a study reported more than 1 eligible instrument for the same outcome, we used the study's primary or prespecified measure and entered only 1 instrument per study to avoid double-counting. If no primary measure was specified, a generic instrument was prioritized over a disease-specific instrument. The instruments used in each study, together with the direction of scoring, are summarized in Multimedia Appendix 3.

Risk-of-Bias Assessment

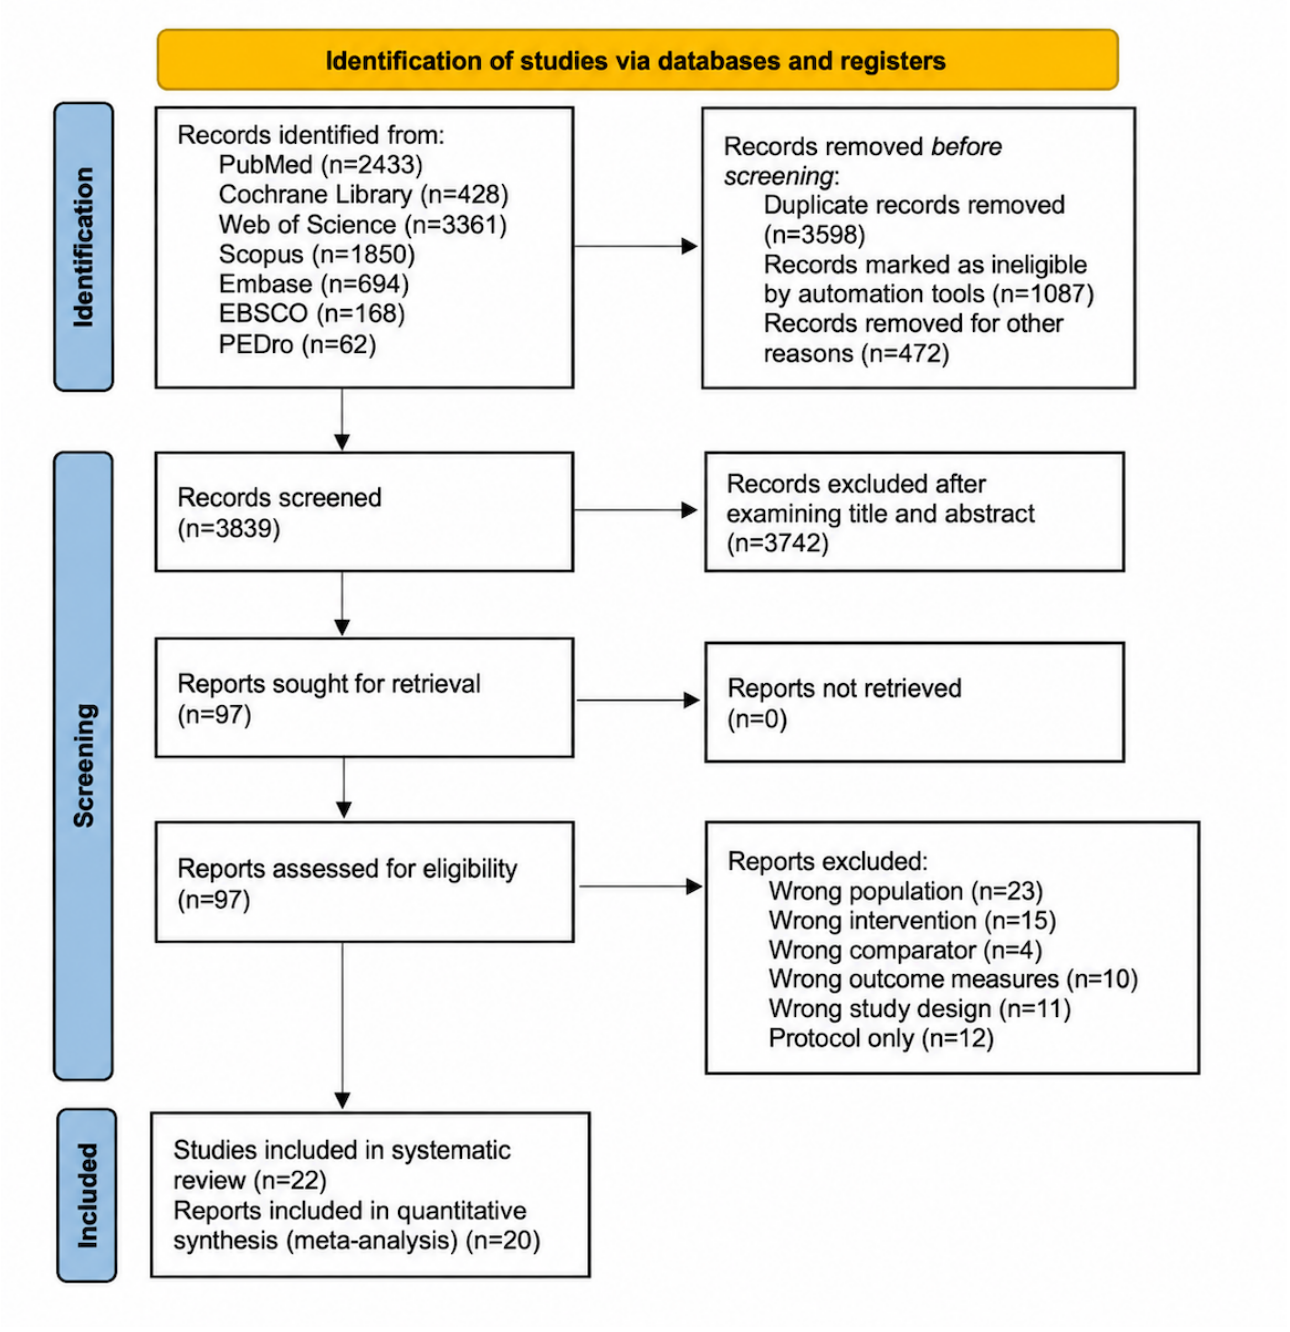
Risk of bias was assessed independently by 2 reviewers (XH and YT) using the Cochrane Risk of Bias tool version 2.0 (RoB 2) [65]. The assessment covered 5 specific domains: the randomization process, deviations from intended interventions, missing outcome data, measurement of the outcome, and selection of the reported result. For each domain, the risk of bias was classified as "low risk," "some concerns," or "high risk." An overall risk-of-bias judgment was derived for each study based on these domain-level assessments. Any discrepancies between the 2 reviewers were resolved through discussion or, when necessary, by consulting a third reviewer.

Statistical Analysis

Meta-analyses were performed using random-effects models to account for expected clinical and methodological heterogeneity across studies. For continuous outcomes, pooled effect estimates with 95% CIs were calculated as mean differences (MDs) when studies used the same measurement scale and as standardized mean differences (SMDs) when different instruments assessed the same construct (eg, HRQoL, dyspnea, and fatigue). For the SF-36, we used the physical component score rather than combining it with the mental component score; where a study reported only the total score, that value was used instead. Before pooling, all effect directions were harmonized so that positive values indicated clinical benefit: instruments on which higher scores reflect worse health were reverse-coded. The scoring direction of each instrument is summarized in Multimedia Appendix 3. Effect sizes were interpreted according to Cohen guidelines, where SMDs of 0.2, 0.5, and 0.8 represent small, medium, and large effects, respectively [66]. In addition to outcome-specific analyses, an overall pooled analysis was conducted to provide a global summary of the effects of telerehabilitation across outcome domains. Between-study heterogeneity was assessed using the I^2 statistic, the between-study variance (τ^2), and 95% prediction intervals (PIs). I^2 values of approximately 25%, 50%, and 75% were considered to indicate low, moderate, and high heterogeneity, respectively [67]. To obtain more conservative and robust confidence intervals, particularly in analyses including a limited number of studies, the Hartung-Knapp-Sidik-Jonkman (HKSJ) method was applied [68]. To explore potential sources of heterogeneity, we prespecified subgroup analyses by delivery mode (synchronous, asynchronous, or hybrid). For the primary outcome (HRQoL), we additionally performed exploratory subgroup analyses by participant's age, time since diagnosis, and intervention duration, with differences assessed using the test for subgroup differences. Sensitivity analyses were performed using a leave-one-out approach by sequentially excluding individual studies to assess the stability of pooled estimates (Multimedia Appendix 4 [42,45-50,52-64]). Publication bias was evaluated using funnel plots and Egger regression test when at least 10 studies were available for a given outcome [69]. Statistical significance was defined as a 2-sided P value <.05. All statistical analyses were conducted in R statistical software using metafor and meta packages (R Foundation for Statistical Computing).

Certainty of Evidence

To assess the certainty of evidence, we applied the GRADE (Grading of Recommendations Assessment, Development and Evaluation) [70-75] approach to the main outcomes, including HRQoL, functional capacity (6MWT and STS), dyspnea, fatigue, and symptoms of anxiety and depression. Two reviewers (XH and YT) independently evaluated the certainty of evidence across the domains of risk of bias, inconsistency, indirectness, imprecision, and publication bias, with disagreements resolved through discussion and consensus. The GRADE assessments are summarized in the Multimedia Appendix 5.



Results

Study Selection

A total of 8996 records were identified through database searching across PubMed, the Cochrane Library, Web of Science, Scopus, Embase, EBSCO, and PEDro. After removal of 5157 records before screening, 3839 records were screened by title and abstract, of which 3742 were excluded. In total, 97 full-text papers were assessed for eligibility, and 75 studies were excluded based on predefined criteria. Finally, 22 RCTs were included in the systematic review [42-64], with 20 studies contributing to the quantitative synthesis (meta-analysis). The study selection process is shown in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart detailing the selection process of randomized controlled trials comparing telerehabilitation with usual care. The search across 7 databases resulted in the inclusion of 22 studies.

Characteristics of the Included Studies

A total of 22 RCTs involving 2294 participants were included in this meta-analysis. Across studies, participants had mean ages ranging from the mid-40s to mid-50s, and female participants accounted for a higher proportion of the study populations. Sample sizes ranged from 21 to nearly 600 participants. The included trials enrolled clinically heterogeneous populations. Eight trials included patients who had been hospitalized or were recruited after hospital discharge; 3 enrolled community-dwelling, nonhospitalized individuals; and 11 did not clearly report hospitalization status. Acute illness severity ranged from mild to critical: 12 trials included patients with severe or critical illness, 9 enrolled only mild to moderate cases, and 1 did not clearly report severity. Time since infection or hospital discharge ranged from less than 1 month to approximately 24 months, with most studies assessing participants between 3 and 12 months after the acute phase. Sociodemographic and clinical characteristics of the participants across the included studies are summarized in Table 3.

[d]IMT: inspiratory muscle training.

[e]RMT: inspiratory/expiratory muscle training,

[f]HEG: home exercise group.

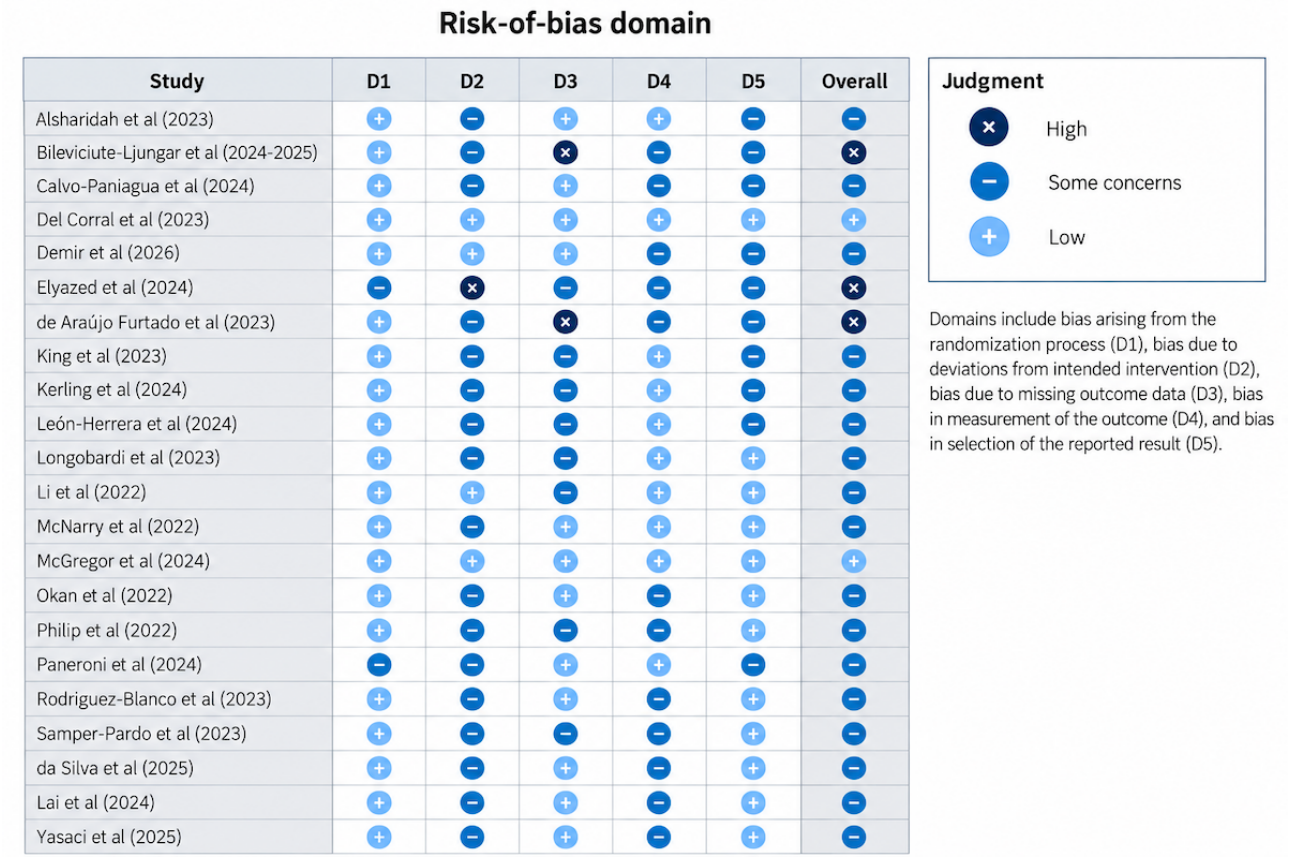
[g]TRG: telerehabilitation group.

[h]ICU LOS: intensive care unit length of stay.

[i]REGAIN: Rehabilitation Exercise and Psychological Support After COVID-19 Infection.

[j]ICU: intensive care unit.

[k]HDU: high dependency unit.



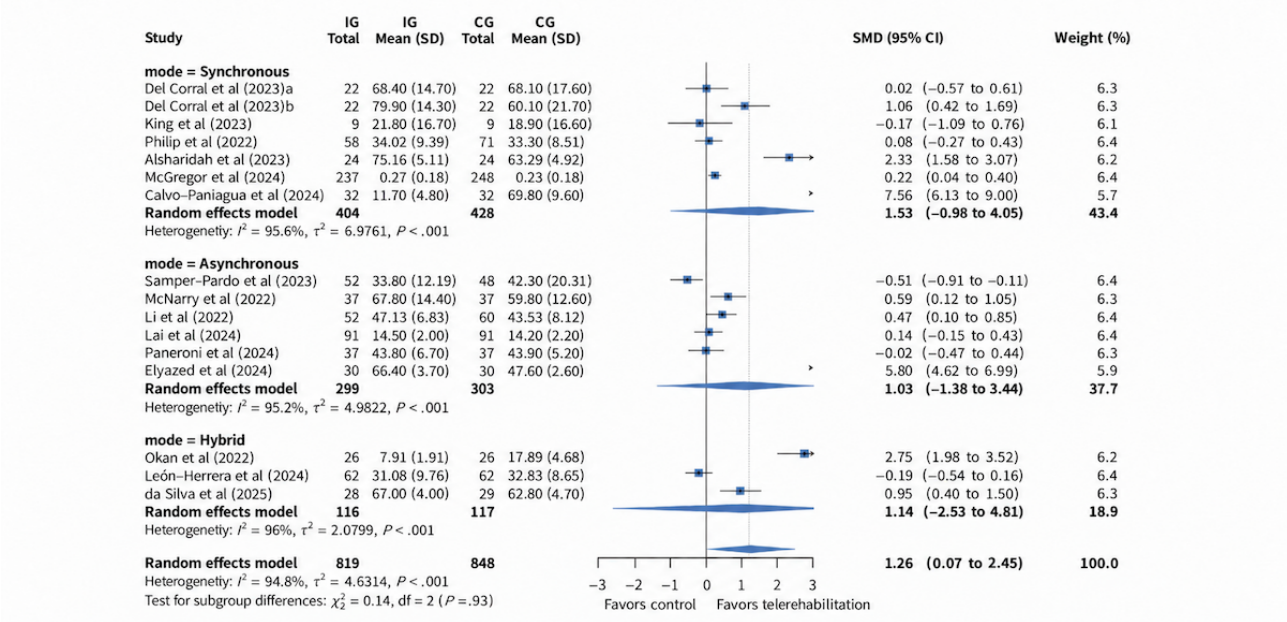
Telerehabilitation was delivered synchronously in 9 trials, asynchronously in 7, and through a hybrid approach in 5; 1 additional trial included both synchronous and asynchronous arms. Intervention duration ranged from 2 to 16 weeks, with 2-6 sessions per week. Most programs were multicomponent: aerobic or endurance training was included in 16 trials, breathing exercises or respiratory muscle training in 15, and resistance or strength training in 12, while 5 incorporated psychological or cognitive components. Comparators most commonly included usual care, educational materials, unsupervised exercise, waiting-list controls, or sham interventions. Outcomes were typically assessed at the end of the intervention, and a subset of trials included follow-up at 2, 3, 6, or up to 12 months. Full intervention details are provided in Table 2.

Risk of Bias and Certainty of the Evidence

All 22 studies were evaluated for bias using the RoB 2 tool (Figure 2), which indicated that 2 of the studies displayed a low risk of bias (9%) [46,56], 17 of them had some concerns (77%) [42,45,47,50-55,57-64], and 3 others had a high risk of bias (14%) [43,44,48,49]. The randomization process (domain 1) was the most methodologically robust domain, with most studies demonstrating a low risk of bias. This indicates that most trials used adequate random sequence generation (eg, computer-generated lists) and allocation concealment mechanisms. In contrast, deviations from the intended interventions (domain 2) and measurement of the outcome (domain 4) presented frequent sources of concern. Due to the nature of telerehabilitation (active exercise training), blinding of participants and personnel was generally not feasible, leading to a rating of “some concerns” or “high risk” in domain 2 for several studies. Similarly, for domain 4, while assessor blinding was implemented in some trials, the use of patient-reported outcome measures, such as quality of life or fatigue, in an unblinded population introduces potential detection bias. Missing outcome data (domain 3) and selection of the reported result (domain 5) were generally rated as low risk, suggesting that most studies performed intention-to-treat analyses and reported outcomes consistent with their protocols. Because these limitations primarily affected the subjective, patient-reported outcomes (HRQoL, dyspnea, and fatigue), the certainty of evidence for these outcomes was downgraded for risk of bias, and their pooled estimates should be interpreted with corresponding caution.

XSL•FO
RenderX

Figure 2. Risk of bias assessed using the Cochrane Risk of Bias tool (RoB 2).



Health-Related Quality of Life

HRQoL was the primary outcome used to evaluate the overall efficacy of telerehabilitation. A total of 16 RCTs involving 1667 participants (819 in the intervention group and 848 in the control group) were included in the meta-analysis. In the pooled analysis using a random-effects model with HKSJ adjustment, telerehabilitation was associated with a statistically significant improvement in HRQoL compared with conventional care. The overall SMD was 1.26 (95% CI 0.07-2.45; P=.04). However, substantial heterogeneity was observed across the studies (I^2=94.8%; τ^2=4.63; P<.001; 95% PI –3.52 to 6.05), indicating considerable variability in the magnitude of the effect.

To investigate whether the delivery mode influenced efficacy, we performed a subgroup analysis stratified by delivery mode. The effect sizes for synchronous (k=7; SMD 1.53, 95% CI –0.98 to 4.05), asynchronous (k=6; SMD 1.03, 95% CI –1.38 to 3.44), and hybrid (k=3; SMD 1.14, 95% CI –2.53 to 4.81) telerehabilitation were comparable. The test for subgroup differences was not statistically significant (χ^2_2=0.14; P=.93), suggesting that the delivery mode was not a primary source of the observed heterogeneity. Notably, while the overall effect was significant, the confidence intervals for all individual subgroups crossed zero, likely attributable to the reduced sample size within subgroups and the conservative nature of the HKSJ adjustment (Figure 3) [42,45,46,48,50,52,54-59,61-63].

Figure 3. Forest plot of standardized mean differences for health-related quality of life comparing telerehabilitation with conventional care. Results are stratified by delivery. A random-effects model was applied. CG: control group; IG: intervention group; SMD: standardized mean difference.

We further explored potential sources of heterogeneity in HRQoL by participant age, time since diagnosis, and intervention duration (Table 4). None of these factors showed statistically significant subgroup differences (age, *P*=.11; time since diagnosis, *P*=.43; duration, *P*=.28), and substantial heterogeneity remained within all strata (I^2=88%-97%). Although point estimates tended to be larger among older participants, those with a shorter time since diagnosis, and in shorter duration programs, confidence intervals were wide and largely overlapping. These findings suggest that the examined characteristics did not meaningfully explain the observed heterogeneity.

Table 4. Subgroup analyses of health-related quality of life by patient and intervention characteristics[a].

Subgroup	Studies, n	SMD[b] (95% CI)	*P* value	I^2 (%)	*P* value for subgroup difference
Age (years)					.11
<50	8	0.40 (−0.33 to 1.13)	.23	88.3	
≥50	8	2.15 (−0.29 to 4.59)	.08	97.0	
Time since diagnosis (months)					.43
<6	6	1.87 (−0.45 to 4.19)	.09	96.6	
≥6	9	0.91 (−0.97 to 2.79)	.30	94.0	
Intervention duration (weeks)					.28
<8	6	2.14 (−0.84 to 5.12)	.12	96.9	
≥8	10	0.75 (−0.52 to 2.01)	.22	92.8

[b]SMD: standardized mean difference.

Functional Aerobic Capacity (6MWT)

Functional aerobic capacity was evaluated using the 6MWT across 10 RCTs involving 470 participants (Figure 4) [42,45,47-50,54,57,60]. In the overall pooled analysis using a random-effects model, telerehabilitation demonstrated a statistically significant improvement in functional aerobic capacity compared with conventional care (MD 77.79, 95% CI 30.44-125.14; *P*=.001). Although substantial heterogeneity was observed, a subgroup analysis stratified by delivery mode revealed comparable effects across synchronous (k=6; MD 77.70, 95% CI –25.31 to 180.71), asynchronous (k=3; MD 87.63, 95% CI 58.49-116.77), and hybrid (k=1; MD 59.07, 95% CI 25.82-92.32) interventions. The test for subgroup differences was not significant (χ^2_2=2.47; *P*=.29), suggesting that the efficacy of telerehabilitation in improving aerobic capacity did not differ significantly by delivery mode.

XSL•FO
RenderX

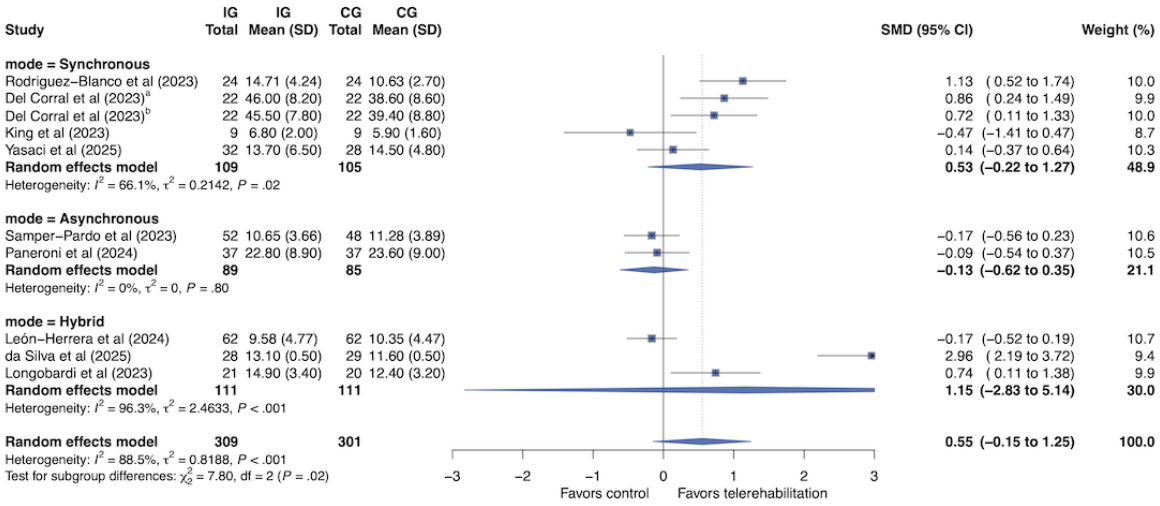

Figure 4. Forest plot of mean differences for functional aerobic capacity comparing telerehabilitation with conventional care. Results are stratified by delivery. A random-effects model was applied. CG: control group; IG: intervention group; MD: mean difference.

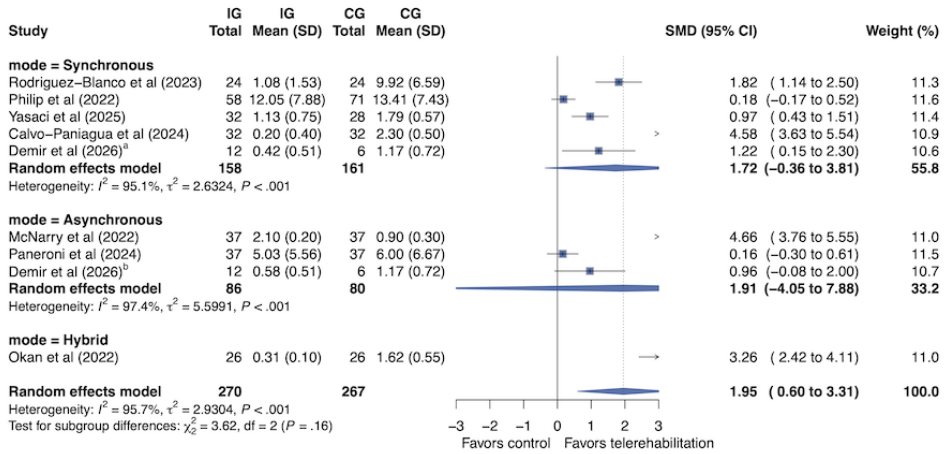
Lower-Limb Muscle Strength (STS)

Lower-limb function was assessed with the STS in 10 RCTs (610 participants). The overall pooled effect did not reach significance (SMD 0.55, 95% CI –0.15 to 1.25; *P*=.12), with substantial heterogeneity (I^2=88.5%). In the subgroup analysis by delivery mode, none of the 3 subgroups was individually significant (synchronous, k=5, SMD 0.53, 95% CI –0.22 to 1.27; asynchronous, k=2, SMD –0.13, 95% CI –0.62 to 0.35; hybrid, k=3, SMD 1.15, 95% CI –2.83 to 5.14). Although the test for subgroup differences was significant (χ^2_2=7.8; *P*=.02), the subgroup estimates were imprecise and within-subgroup heterogeneity was high, most notably in the hybrid group (I^2=96.3%), where the pooled estimate was strongly influenced by a single trial. This subgroup difference should therefore be interpreted with caution (Figure 5) [46,50,52,53,59-62,64].

Figure 5. Forest plot of standardized mean differences for lower-limb muscle comparing telerehabilitation with conventional care. Results are stratified by delivery. A random-effects model was applied. CG: control group; IG: intervention group; SMD: standardized mean difference.



Dyspnea

Dyspnea was evaluated in 9 RCTs involving 537 participants. In the pooled analysis, telerehabilitation yielded a statistically significant reduction in dyspnea compared with conventional care (SMD 1.95, 95% CI 0.60-3.31; *P*=.005). Subgroup analysis stratified by delivery mode showed that the synchronous intervention (k=5) achieved a large effect size (SMD 1.72, 95% CI –0.36 to 3.81), and the asynchronous intervention (k=3) similarly demonstrated positive outcomes (SMD 1.91, 95% CI –4.05 to 7.88). Additionally, the hybrid intervention (k=1) showed a substantial effect (SMD 3.26, 95% CI 2.42-4.11). The test for subgroup differences was not statistically significant (χ^2_2=3.6; *P*=.16), indicating that the delivery mode did not significantly alter the therapeutic benefit (Figure 6) [45,47,55,57-60,64].

XSL•FO
RenderX

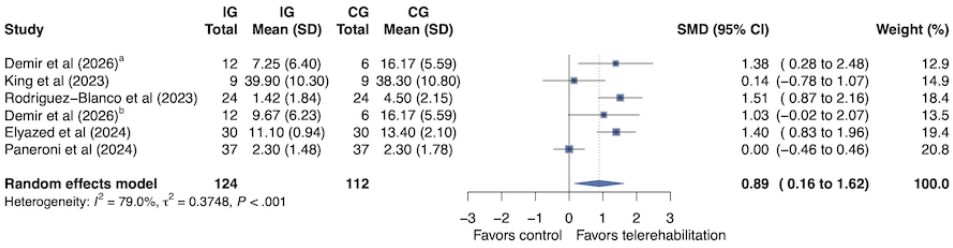


Figure 6. Forest plot of standardized mean differences for dyspnea comparing telerehabilitation with conventional care. Results are stratified by delivery mode. A random-effects model was applied. CG: control group; IG: intervention group; SMD: standardized mean difference.

Fatigue

Fatigue was evaluated in 6 RCTs (n=236). The pooled analysis indicated that telerehabilitation yielded a statistically significant reduction in fatigue compared with conventional care (SMD 0.89, 95% CI 0.16-1.62; *P*=.02) (Figure 7) [47,48,50,59,60].

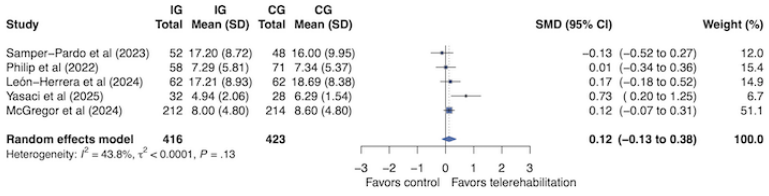

Figure 7. Forest plot of standardized mean differences for fatigue comparing telerehabilitation with conventional care. A random-effects model was applied. CG: control group; IG: intervention group; SMD: standardized mean difference.

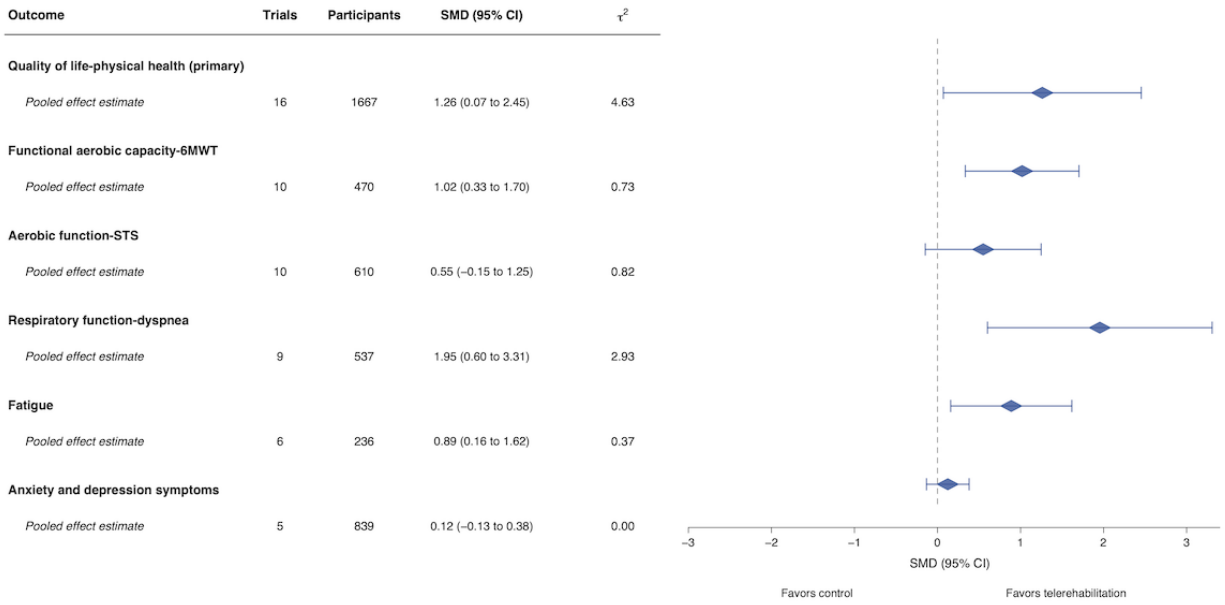
Anxiety and Depression Symptoms

Five RCTs reported anxiety and depression outcomes. Because these were assessed with different instruments (the HADS total score in 2 trials, the HADS anxiety subscale in 2, and the GAD-7 in 1), effects were pooled as SMDs. The random-effects meta-analysis showed no significant difference between telerehabilitation and control interventions (SMD 0.12, 95% CI –0.13 to 0.38; P=.36). Between-study heterogeneity was low to moderate (I^2=43.8%, P=.13). Owing to the limited number of studies, no subgroup analyses were performed (Figure 8) [52,56,58,61,64].

Figure 8. Forest plot of standardized mean differences for anxiety and depression symptoms comparing telerehabilitation with conventional care. A random-effects model was applied. CG: control group; IG: intervention group; SMD: standardized mean difference.



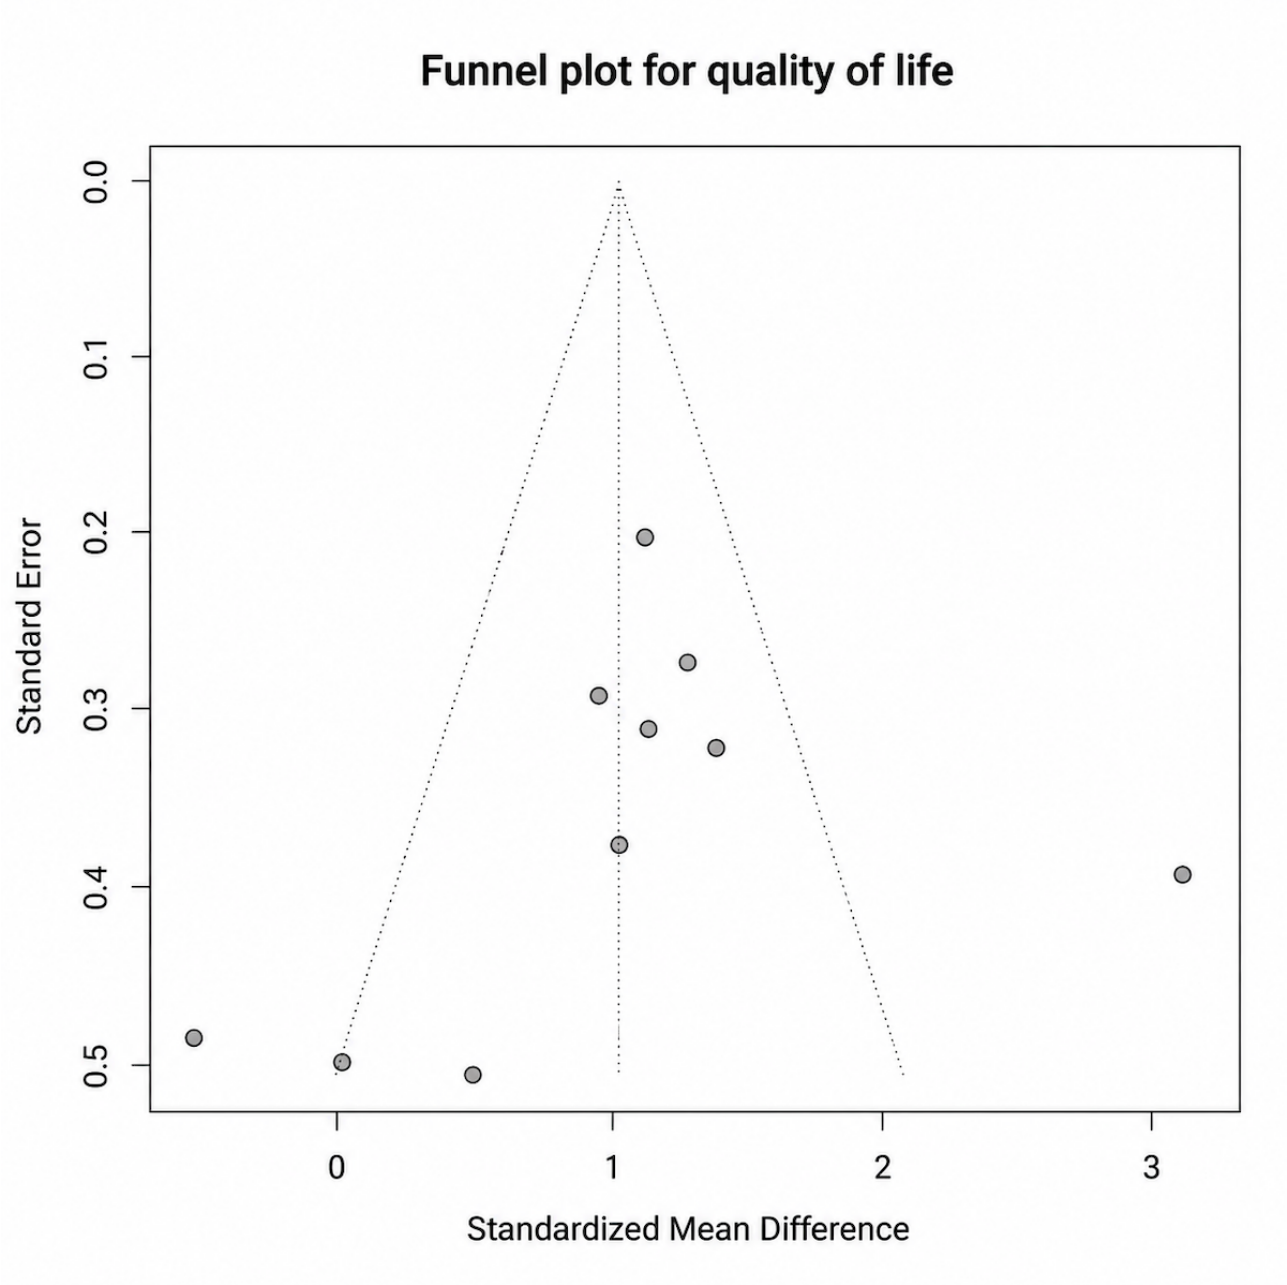
Overview of Effects Across Outcomes

An overview forest plot was used to summarize pooled effects across outcome domains. Overall, telerehabilitation showed a consistent favorable direction of effect for most physical and functional outcomes, with the largest effects observed for dyspnea and HRQoL, followed by improvements in aerobic capacity (6MWT) and fatigue. In contrast, mental health outcomes assessed by symptoms of anxiety and depression showed small and nonsignificant effects, with estimates centered around the null. Heterogeneity varied across outcomes and was generally more pronounced for physical and respiratory measures. Collectively, these findings suggest that telerehabilitation confers more robust benefits in physical and functional domains than in psychological outcomes (Figure 9).

XSL•FO
RenderX

Figure 9. Summary forest plot of pooled standardized mean differences for primary and secondary outcomes comparing telerehabilitation with conventional care. A random-effects model was applied. 6MWT: 6-minute walk test; SMD: standardized mean difference; STS: sit-to-stand test.

Sensitivity Analysis



Given the high heterogeneity across outcomes, a leave-one-out sensitivity analysis was performed to test the stability of the pooled results. Detailed results are shown in Multimedia Appendix 4. The analysis confirmed the robustness of the primary findings, as omitting any single trial did not alter the statistical significance for HRQoL, 6MWT, or STS. For Fatigue and the anxiety and depression outcome, specific outliers were identified. Excluding 2 studies [59,64] significantly reduced heterogeneity (I^2 dropped to 39.0% for fatigue and 0% for anxiety and depression) while maintaining the direction of the therapeutic effect, thereby validating the reliability of our conclusions.

Publication Bias Test

Publication bias was assessed exclusively for the primary outcome (HRQoL) because other outcomes did not meet the recommended threshold of included studies (k<10) for reliable testing. The funnel plot for HRQoL (Figure 10) displays a symmetrical distribution of studies, and Egger linear regression test confirmed no evidence of significant small-study effects (t=–0.78; P=.46), indicating a low risk of publication bias.

XSL•FO
RenderX

Figure 10. Funnel plot for small-study effects in health-related quality of life meta-analysis.

Certainty of Evidence

According to the GRADE approach, the certainty of evidence was rated as low for all outcomes (Multimedia Appendix 5). For HRQoL, functional capacity (6MWT and STS), dyspnea, and fatigue, the certainty was downgraded primarily due to risk of bias and inconsistency, reflecting methodological limitations and substantial between-study heterogeneity. In contrast, the certainty of evidence for symptoms of anxiety and depression was downgraded due to risk of bias and imprecision, owing to the limited number of contributing trials and relatively wide confidence intervals. No serious concerns regarding indirectness or publication bias were identified across outcomes. Overall, these findings indicate that the pooled estimates should be interpreted cautiously.

Discussion

Principal Results

This systematic review and meta-analysis of 22 RCTs evaluated the effects of telerehabilitation in adults with PCC. Our synthesis indicates that telerehabilitation was associated with significant improvements in HRQoL, functional aerobic capacity (6MWT), dyspnea, and fatigue compared with control group. From a clinical perspective, the observed improvement in functional aerobic capacity also appears meaningful: the pooled increase in 6-minute walk distance (MD 77.79 meters) exceeded the minimal clinically important difference of approximately 30 meters reported for chronic respiratory disease [33], suggesting that the effect is likely to be clinically relevant. This estimate is broadly consistent with a recent updated meta-analysis, which reported a mean improvement of 85.83 meters in 6-minute walk

XSL•FO
RenderX

distance [28]. In contrast, HRQoL, dyspnea, and fatigue were synthesized using SMDs across multiple instruments and therefore could not be interpreted against a single minimal clinically important difference threshold. Beyond these overall benefits, the present findings suggest that the role of supervision in telerehabilitation may vary according to the targeted outcome. Stratified analyses suggested that the benefits for general aerobic capacity and HRQoL were broadly comparable across delivery modes, whereas a subgroup difference favoring synchronous delivery was observed for lower-limb muscle strength. These subgroup findings were exploratory and should be interpreted with caution.

Because the subgroup differences for HRQoL and 6MWT were not significant, our data do not suggest that continuous real-time supervision is required to improve general aerobic capacity, although the limited power of these comparisons means equivalence cannot be assumed. Asynchronous protocols may be sufficient for these outcomes, possibly because they allow patients to incorporate low-to-moderate intensity activity into daily routines, consistent with evidence that structured home-based rehabilitation can improve endurance regardless of direct supervision [76,77]. For lower-limb strength (STS), by contrast, a significant subgroup difference favored synchronous delivery; however, neither modality reached significance on its own, so synchronous supervision may play a more important role in strength training rather than being essential. A possible explanation is that real-time monitoring helps therapists gauge exertion and progress intensity safely [78], while supervised sessions may support adherence and correct exercise technique [79]. These factors may be particularly important for strength training, which requires adequate progression and training intensity to achieve meaningful gains.

Data on adherence and patient satisfaction were reported in limited studies, preventing a quantitative meta-analysis. Nevertheless, these factors are clinically relevant, as satisfaction is a key predictor of long-term adherence and outcomes [80]. Based on current evidence, the mode of delivery appears to influence patient engagement [76]. Asynchronous telerehabilitation provides temporal flexibility, allowing patients with fatigue to adjust exercise timing to their energy levels. This feasibility likely contributed to the QoL improvements observed in the self-managed group. Conversely, synchronous modes involve real-time interaction that may strengthen the therapeutic alliance and accountability. This supervision may help sustain participant engagement and adequate training intensity. A hybrid approach combining asynchronous delivery with periodic synchronous supervision may therefore provide a practical balance between accessibility and clinical support, although this hypothesis requires confirmation in future studies.

With respect to persistent symptoms, telerehabilitation was associated with significant improvements in both dyspnea and fatigue. The heterogeneity in dyspnea outcomes is consistent with prior evidence syntheses and may reflect differences in intervention focus [18]. Programs that included dyspnea-targeted components, such as inspiratory muscle training, appeared more likely to yield clinically meaningful benefit. The reduction in fatigue represented a large effect size (SMD 0.89), underscoring its clinical importance and aligning with accumulating evidence supporting structured exercise for PCC [26]. This benefit may reflect the counteracting of physical deconditioning through pacing and gradual, individualized reconditioning, without worsening symptoms. Conversely, consistent with prior evidence, we found no significant impact of physical telerehabilitation on symptoms of anxiety and depression [81]. Anxiety in PCC may involve complex neuroinflammatory and psychosocial mechanisms [82], which physical rehabilitation alone may not sufficiently address. Among the studies that reported adverse events, none were serious or intervention-related, although adverse event reporting was inconsistent across trials. The available evidence therefore suggests that telerehabilitation appears to be safe under the conditions evaluated, but trials with standardized safety reporting are warranted. This underscores the need for integrated, multicomponent interventions that combine physical training with structured psychological strategies, such as cognitive behavioral approaches.

Substantial heterogeneity was observed across several pooled outcomes, particularly HRQoL, and the findings should therefore be interpreted with caution. Subgroup analyses by delivery mode, participant age, time since diagnosis, and intervention duration did not identify statistically significant subgroup differences, and substantial residual heterogeneity remained within strata. Several other factors may contribute. First, HRQoL was assessed using different instruments, including generic measures (eg, SF-36 and EQ-5D) and disease-specific tools such as the St George Respiratory Questionnaire, which differ in construct, scaling, and responsiveness; such variation in measurement may contribute to between-study variability. Second, the populations ranged from mild symptoms to survivors of critical illness, and from community to posthospital settings, implying different baseline impairment and recovery trajectories. Third, the interventions differed in content, progression, and exercise dose, from single-component breathing or inspiratory muscle training to multicomponent aerobic and resistance programs (Table 2); their predominantly multicomponent nature limited the feasibility of a clean subgroup analysis by individual component, so these differences were considered narratively. Because none of these factors were formally tested as moderators, they should be regarded as plausible explanations rather than definitive sources of heterogeneity. Practically, this uncertainty is reflected in the wide PI, indicating that the true effect may vary substantially across future settings and patient populations, whose broader dynamics have also been characterized through population-level pandemic modeling [83]. These findings should therefore be interpreted as average effects across heterogeneous contexts rather than precise estimates applicable to every patient.

Although subgroup analysis by intervention component was not feasible because of the limited number of studies, the interventions can be broadly summarized using the frequency, intensity, time, and type framework (Table 2). Most programs prescribed exercise 2-6 times per week for 20-90 minutes over 2-16 weeks. Exercise intensity was generally individualized using Borg ratings of perceived exertion, percentages of maximal heart rate or heart rate reserve, American College of

XSL•FO
RenderX

Sports Medicine recommendations, or, for inspiratory muscle training, percentages of maximal inspiratory pressure. Interventions ranged from single-component breathing or inspiratory muscle training to multicomponent programs combining aerobic and resistance exercise. Overall, these findings suggest that individualized exercise programs delivered regularly over several weeks may be beneficial, although considerable variation remained in exercise intensity and program composition, and an optimal exercise prescription cannot be established from the current evidence.

Limitations

This systematic review and meta-analysis has several limitations that warrant consideration. First, substantial heterogeneity was present across the main pooled outcomes and, as discussed previously, likely reflected differences in measurement instruments, clinical populations, and intervention characteristics; although we used random-effects models and subgroup analyses, much of it remained unexplained. Second, the evidence base is constrained by the nature of rehabilitation interventions, where blinding of participants and therapists was largely infeasible, introducing potential performance and detection biases, particularly for subjective patient-reported outcomes such as HRQoL and dyspnea. Moreover, several key outcomes, including HRQoL, fatigue, and anxiety and depression, were assessed using patient-reported measures and are therefore inherently subjective. These outcomes may be influenced by participants' expectations, mood, social context, and the absence of blinding. Accordingly, they should be interpreted together with the objective functional outcomes and in light of the overall certainty of evidence. Third, the limited number of studies in certain subgroups constrained statistical power. Nevertheless, these exploratory analyses were included to discern potential trends regarding delivery modes; consequently, the findings should be interpreted as hypothesis-generating rather than definitive. Finally, most included trials had relatively short follow-up periods (typically 4-12 weeks) and often lacked rigorous assessments of patients' digital literacy, limiting our ability to determine the long-term sustainability of benefits and the generalizability of findings to older or less tech-savvy populations in real-world settings.

Future Perspectives

Collectively, these findings are consistent with a tentative stepped-care approach, although they should be regarded as hypothesis-generating given the low certainty of evidence and the wide, overlapping confidence intervals of the subgroup estimates. For most patients aiming to recover general fitness and quality of life, asynchronous telerehabilitation appears to be a reasonable and scalable option, given its broadly comparable effects and lower resource demands. For patients with marked muscle weakness or those requiring closer safety monitoring, synchronous supervision may be preferable. These suggestions require confirmation in adequately powered trials. Considering the limitations of the current evidence base, future research should prioritize 3 directions. First, to address the null effects observed for mental health outcomes, telerehabilitation protocols should move beyond a solely physical rehabilitation paradigm. The integration of structured physical exercise with remotely delivered psychological components, such as online cognitive behavioral therapy or mindfulness-based interventions, may offer a more comprehensive approach to the neuropsychiatric burden of PCC, consistent with emerging multidisciplinary models proposed in recent literature [81]. Second, given that most included trials were characterized by relatively short follow-up periods, there is a clear need to examine the long-term sustainability of observed benefits, particularly for outcomes such as muscle strength and functional capacity. Future studies should assess whether intervention effects are maintained at 6- and 12-month follow-up and explore whether incorporating periodic synchronous booster sessions into predominantly asynchronous programs can enhance adherence and prevent functional regression over time. Finally, although asynchronous telerehabilitation is often assumed to be more cost-efficient than conventional face-to-face rehabilitation [84], robust economic evaluations remain scarce. Rigorous cost-effectiveness and cost-utility analyses are therefore required to quantify potential economic advantages and to inform health policy decisions, particularly with respect to the inclusion of telerehabilitation within insurance reimbursement frameworks.

Conclusions

This review synthesized randomized evidence on telerehabilitation for adults with PCC, with a focus on HRQoL and delivery mode. Telerehabilitation may improve HRQoL, aerobic capacity, dyspnea, and fatigue, whereas no clear benefit was observed for symptoms of anxiety or depression. Evidence for lower-limb strength remained inconclusive, and any added value of synchronous supervision should be interpreted cautiously. Given the limited certainty of evidence for several outcomes and substantial heterogeneity across studies, telerehabilitation should be viewed as a promising and accessible rehabilitation option rather than an established standard of care. Future trials should use standardized outcomes, longer follow-up, and prespecified analyses of delivery mode to confirm benefits and clarify which patients are most likely to benefit.

Abstract

Background: Speech recognition technology is widely used by individuals who are Deaf/deaf and hard-of-hearing (DHH) in everyday communication, but its clinical applications remain underexplored. Communication barriers in health care can compromise safety, understanding, and autonomy for individuals who are DHH.

Objective: This study aimed to evaluate a real-time speech recognition system (SRS) tailored for clinical settings, examining its usability, perceived effectiveness, and transcription accuracy among users who are DHH.

Methods: We conducted a pilot study with 10 adults who are DHH participating in mock outpatient encounters using a custom SRS powered by Google's speech-to-text application programming interface. We used a convergent parallel mixed-methods design, collecting quantitative usability ratings and qualitative interview data during the same study session. These datasets were subsequently merged and jointly interpreted. Participants completed postscenario surveys and structured exit interviews assessing distraction, trust, ease of use, satisfaction, and emotional response. Caption accuracy was benchmarked against professional communication access real-time translation transcripts using word error rate (WER). Because WER assigns equal weight to all tokens, it does not differentiate between routine transcription errors and those involving safety-critical clinical terms (eg, medications or diagnoses). Therefore, WER may underestimate the potential impact of certain errors in medical contexts.

Results: Across 29 clinical scenario simulations, 86% (25/29) of participants found captions nondistracting, 90% (26/29) reported them easy to follow and trustworthy, and 76% (22/29) were satisfied with the experience. Participants described the SRS as intuitive, emotionally grounding, and preferable to lip reading in masked settings. WER ranged from 12.7% to 22.8%, consistent with benchmarks for automated SRSs. Interviews revealed themes of increased confidence in following clinical conversations and staying engaged despite masked communication. Participants reported less anxiety about missing critical medical information and expressed a strong interest in expanding the tool to real-world settings, especially for older adults or those with cognitive impairments.

Conclusions: Our findings support the potential of real-time captioning to enhance accessibility and reduce the cognitive and mental burden of communication for individuals who are DHH in clinical care. Participants described the SRS as both functionally effective and personally empowering. While accuracy for complex medical terminology remains a limitation, participants consistently expressed trust in the system and a desire for its integration into clinical care. Future research should explore real-world implementation, domain-specific optimization, and the development of user-centered evaluation metrics that extend beyond transcription fidelity to include trust, autonomy, and communication equity.

Introduction

Effective communication is foundational to safe, equitable, and high-quality health care [1]. However, individuals who are Deaf/deaf and hard-of-hearing (DHH) often face communication barriers that compromise understanding and autonomy [2]. These barriers contribute to poor health outcomes and reduced patient engagement in real-time clinical settings [2]. The scale of this issue highlights the need to understand which communication support tools are available and provided, and to whom. In the United States, an estimated 48 million people live with some degree of hearing loss (HL), and 1 in 3 adults older than 65 years experiences disabling age-related hearing loss [3,4]. Despite this growing population, access to communication supports remains inconsistent [5,6].

Deaf individuals who use American Sign Language often receive interpreter services [7]. In contrast, oral communicators with people with HL who normally rely on spoken English are less likely to receive accommodations such as captioning, assistive listening devices, or environmental modifications [7]. Especially in clinical workflows, interpreter services are systematically implemented, whereas accommodations for oral communicators are likely not [8-12]. This gap persists despite longstanding mandates under the Americans with Disabilities Act, which mandates effective communication in health care [13]. As a result, many patients who are DHH still receive incomplete or delayed health information [5]. These gaps undermine informed decision-making, autonomy, and overall care outcomes [14,15]. Far from logistical oversights, these structural inequities perpetuate persistent disparities in care for individuals who are DHH.

These long-standing disparities became even more visible during the COVID-19 pandemic [14]. Universal masking eliminated lip reading and facial cues, which were essential supports for many individuals who are DHH and rely on oral communication [16]. This shift underscored the need for scalable solutions to maintain accessible communication in high-stakes settings [14,17].

Real-time captioning is 1 solution for improving communication access for individuals who are DHH when traditional strategies (eg, lip reading or interpreters) are unavailable [18]. Captioning tools can be deployed quickly and readily support both in-person and virtual communication [19]. However, captioning accuracy of clinical conversations may be affected by terminology unique to the medical field or speaker attribution and is understudied [19,20]. This has left a critical gap in the development of effective and equitable access tools.

By allowing both conversation partners to see each other's faces while reading the same captions, transparent or dual-visibility captioning preserves the natural flow of spoken interaction and is a promising solution for clinical communication. Prior work, such as See-Through Captions [21], See-Through Captions in a Museum Guided Tour [22], and Wearable Subtitles [23], has primarily focused on general or educational settings. Our study extends this line of research into medical contexts, where communication accuracy can directly affect patient safety and outcomes. It also emphasizes the emotional and psychological impact of captioning during clinical interactions and addresses the unique technical challenges posed by medical vocabulary and workflow integration.

In summary, we developed and evaluated a real-time captioning tool using Google's speech-to-text engine to generate live captions during simulated clinical encounters. We tested this system in dynamic, medically relevant scenarios designed to simulate typical ambulatory care encounters. In this pilot study, we explored how individuals who are DHH experienced the captioning system in these simulated encounters, focusing on usability, accuracy, and communication access.

Methods

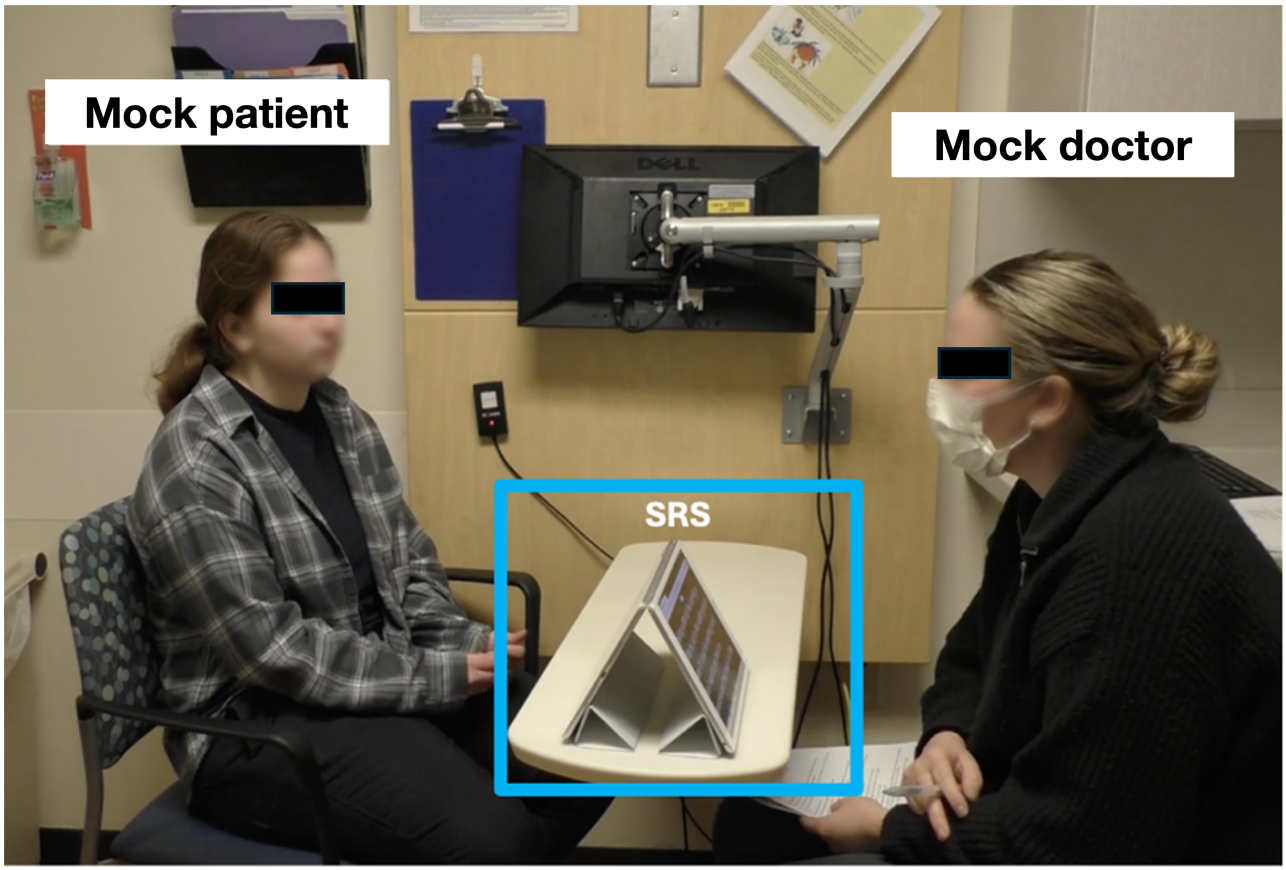
Background

The pilot took place in a patient room at one of the Department of Family Medicine clinics. The primary goal was to assess the feasibility and acceptability of a real-time captioning tool in a clinical setting. Secondary objectives included evaluating ease of use, distraction, trust, and satisfaction, factors critical to determining whether the tool supports communication access. Quantitative and qualitative data were collected concurrently within the same study session using a convergent parallel mixed-methods design. Participants completed postscenario surveys and a brief structured exit interview during the same visit, allowing us to analyze both datasets in parallel before merging findings during the interpretation phase.

Recruitment

We recruited participants who self-identified as DHH through internal email lists compiled from prior studies, social media, and snowball sampling. Inclusion criteria included people who were DHH, preferred to communicate in spoken English, and were at least 18 years old. Recruitment materials explained that the study evaluated a real-time captioning system in simulated medical scenarios.

Mock Clinical Scenarios



Participants completed 3 mock clinical scenarios using the automated speech recognition system (SRS) which was developed by us. The SRS used Google's speech-to-text application programming interface to transcribe speech to text with low latency and competitive accuracy [24]. The setup included 2 iPads arranged in a tented position so that each device faced either the participant or the mock doctor. Both iPads displayed the generated captions simultaneously (Figure 1).

Before each experiment, we used a random number generator to assign scenario order for each participant. Two team members (both medical students) alternated between serving as the mock doctor (administering scenarios) or facilitator (administering postscenario surveys and exit interviews).

The scenarios were based on commonly reported primary care concerns: (1) back pain, (2) headache, and (3) high blood pressure. Scenario scripts were designed by trained medical students and a clinical faculty member to closely replicate real clinical conversations. The mock doctors wore surgical masks to simulate real-life communication barriers, such as muffled sound and loss of visual cues.

XSL•FO
RenderX

Figure 1. An example of a mock clinical scenario with the real-time speech recognition system set up on a table between the participant (left) and the mock doctor (right). A microphone on the iPad facing the mock doctor detects audio during interviews. Transcripts are displayed on both iPads in real time. SRS: speech recognition system.

Postscenario SRS Assessments

Following each scenario, participants provided feedback on the captioning system, rating it across 4 domains: distraction, ease of use, trust, and overall satisfaction (Multimedia Appendix 1). Scenario-specific questions included: “In your discussion with the mock doctor, how distracting were the captions?” “How easy or difficult was it to watch the caption while talking with the mock doctor?” “How much did you trust the accuracy of the generated captions?” “In this scenario, how satisfied were you with the captioning technology?” To reduce response bias, we alternated the direction of the scales: ease of use and trust rated from 1 (strong agreement) to 5 (strong disagreement), and satisfaction rated from 1 (strong disagreement) to 5 (strong agreement). Distraction was scaled separately from 1 (strong disagreement) to 3 (strong agreement).

Participant Survey Questions

To evaluate user experience with the SRS, participants completed a structured exit interview consisting of 9 questions (5 scalar and 4 open-ended items; Multimedia Appendix 1). To ensure accessibility, a study team member read all questions aloud while they were displayed on an iPad (Apple Inc). We audio-recorded and transcribed responses verbatim using a third-party service, then deidentified the transcripts. We reviewed audio files to clarify unclear segments. Given the brief interviews, we organized and analyzed responses in Microsoft Excel (version 16.77).

Open-ended responses were reviewed using a structured framework aligned with predefined domains: ease of use, comfort, satisfaction, trust, emotional response, and the captioning system’s ability to support or replace lip reading. Overall, 3 team members (SEH, LJM, and LW) independently applied initial codes to a subset of transcripts. Coding discrepancies were resolved through discussion, and the codebook was refined iteratively. Consistency was maintained through regular team meetings, and reflexive discussions were used to address potential bias.

Themes were identified based on frequency, relevance to study aims, and salience across participants. Representative participant comments were selected to illustrate key insights. Thematic saturation was reached when no new concepts emerged from successive interviews.

Mixed Methods Integration

To integrate quantitative and qualitative data, we used a convergent parallel approach in which both datasets were collected during the same phase, analyzed separately, and then merged during the interpretation phase. Integration occurred through (1) narrative weaving of findings across domains and (2) construction of a joint display that juxtaposed quantitative ratings with representative qualitative insights to generate meta-inferences. This approach allowed identification of areas of convergence and divergence between usability ratings and participants’ lived communication experiences.

XSL•FO
RenderX

Closed Captioning Accuracy

In addition to participant feedback, we analyzed the accuracy of the system's transcriptions. We compiled all transcripts generated by the mock doctors and compared them to professional communication access real-time translation transcripts.

We used word error rate (WER), a standard metric in automatic speech recognition (ASR) that calculates errors as the ratio of insertions, deletions, and substitutions required to align the system output with the reference [25,26]. We implemented WER calculations using the Python-based *jiwer* library, which provides standardized scoring for automated SRSs. This approach allowed us to assess how closely the SRS-generated captions matched professional-level transcription, validating the system's effectiveness in realistic use cases.

Statistical Analysis

We performed univariate analyses on demographic data and postscenario survey responses. Because of the small sample size, the study was not powered to detect subgroup differences. For transcript analysis, we segmented transcripts from mock sessions into 3 distinct scenarios. To focus on the primary use case, captioning clinician speech, we excluded utterances from participants who are DHH and analyzed only the mock doctors' speech.

Ethical Considerations

This study was approved by the University of Michigan Institutional Review Board (IRB; HUM00240244). All participants provided informed consent prior to participation. Participants were informed of the study purpose, procedures, potential risks, and their right to withdraw at any time without penalty. All study data were deidentified prior to analysis, and transcripts were reviewed to remove personally identifiable information. Audio recordings and transcripts were stored on secure, password-protected institutional servers accessible only to the study team. Participants received a US $25 Amazon gift card for their participation. The individuals depicted in the figure provided explicit written consent for publication of their images. The individuals shown in Figure 1 provided explicit written consent for their images to be published.

Results

Participant Characteristics

Overall, 11 participants who are DHH enrolled and participated in the pilot study. Due to equipment failure resulting in complete data recording loss with Participant 5, this participant was excluded from the analysis. The 10 remaining participants had an even distribution of genders (Table 1).

Table . Study participant demographics.

ID	Age (years)	Sex	Identity	Hearing loss levels[a]	Wearable technology[b]	Lip reader
P01	61	Female	HoH[c]	Severe	Yes	All of the time
P02	66	Male	HoH	Severe	Yes	Sometimes
P03	66	Male	HoH	Severe	Yes	No
P04	66	Female	HoH	Moderately severe	Yes	Sometimes
P06	43	Female	Deaf	Profound	Yes	All of the time
P07	21	Female	deaf	Moderately severe	Yes	Sometimes
P08	39	Female	HoH	Severe	Yes	All of the time
P09	24	Male	Deaf	Profound	Yes	No
P10	56	Male	deaf	Profound	Yes	Sometimes
P11	20	Male	HoH	Mild	Yes	Sometimes

[a]Hearing loss levels were self-identified, and all participants reported equal hearing loss levels bilaterally.

[b]Wearable technology includes hearing aids and cochlear implants.

[c]HoH: hard of hearing.

The mean age of the participants was 46.2 (SD 19.3) years. Six participants identified as "hard of hearing," 22 as "Deaf," and 2 as "deaf." Seven participants self-reported severe to profound HL, and all participants had bilateral HL. Five participants self-reported congenital HL, 2 reported childhood onsets of HL (<12 y old), and 2 reported HL as adults (>18 y old). Hearing aids were used by 8 participants, and 2 participants used cochlear implants. Seven participants used captioning services in the past. Seven also incorporated smartphone-based hearing assistive technology. Three used "other" tools, including using cupped hands behind ears to assist in hearing. Eight participants reported varying degrees of dependence on lip reading, but 5 participants depended sometimes on lip reading and 5 depended fully on lip reading.

Postscenario SRS Assessments

There were 29 postscenario SRS assessment surveys, 3 survey responses each from 9 participants and 2 survey responses from 1 participant. One survey response from participant P11 was not collected due to a technician error. Overall, participants found the captioning technology not distracting in 86% (25/29) of scenarios (Table 2). In 90% (26/29) of scenarios, participants

XSL•FO
RenderX

trusted the accuracy of generated transcription and felt the captions were easy to watch while conversing with the mock doctor. In 76% (22/29) of scenarios, participants were satisfied with the captioning technology. The technology was least satisfying to participants in the back pain scenarios (70% satisfaction) compared to the high blood pressure (78% satisfaction) and headache (80% satisfaction) scenarios.

Table . Summary of participant assessments regarding live captioning technology compiled from all 3 scenarios and dichotomized.

Questions[a]	Assessments	Values, n (%)
In your discussion with the mock doctor, how distracting were the captions?	Not distracting[b]	25 (86)
How easy or difficult was it to watch the caption while talking with the mock doctor?	Easy[c]	26 (90)
How much did you trust the accuracy of the generated captions?	Trusted[d]	26 (90)
In this scenario, how satisfied were you with the captioning technology?	Satisfied[e]	22 (76)

[a]For all 4 questions, n=29 since 1 of the 10 participants did not participate in 1 of the 3 scenarios.

[b]Not distracting: not at all distracting.

[c]Easy: very easy + somewhat easy.

[d]Trusted: completely trusted + somewhat trusted.

[e]Satisfied: very satisfied + somewhat satisfied.

Participant Experience Surveys

All 10 participants completed structured exit interviews following the captioning scenarios, providing reflections on their overall experience with the SRS (Table 3). Interview responses were analyzed using a predefined framework aligned with domains explored in the postscenario ratings (eg, ease of use, comfort, satisfaction, trust, emotional impact, and support for lip reading). This section summarizes participant perspectives and provides representative quotes to contextualize the quantitative results described above.

Table . Representative participant reflections by theme.

Themes	Relevant quotes[a]	Interpretation
Ease of use	“At first I wasn’t sure what to expect, but after a few lines of text I stopped even thinking about it—it just worked. That made me feel more in control.” (P04)	Participants found the system intuitive and accessible.
Comfort	“I didn’t have to strain or overthink. It just flowed naturally and I didn’t even realize how relaxed I was until the end.” (P08)	Technology reduced cognitive effort and fostered emotional ease.
Satisfaction	“I was happy. I wish all the doctors would have something like this. It made me feel like my experience mattered.” (P03)	Participant expresses satisfaction and a sense of being valued.
Safety and trust	“Because it’s live, it feels very safe. You’re not left guessing, and I felt confident nothing important was missed.” (P01)	Real-time functionality enhanced user confidence and perception of safety.
Emotional response	“I didn’t realize how much stress I usually carry during appointments. This made me feel heard and like I could finally breathe.” (P09)	System reduced communication-related anxiety and supported emotional well-being.
Support or replace lip reading	“With the mask on, it would have been extremely difficult to follow—and with the captioning, it was just leaps better. I wasn’t exhausted from trying to read lips the whole time.” (P07)	The technology was viewed as a vital alternative to lip reading, especially in masked settings.

[a]Relevant quotes from individual participants illustrating each core theme, including insight into perceived usability, comfort, satisfaction, emotional impact, and the role of real-time captions in supporting communication.

Most participants (9/10) described the system as easy to use, frequently using phrases like “very easy” or “easier than usual.” One participant remarked,

XSL•FO
RenderX

> *After a few lines of text I stopped even thinking about it—it just worked. That made me feel more in control.*

Another noted,

> *It was easier than usual because we don't have captioning. It's always nice to have it just in case you miss something.*

Participants also reported high comfort with the system. Descriptions included "very comfortable," "easy to work with," and "high comfortability."

As 1 participant shared,

> *It just flowed naturally, and I didn't even realize how relaxed I was until the end.*

Satisfaction was also high across interviews. While 76% of scenario ratings reflected satisfaction, all participants described themselves as satisfied or very satisfied in exit interviews. One stated,

> *I was happy. I wish all the doctors would have something like this.*"

Another shared,

> *I was pretty satisfied, and the captioning was spot-on.*

When asked about trust in the system, participants frequently described the captions as reliable. One participant reflected,

> *Because it's live, it feels very safe. You're not left guessing.*

A few raised questions about data privacy, with one noting,

> *I would also want to know what happens to the transcript and who has access to it.*

Participants also described emotional benefits from the technology. In total, 9 of 10 participants used words like "reassured," "relaxed," and "comfortable" to describe how the SRS made them feel. One participant shared,

> *This made me feel heard and like I could finally breathe.*

Perceptions of the captions' ability to support or replace lip reading were more varied. Several participants described the system as a helpful supplement or improvement, particularly in masked settings. As one noted,

> *With the mask on, I definitely depended on it more.*

Another stated,

> *I think it's better than lip reading.*

Others expressed that lip reading remained important, with one participant saying,

> *Not going to replace lip reading... captions help, but I still rely on visual cues.*

Beyond these predefined domains, participants spontaneously shared reflections on broader applications of the SRS. Several expressed enthusiasm for expanding its use in real-world clinical settings, with one stating,

> *I would like to see that in many doctor's offices tomorrow.*

Others suggested the system may be particularly helpful for patients who are older, have cognitive impairments, or use interpreters. A few noted that having real-time captions reduced the pressure to maintain constant visual attention, allowing for more natural communication and less fatigue.

Closed Captioning Accuracy

We collected and preprocessed transcripts from 10 mock clinical sessions. Due to varying levels of verbosity among the participants, the total transcript lengths varied substantially, ranging from 1144 to 4704 words.

Overall, participants found the SRS to be sufficiently accurate (Table 4). For instance, P04 noted that the system was *"more accurate than the phone captions"* she typically uses in daily conversations. Similarly, P06 commented on the system's effectiveness compared to human captioners, stating,

> *A lot of the captions I had were court reporters—they caption fast, but sometimes they make mistakes. ... And this one [the SRS], it's more accurate and I see words better.*

Nonetheless, participants expressed concerns about the system's ability to handle more complex or specialized medical vocabulary. For example, P10 questioned *"how it would be with more complex medical terminologies,"* in real clinical settings where more technical jargon and medication names were frequently used.

XSL•FO
RenderX

Table . The word error rate for each scenario, along with the accumulated word error rate for each participant across all 3 scenarios. These word error rate scores specifically reflect the accuracy of the automated speech recognition system in transcribing the mock doctors' speech.

ID	Mock doctor	Scenario 1[a]	Scenario 2[a]	Scenario 3[a]	Accumulated (range: 0.127-0.167)
P01	M1	0.136	0.133	0.125	0.131
P02	M2	0.193	0.141	0.133	0.153
P03	M1	0.129	0.122	0.133	0.127
P04	M2	0.228	0.128	0.151	0.167
P06	M2	0.137	0.152	0.135	0.144
P07	M1	0.127	0.134	0.132	0.133
P08	M2	0.155	0.142	0.152	0.149
P09	M1	0.136	0.131	0.141	0.137
P10	M1	0.127	0.126	0.133	0.129
P11	M2	0.147	0.185	0.134	0.151

[a]The scenario-level word error rates ranged between 0.122 and 0.228.

Joint Display of Integrated Findings

To illustrate convergence between quantitative usability ratings and qualitative interview themes, we constructed a joint display summarizing merged findings and resulting meta-inferences across key domains (Table 5).

Table . Joint display of integrated quantitative and qualitative findings

Domain	Quantitative result	Representative quote	Integrated meta-inference
Ease of use	90% rated captions "easy"	"After a few lines of text I stopped even thinking about it—it just worked."	High usability with minimal cognitive load Captions supported natural conversational flow
Comfort	Not directly measured	"It just flowed naturally, and I didn't realize how relaxed I was."	Technology reduced strain and fostered emotional ease during communication
Satisfaction	76% satisfied	"I wish all the doctors would have something like this."	Satisfaction tied to both functional value and feeling understood and supported
Safety and trust	90% trusted accuracy	"Because it's live, it feels very safe. You're not left guessing."	Real-time display strengthened perceived safety and reliability despite minor errors
Emotional response	Not directly measured	"This made me feel heard and like I could finally breathe."	Captions enhanced psychological safety and reduced anxiety—benefits not captured numerically
Support or replace lip reading	Not directly measured	"With the mask on, I depended on it more… it was leaps better."	Captions supplemented or replaced lip reading, reducing fatigue in masked settings

Discussion

Principal Results

To successfully deploy SRS in clinical settings, it is essential that the system accurately captures and reflects clinicians' speech. Our findings show that although the SRS output was not flawless, its WERs fell between 0.10 and 0.20, a range generally considered acceptable for real-world ASR use [19,26]. Furthermore, participants understood the captions with relative ease, suggesting that transcription quality was sufficient to support comprehension in simulated outpatient scenarios. However, stricter accuracy standards may be required in high-stakes contexts, such as discussions of medications or treatment options, where small errors can have serious consequences.

Although WER is widely used to evaluate ASR performance, it weighs all error types equally, regardless of their impact on comprehension [27]. Prior work has proposed alternative evaluation approaches that aim to capture semantic accuracy or user-centric measures of intelligibility and usefulness [20]. In clinical communication, we support developing evaluation metrics that align more closely with safety-critical requirements. Such metrics would be instrumental in determining when ASR

XSL•FO
RenderX

systems are truly ready for deployment in health care environments. In clinical settings, misrecognition of medical terminology can have consequences far more serious than common transcription errors, especially when involving medication names, diagnoses, or treatment instructions. Because of this, future work should consider safety-critical evaluation frameworks that go beyond traditional WER. Approaches, such as semantic error analysis, comprehension-based scoring, or accuracy, weighting for medically significant terms could better capture the real-world implications of captioning errors in health care communication.

Our participants represented a variety of ages, genders, HL levels, and degrees of dependence on lip reading. However, most participants had previously used captioning technology as an accommodation, so our usability findings may be less generalizable to individuals who are DHH with no prior captioning experience. Also, only 2 participants preferred written communication with hearing people. Therefore, satisfaction with our captioning technology may be higher than our results suggest for people who are DHH and depend more on written communication. Regardless of the scenario, most participants were satisfied with the SRS, trusted its accuracy, found it easy to watch, and were not distracted.

Participants trusted the captioning system despite occasional transcription errors, which embodies the concept of trust-in-automation frameworks, where user reliance is shaped by perceived system reliability and predictability [28]. Exit interviews revealed that beyond meeting technical expectations, the captioning system also meaningfully supported emotional connection, trust, and autonomy during clinical interactions. Participants described the captions as easy to use and grounding. They also noted reduced stress, lower cognitive fatigue, better understanding, and a stronger sense of being heard. Encouragingly, the observed reduction in stress and fatigue is consistent with prior work where assistive technology helped manage cognitive effort during information processing [29,30]. These findings suggest that accessibility tools should be evaluated not only by their accuracy but by their ability to support psychological safety and communication equity [31].

Additionally, although participants generally trusted the captioning system, a few raised concerns about transcript privacy and data handling. These concerns highlight the ethical need for transparency when implementing automated captioning in health care. This pilot used secure, locally stored recordings without identifiable data, but clinical deployment will require Health Insurance Portability and Accountability Act (HIPAA)-compliant encryption and explicit consent protocols. Adding user controls, such as options to delete transcripts or disable storage, could further strengthen trust among users who are DHH and other vulnerable populations. Nevertheless, participants recommended broader adoption of SRS, particularly for older adults and others facing progressive hearing-related communication barriers, underscoring the system's potential to improve care for a heterogeneous population of DHH patients.

Limitations

While our findings are promising, this study has several limitations. Most participants were experienced caption users and had prior familiarity with assistive communication technologies, which may have positively influenced usability and satisfaction ratings. As a result, these findings may not fully represent the experiences of individuals who are DHH and are less familiar with captioning or other accessibility tools or primary American Sign Language users. Future research should include participants with varying levels of captioning experience and a broader demographic range to better assess generalizability and identify barriers for first-time users. This study was conducted in controlled, simulated settings, which may not fully reflect the complexity and spontaneity of real-world medical encounters. Because these mock scenarios involved medical students rather than practicing clinicians, the communication dynamics may differ from authentic physician–patient interactions. Future work should therefore include real-world clinical deployments to evaluate how captioning systems perform in active care settings and adapt to diverse communication styles and environmental conditions.

Second, although our participant pool included individuals with diverse hearing identities and varying degrees of familiarity with assistive technologies, it does not capture the full range of experiences within the broader community who are DHH. Future work should include longitudinal application in various clinical settings and recruitment of a more diverse participant population to better assess long-term usability and impact.

In addition, our SRS was not specifically optimized for medical vocabulary. This limitation was evident in the system's tendency to misrecognize medical terminology, words that are infrequent in everyday speech yet crucial for accurate clinical communication. Furthermore, while we used WER as a standard quantitative evaluation metric, it does not fully capture how users who are DHH interpret and understand captions, particularly in high-stakes contexts. Future research should explore the development of domain-specific SRS trained on medical speech and adopt evaluation metrics that better reflect comprehension and user experience among individuals who are DHH. Finally, since WER assigns equal weight to all tokens, it does not differentiate between routine transcription errors and those involving safety-critical clinical terms (eg, medications or diagnoses). Therefore, WER may underestimate the potential impact of certain errors in medical contexts.

Future Directions

Improving SRS accuracy for medical terminology remains a key technical priority for clinical use. Strategies may include (1) speech recognition models on deidentified clinical audio to capture the acoustic variability of real-world medical speech [32], (2) embedding domain-specific medical dictionaries and medication name libraries into the language model of the SRS systems to reduce substitution errors [33], (3) leveraging context-aware large language models that can infer meaning from partial or uncertain input [34], and (4) integrating clinician feedback loops for rapid correction of recurring misinterpretations [35]. These enhancements would not only improve accuracy for technical vocabulary but also strengthen user trust and perceived reliability in clinical environments.

Building on these preliminary findings, future work should also explore integration with medical-domain ASR models to

XSL•FO
RenderX

enhance accuracy for specialized terminology and complex clinical dialog. Longitudinal studies will be valuable for assessing maintained usability, user trust, and performance over time. Additionally, testing captioning systems in broader clinical contexts, such as emergency care, geriatrics, and among patients with cognitive impairment, will help determine their adaptability and impact across diverse care settings.

Implications for Clinical Workflow Integration

Our findings demonstrate that real-time captioning is usable and beneficial in clinical settings for patients who are DHH, aligning with prior evidence that captioning improved recall of anesthesia-related consent conversations [36]. Given this demonstrated value, practical integration of captioning tools into clinical workflows will require thoughtful design to minimize disruption while enhancing accessibility. Participants envisioned use cases in which SRS displays could be embedded within existing electronic health record systems or mirrored on clinician tablets to preserve natural eye contact and conversational flow. Integration will also depend on clear institutional protocols for activating captioning on demand, ensuring confidentiality, and providing clinician training on how to engage with patients who are DHH using this technology. Establishing these processes could enable captioning to function as a routine accessibility feature rather than an exception, supporting both efficiency and equitable communication in care delivery.

Conclusions

This pilot study demonstrates that artificial intelligence–enhanced captioning can meaningfully improve communication experiences for individuals who are DHH in clinical settings. Participants found the system intuitive, emotionally supportive, and effective in bridging common communication barriers, especially those worsened by face masks and unfamiliar environments. While traditional captioning tools often fall short in medical contexts, integrating large language models into the speech recognition process offers a promising path toward more coherent, accurate, and human-centered accessibility. By centering on user perspectives, this study highlights the importance of evaluating assistive technologies not only for transcription quality, but for their impact on trust, inclusion, and psychological safety. Future research should build on these early insights to further refine captioning systems, examine their use in real-world clinical care, and ensure that patients who are DHH are active partners in the design of accessible digital health solutions.

Acknowledgments

The authors thank the Deaf/deaf and hard-of-hearing community members who participated in this study for generously sharing their insights and experiences. We are grateful to the Dexter Family Medicine clinic at the University of Michigan for their support in facilitating pilot testing.

Funding

This work was supported by funding from the Blue Cross Blue Shield of Michigan Foundation (2024010111) and by the University of Michigan's e-HAIL (e-Health and Artificial Intelligence Laboratory) program.

Abstract

Background: Chronic pain is a critical cause of personal suffering and societal concern. However, treatment options remain inadequate, and access to efficacious treatment is limited by geography, economics, and scale. Digital health interventions for chronic pain are easily scaled solutions to this problem, and autonomous conversational agents represent a new frontier in this treatment domain. Despite their potential impact, conversational agents powered by generative artificial intelligence (AI) have yet to be developed or examined for the treatment of chronic pain.

Objective: We aimed to develop and test Solace, a first-of-its-kind, expert-trained generative AI conversational agent designed to deliver support grounded in principles of evidence-based pain psychology.

Methods: We conducted an acceptability and usability study of Solace in a group of individuals with chronic pain. Participants (n=175) were recruited from Prolific, an online crowdsourcing platform, and interacted with Solace for at least 25 minutes. Self-report measures of system usability, treatment acceptability, and therapeutic alliance were completed after the interaction, and clinically relevant pain-related measures were completed before and after the interaction.

Results: Participants rated the usability of Solace to be excellent (System Usability Scale mean score 85.04, SD 13.6) and found it to be an acceptable intervention for chronic pain. The therapeutic alliance between participants and Solace was rated highly. Participants also demonstrated improvements in anxiety, pain interference, kinesiophobia, and pain resilience. Safety guardrails designed to identify and manage instances of suicidal ideation, injury, or requests for medication recommendations performed appropriately during the study. Solace is a usable and acceptable treatment for chronic pain that facilitates forming a strong therapeutic alliance with users. A single 30-minute conversation with Solace was also associated with improvements in several clinically relevant domains.

Conclusions: Solace is a usable and acceptable expert-trained generative AI conversational agent for pain management. Randomized clinical trials are needed to evaluate the efficacy of Solace as a strategy for the treatment of chronic pain.

KEYWORDS

artificial intelligence; chatbot; chronic pain; digital health; pain psychology

Introduction

Chronic pain affects approximately 20% of adults worldwide, and is an enormous source of personal suffering as well as a major public health challenge [1,2]. Psychological interventions are efficacious for chronic pain. Across numerous large-scale randomized controlled trials, cognitive behavioral therapy, in particular, has been robustly associated with improvements in pain intensity and pain-related disability [3]. There is also accumulating evidence that other psychological treatment approaches, including mindfulness-based interventions and acceptance and commitment therapy (ACT), are similarly effective [4-7].

Despite the wealth of evidence for pain psychology interventions, widespread implementation of these interventions has been limited. This may be due, in part, to systemic barriers to adoption, including insufficient finances, time constraints, poor accessibility, and social stigma [8,9]. However, one of the key limitations is simply the lack of competent providers. For instance, difficulty accessing competent providers is the most common barrier reported by individuals with chronic pain [8]. This is further complicated by the fact that most licensed health care providers practicing therapy (eg, psychiatrists, psychologists, counselors, and social workers) report little to no education or training in pain treatment [8].

Digital health interventions (DHIs) have emerged as one of the primary means to overcome these barriers and bring psychological interventions for pain to scale [10,11]. DHIs exist in many forms, ranging from distance-based replications of services via telephone or videoconferencing to web-based treatment programs and mobile applications. Across these services, content can be delivered in either a fully self-guided format or supported by a provider or "coach," either synchronously or asynchronously [12]. These interventions have broadly demonstrated efficacy, but uptake remains limited, with studies reporting high dropout rates and low adherence [10,13].

More recently, researchers have begun to examine the provision of therapy by conversational agents, or chatbots, that enable patients to have interactive conversations in real time [13]. A recent scoping review identified beneficial effects of chatbots on pain intensity, but results were equivocal for pain interference and mental health outcomes [13]. These chatbots have generally been designed according to rule-based response algorithms rather than large language model (LLM)–based conversational support [13-16]. Such approaches have demonstrated that conversational agents can build a strong therapeutic alliance with users [15].

The use of LLM-based generative artificial intelligence (AI) conversational agents offers an alternative to algorithm-based chatbots. To date, not one study has examined fully generative AI conversational agents for the treatment of chronic pain. However, such generative AI chatbots have been studied for general mental health treatment. A clinical trial of a generative AI chatbot, Therabot, identified clinically significant improvement in symptoms of depression, anxiety, and feeding/eating disorder risk after 4 and 8 weeks, compared to waitlist controls [17]. Generative AI chatbots are also being applied to coping with medical concerns. In a recent study, health care providers identified a generative AI chatbot designed to provide coping support for adolescents with cancer as a feasible option for support provision, although the impact on clinical outcomes remains to be examined [18].

We sought to develop and test Solace, an expert-trained, generative AI chatbot built by ManagingLife, Inc. Solace was created by pairing a purpose-built knowledge base with a multiagent architecture leveraging a variety of commercially available foundational models. This study describes a prospective feasibility evaluation of the acceptability and usability of Solace in a group of participants reporting chronic pain (n=175). Participants engaged in an open-ended 30-minute interaction with Solace and completed measures of treatment acceptability, system usability, and therapeutic alliance after the conversation. Pain-related self-report measures were also completed before and after the participant's interaction with Solace. We hypothesized that individuals would find Solace to be a usable and acceptable treatment for chronic pain.

Methods

Study Design

This study was a prospective feasibility evaluation [19,20] of the AI-driven conversational agent, Solace. The design was guided by the Developmental and Exploratory Clinical Investigation of Decision-Support Systems Driven by Artificial Intelligence (DECIDE-AI), providing an early-stage clinical evaluation checklist of AI-specific reporting items (Multimedia Appendix 1) [21].

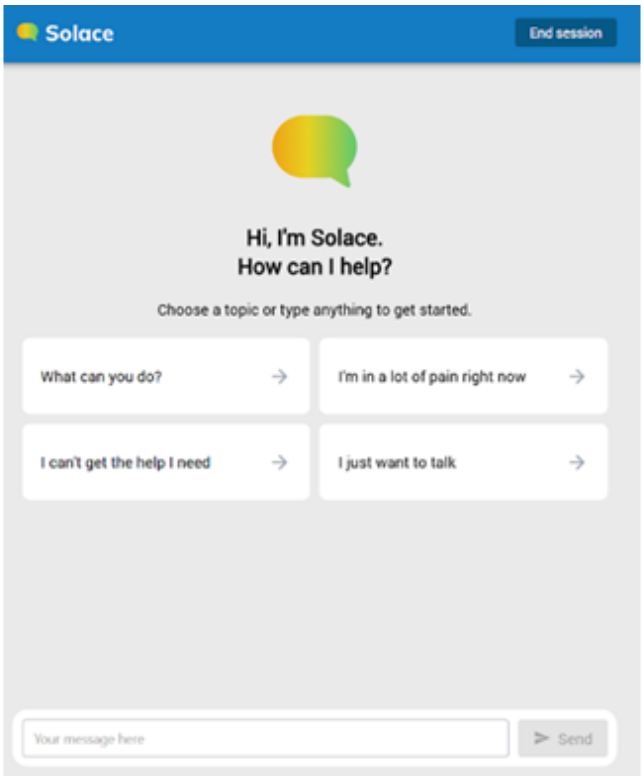
AI Chatbot

Overview

Solace is a stand-alone, web-based digital health application developed by ManagingLife [22]. It interacts with users to gather information related to the user's experience of pain and delivers appropriate, structured, interactive support grounded in evidence-based pain psychology techniques (eg, psychoeducation and ACT) to bolster emotional coping and self-management in individuals living with chronic pain. The development process focused on ensuring appropriate psychological support for adults with chronic pain through systematic programming and testing phases.

Technical Infrastructure

This study used the Solace v1.0 beta system version. The technical backbone of the chatbot system was built on top of a cloud-based digital health platform, Manage My Pain, developed by ManagingLife [22]. The main components of the Manage My Pain platform included user authentication, secure cloud hosting, and compliance with international data privacy



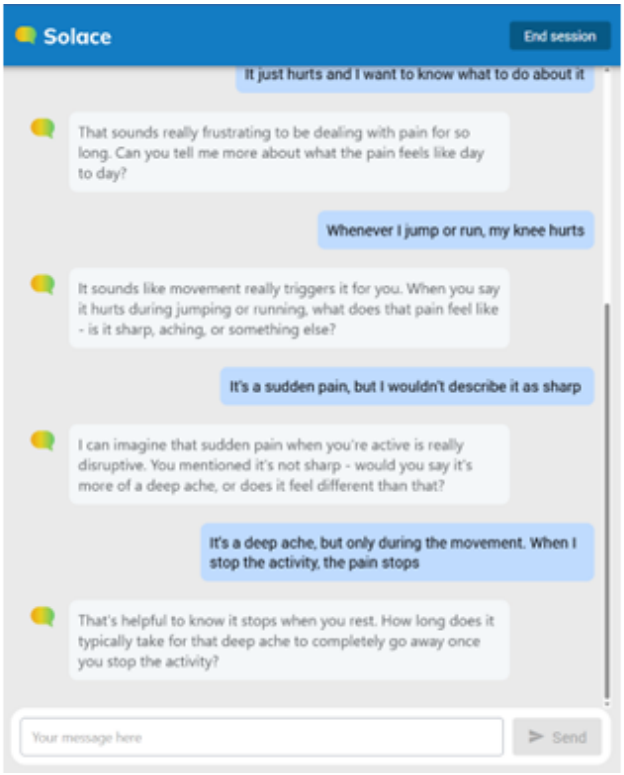
XSL•FO
RenderX

regulations, including end-to-end encryption and role-based access controls. Solace was designed to extend this platform by leveraging Amazon Web Services Bedrock to build a multiagent architecture using a library of LLMs. Each agent is responsible for a specialized task, and, together, these agents are coordinated by a centralized orchestration layer that manages conversational flow, memory retention, response timing, and system-level safety controls [23]. The foundational model versions, underlying platform, and all settings were fixed throughout the study period.

Conversational Design and Rules

Users began their experience with Solace by typing freely or selecting from starter prompts (Figure 1). User inputs were accepted without restrictions on length or content. Solace followed a set of core design principles developed through iterative collaboration with subject matter experts (SMEs) to ensure therapeutic integrity and user safety. These included the following:

Figure 1. The user options for starting a Solace conversation, including the use of the free-text field or starter prompts.



1. Open-ended engagement, encouraging users to freely express their thoughts and emotions
2. Plain language to ensure accessibility and reduce cognitive burden
3. Emotional sensitivity, with empathic responses embedded throughout the conversation
4. Therapeutic guidance toward evidence-based strategies and self-understanding
5. Context continuity, using memory variables to support coherent, personalized dialogue
6. Multilevel safety guardrails, with screening for sensitive content (eg, mention of self-harm, harm to others, and opioid use) and fallback responses designed in collaboration with clinical experts.

Solace's outputs drew from knowledge bases composed from psychological frameworks, including but not limited to ACT, CBT, and dialectical behavior therapy and were presented to the user as (typically) 1-4 sentences (Figure 2).

XSL•FO
RenderX

Figure 2. Examples of Solace outputs during a user conversation.

Testing and Optimization

Initial development and testing were led by a clinical pain psychologist (PMS) and included a cohort of 8 SMEs, including other clinical psychologists, pain physicians, and pain researchers. SMEs conducted simulated therapy sessions with Solace and provided both real-time "think-aloud" feedback and postsession feedback to the development team, focusing on the conversational tone of Solace, therapeutic alignment, and emotional sensitivity. The development team worked with SMEs to translate their feedback into Solace's conversational logic, which included refining pacing, language, and safety mechanisms.

Within Solace, user interactions are processed as string-based text inputs and routed through an orchestration layer that assigns each request to an appropriate specialized agent, which generates a response. Each specialized agent represents a specific element within the structure and therapeutic style of a clinical psychology session (eg, 1 agent for managing transitions between stages within a session), and has been fine-tuned and reviewed during development by an SME.

All generated responses are subsequently evaluated by a guardrail validation component that performs safety and compliance checks. If the validator fails, the response is discarded, and a specialized guardrail agent generates an alternative response (see "Safety and Errors" below); this agent and its outputs are likewise reviewed and refined by the SME. If validation succeeds, the approved response is returned to the user.

Stress-testing scenarios were used to explore how the system responded to ambiguous or sensitive inputs. System-level performance metrics, including response latency, session duration, and output length, were recorded during internal testing. This series of tests was part of an iterative process, informing and optimizing prompt development and the design of response templates.

Safety and Errors

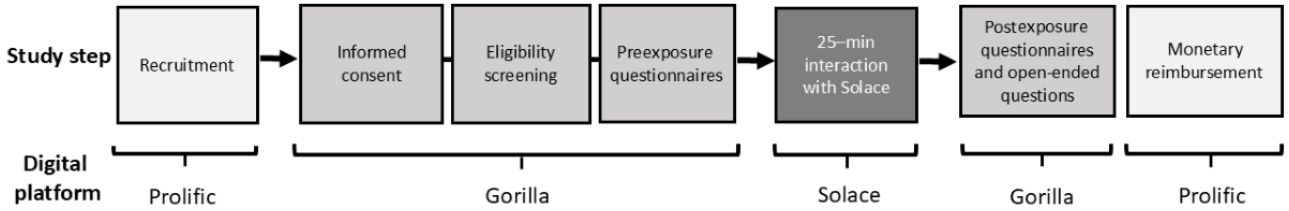
System-level errors were defined as failure to generate a response, excessive latency, or loss of conversational flow. Errors were identified using a series of validator checkpoints embedded within the system architecture. Checkpoints initiated fallback mechanisms to trigger predefined safe response templates. System anomalies and platform reliability were further monitored using session-level logs and performance data. Detection of risks was supported by multilevel safety guardrails built into Solace's conversation logic and prompt structures and relied on a combination of rule-based screening and automated classification techniques. The safety guardrails were designed to identify and mitigate risks in the following safety-sensitive domains: (1) disclosure of content indicating potential harm to self, suicidal ideation, or harm to others; (2) active psychological or medical emergencies; and (3) recommendations related to prescription medication use.

When high-risk content was detected, Solace generated predefined fallback responses designed to redirect the user to seek professional help, reinforce system boundaries, and discourage further engagement with unsafe topics.

Participant Eligibility and Enrollment

Participants were recruited online through Prolific [24], an online research participation platform, and assigned an anonymous Prolific identification number. The target sample size for this study was 145 participants based on sufficiently approximating the population means across multiple continuous

XSL•FO
RenderX



variables that are expected to have normal distributions. We aimed to recruit 195 participants to accommodate an anticipated 25% rate of attrition [25].

Those who consented were redirected to Gorilla [26], a cloud-based research platform hosting the questionnaires, to screen for eligibility and to access the survey. Participants were considered eligible based on the following criteria: (1) 18 years of age or older, (2) English speaking, and (3) living with chronic pain (ie, pain that has persisted for longer than 3 months). Chronic pain status and participant demographics were provided via the Prolific platform. Those eligible were asked to enter demographic information (age and sex) and to complete the baseline self-report measures.

Chatbot Engagement

Participants were informed that Solace is a nonclinical investigational tool under development and is not intended to provide medical advice or replace professional care. Training or an opportunity for familiarization with Solace was not provided to the participants prior to the study. Participants were prompted to engage with Solace, which was described as a "conversational agent, developed by ManagingLife. Solace provides pain management support and evidence-based strategies to help you understand and manage pain in your daily life." Participants were instructed to engage with Solace for at least 30 minutes from the start of the conversation, and then manually end the session. If users ended the session earlier than 30 minutes, they were informed how much time was left. Participants were then congratulated for completing their time with Solace and were provided with a link to return to Gorilla to complete the same self-report measures as at baseline, as well as a set of postexposure self-report measures. After completing the questionnaires, they were thanked for their participation, debriefed about the study hypotheses, and signposted to additional support if needed. The full participant flow through the study is depicted in Figure 3.

Figure 3. Participant flow through the study steps and associated digital platforms.

Measures

Participant Demographics

Participant demographics, including sex, ethnicity, employment status, and pain duration, were obtained from Prolific records.

System Usability

The System Usability Scale (SUS) is a 10-item questionnaire designed to measure the usability of a system, including digital products or digital systems [27]. Participants are asked to respond to items regarding usability (eg, "I thought the system was easy to use") on a scale from 1=strongly disagree to 5=strongly agree. The SUS is scored by subtracting the sum of the negatively worded items (eg, "I thought there was too much inconsistency in this system") from the sum of positively worded items (eg, "I think that I would use this system frequently"), adding 20, and multiplying by 2.5 to get a score out of 100. An SUS score of ≥85 has been identified as "excellent."

Treatment Acceptability

Two self-report inventories were included to examine treatment acceptability. The Treatment Acceptability/Adherence Scale (TAAS) is a 10-item self-report questionnaire designed to assess treatment acceptability and anticipated adherence to psychological interventions for anxiety and related disorders [28]. The TAAS has shown strong convergent and discriminant validity as well as excellent internal consistency [28]. In this study, the TAAS also demonstrated excellent internal consistency (α=.85). The Treatment Evaluation Inventory-Short Form (TEI-SF) is a 9-item measure of the perceived acceptability of behavioral treatments, and captures both positive (eg, "I would find this treatment to be an acceptable way of dealing with my chronic pain") and negative (eg, "I believe this treatment is likely to harm or injure me") perceptions of treatment [29]. The TEI-SF had excellent internal consistency in this study (α=.85). Both measures were adapted to the context of chronic pain treatment, which has been done in previous studies.

Therapeutic Alliance

The Working Alliance Inventory-Client Version (WAI-C) is a 36-item questionnaire used to measure therapeutic alliance in face-to-face therapy [30]. The WAI-C captures the client's perspective on 3 elements of therapeutic alliance, including the bond between therapist and client, agreement on the goals of therapy, and agreement on tasks to accomplish those goals. The WAI-C has excellent internal consistency (α=.87) and is strongly related to psychotherapy treatment satisfaction and outcomes. It has also been shown to predict treatment response to therapeutic interventions for pain. This instrument was adjusted for use within the context of an interaction with an AI-agent to align with the study's exploratory aims.

Pain-Related Measures

Patient Reported Outcomes Measurement Information System-29, version 2.0 (PROMIS-29) provides a profile of physical and mental health and assesses 7 health domains, including physical function, pain interference, pain intensity, anxiety, depression, fatigue, sleep disturbance, and social role integration. The PROMIS-29 has demonstrated strong validity in chronic pain populations. Internal consistency of subscales ranged from α=.88 to α=.96, indicating excellent consistency.

XSL•FO
RenderX

The questionnaire was administered using the static short forms of the domains [31].

The Tampa Scale of Kinesiophobia (TSK) was included as a measure of fear of movement (and reinjury) [32]. Participants rate items relevant to this fear (eg, "Pain always means I injured my body") on a scale from 0=strongly disagree to 4=strongly agree. The TSK has been extensively validated for individuals with chronic pain, and internal consistency in this study was adequate (α=.70)

The Pain Resilience Scale (PRS) is a 14-item measure of an individual's ability to maintain positive physical and emotional functioning despite pain. Participants are asked to rate agreement to items (eg, "I push through the pain") on a Likert scale from 0=not at all to 5=all the time [33,34]. The PRS has 2 subscales, behavioral perseverance and cognitive-affective positivity. The PRS has demonstrated psychometric validity among individuals with chronic pain [33], and internal consistency in this sample was excellent (α=.95).

The Chronic Pain Acceptance Questionnaire (CPAQ) is a 20-item measure with two subscales: (1) the degree to which one engages in life activities regardless of pain and (2) willingness to experience pain [35]. The CPAQ has been extensively validated for individuals with chronic pain [36,37], and the internal consistency in this study was adequate (α=.70).

System Metrics

User engagement and system performance were abstracted from transcripts of each participant session and associated data. User engagement characteristics included the number and length of prompts entered into Solace, the number and length of Solace's responses, and total session duration. Response readability was calculated using the Flesch Reading Ease Score and the Flesch-Kincaid Grade Level [38,39]. Safety was assessed by manual review of all conversations that contained content relevant to the guardrails.

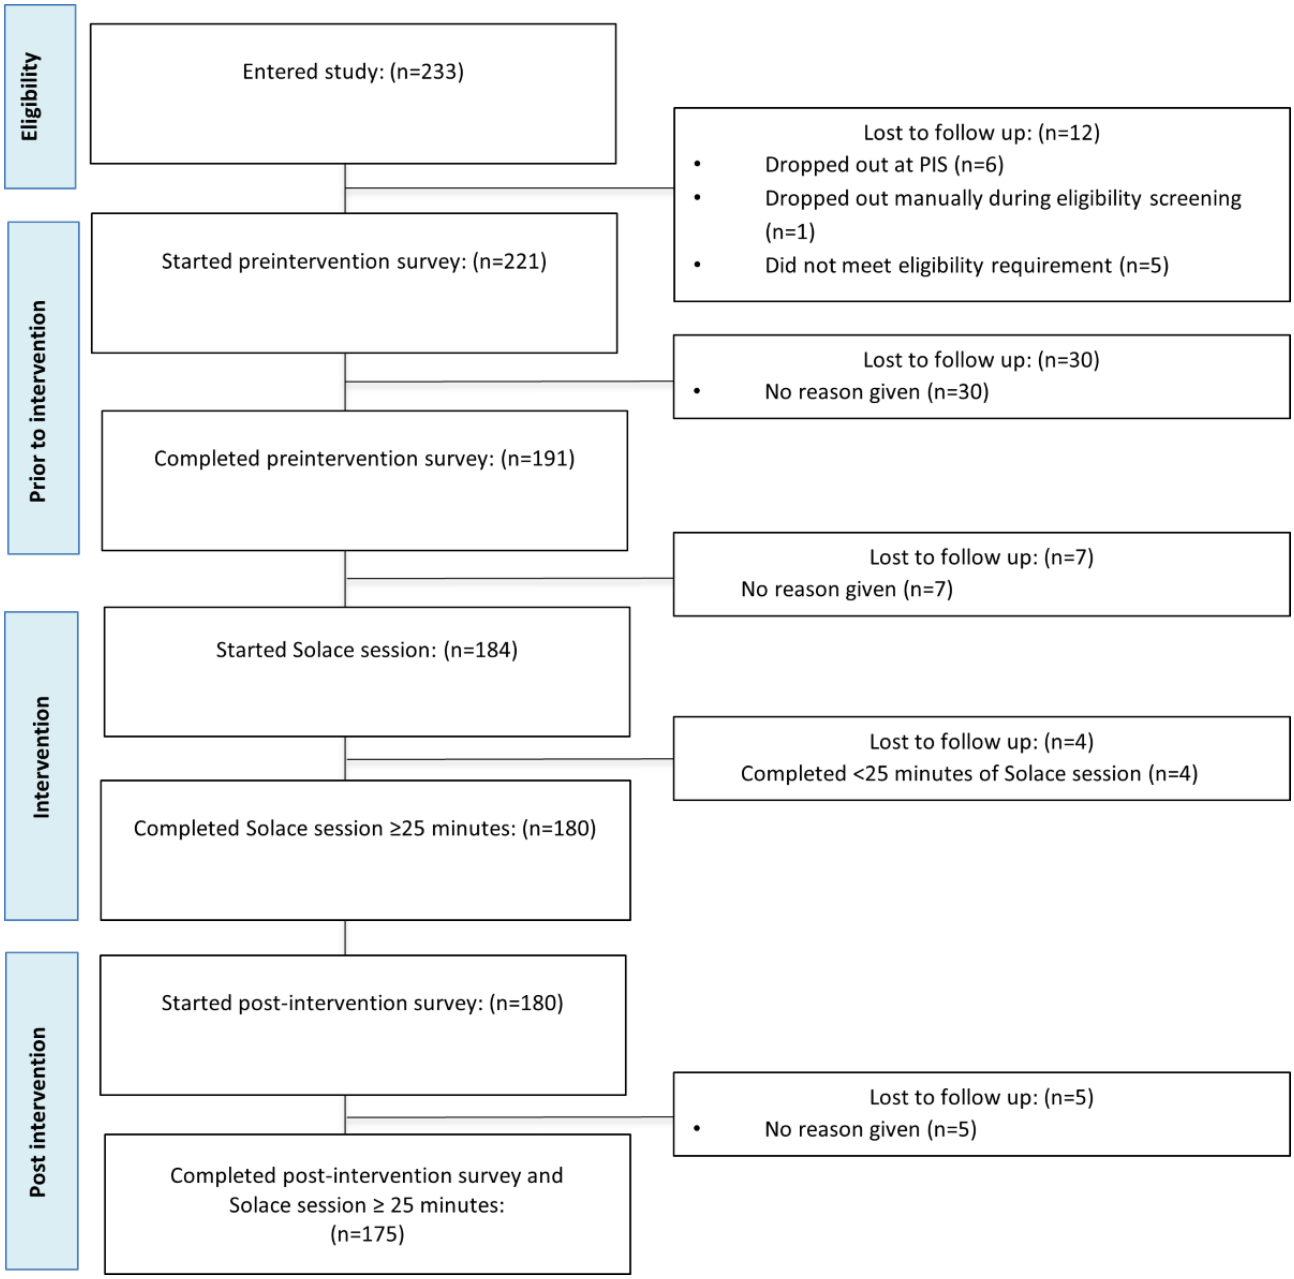
Analysis

Analyses were primarily descriptive in nature. Participant responses on measures of usability, treatment acceptability, and therapeutic alliance were averaged (rather than summed) to give an indication of the overall level of agreement with measure items. Median (IQR) ratings for individual items were also reported. Averages with SD or counts, where applicable, were reported for system-level metrics. Only participants who completed at least 25 minutes of interaction with Solace were included for analyses of usability, treatment acceptability, and therapeutic alliance, whereas intent-to-treat analyses (eg, including all participants) were conducted using linear mixed effects models to analyze changes in clinically relevant self-report outcomes. Of note, due to a technical issue, 1 item was missed from the WAI-C (item 31) and 1 item from the CPAQ (item 8).

Ethical Considerations

The University of Portsmouth Ethics Board approved this study (REB SHFEC 2025-073), and the study has been registered with the Open Science Framework. Written informed consent was obtained from all participants prior to taking part in the study. Participants were presented with information about the study, made aware of their right to withdraw from the study at any time, and provided consent. Participants were compensated £18 (approximately US $24) for completing the study.

All identifying information was removed from the data before storage, and the data were further anonymized by assigning ID codes. Data pertaining to participants' responses to the structured and open-ended questionnaires and to their interactions with Solace were anonymized. Anonymized data were temporarily stored on the servers of Gorilla and ManagingLife, respectively. Data were extracted and transferred to the University of Portsmouth's secure server. The data will be retained for a minimum of 10 years in accordance with the University of Portsmouth Retention Schedule for Research Data.



Results

Participant Characteristics and Flow

The flow of participants through the study is depicted in Figure 4. A total of 221 participants consented and completed the preinteraction survey. Of these, 184 began a session with Solace, and 175 engaged with Solace for at least 25 minutes. Participant demographics are listed in Table 1. All participants passed attention checks.

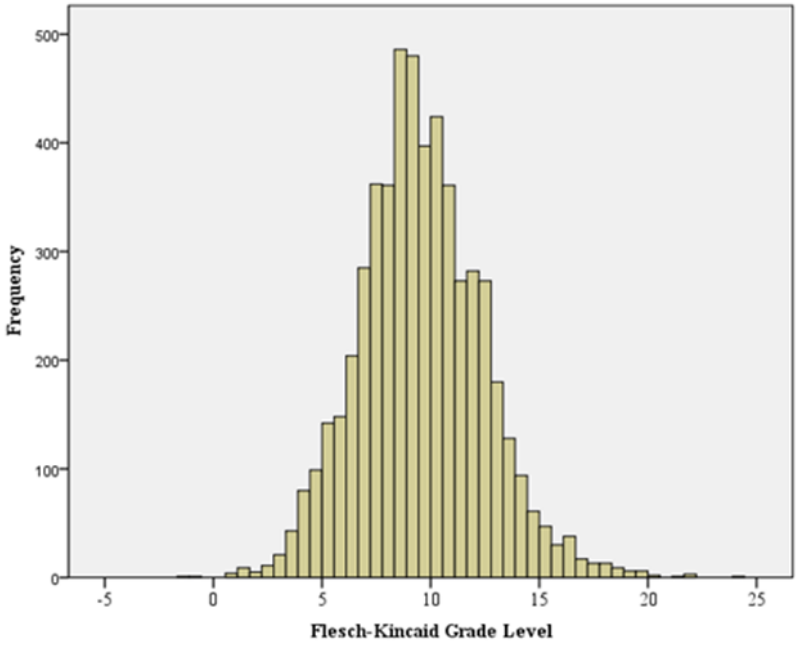
Usage Characteristics and Safety Performance

The interaction sessions with Solace lasted an average of 38.74 (SD 11.7) minutes. On average, participants provided 29.2 (SD 10.1) input prompts to the system with an average length of 19.8 (SD 12.4) words, and Solace gave responses averaging 49.73 (SD 9.8) words on each occasion. On average, the readability of Solace's responses was at the early high school level (Flesch-Kincaid Grade Level mean 9.56, SD 2.8; Flesch Reading Ease mean 56.44, SD 15.6). The distribution of Flesch-Kincaid Grade Levels and Flesch Reading Ease scores is depicted in Figures 5 and 6, respectively.

XSL•FO
RenderX

Figure 5. Distribution of Flesch-Kincaid Grade Levels across all responses generated by Solace.



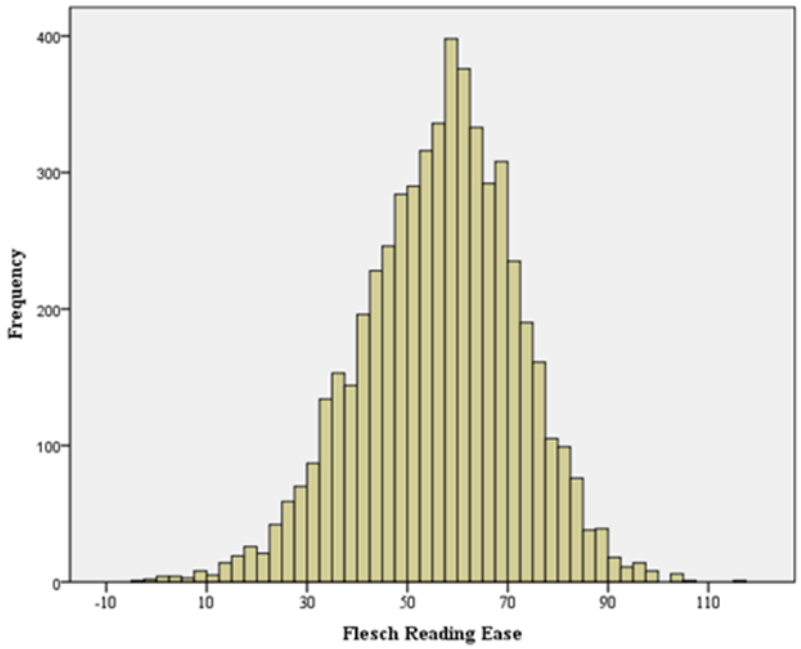


Figure 6. Distribution of Flesch Reading Ease scores across all responses generated by Solace.

Notably, 2 transcripts featured discussions of death, and 89 transcripts featured discussions of medication. Upon review by a clinical health psychologist (PMS), neither instance where death was discussed constituted suicidal ideation, self-harm, or harm to others, and Solace's responses were appropriate. Likewise, none of the conversations regarding medication included elicitation of recommendations, and, as such, guardrails were not activated.

System Usability

The SUS was completed as a measure of how easy participants found Solace to use. Participants rated the usability of Solace as excellent (mean 85.04, SD 13.6). On a scale from 1=strongly disagree to 5=strongly agree, participants rated all items as "strongly agree" except "I would like to use this system frequently," and "I found the various functions in this system were well-integrated," which were both rated as "agree." Item-level results are presented in Table 2.

XSL•FO
RenderX

Table 2. System Usability Scale item-level results (n=175). Scale ranges from 1=strongly disagree to 5=strongly agree.

Items	Median (IQR)
1. I think that I would like to use this system frequently	4.00 (2.00)
2. I found the system unnecessarily complex	1.00 (1.00)
3. I thought the system was easy to use	5.00 (1.00)
4. I think that I would need the support of a technical person to be able to use this system	1.00 (0.00)
5. I found the various functions in this system were well integrated	4.00 (2.00)
6. I thought there was too much inconsistency in this system	1.00 (1.00)
7. I would imagine that most people would learn to use this system very quickly	5.00 (1.00)
8. I found the system very cumbersome to use	1.00 (1.00)
9. I felt very confident using the system	5.00 (1.00)
10. I needed to learn a lot of things before I could get going with this system	1.00 (0.00)

Treatment Acceptability

Participants completed 2 measures of treatment acceptability, the TEI-SF and the TAAS. Average scores for the TEI-SF and TAAS, as well as individual item characteristics (median, IQR), are presented in Tables 3 and 4, respectively. On a scale from 1=strongly disagree to 5=strongly agree, participants reported an average rating of 3.77 (SD 0.7) on the TEI-SF. On the TAAS, participants, on average, rated treatment acceptability as 5.47 (SD 0.92) on a scale from 1=disagree strongly to 7=agree strongly.

Table 3. Treatment Evaluation Inventory-Short Form item-level results (n=175). Scale ranges from 1=strongly disagree to 5=strongly agree.

Items	Median (IQR)
1. I would find this treatment to be an acceptable way of dealing with my chronic pain	4.00 (1.00)
2. I would be willing to use this procedure if prescribed or recommended by a physician	4.00 (1.00)
3. I like the procedures that may be used in this treatment	4.00 (1.00)
4. I believe this treatment is likely to be effective	4.00 (2.00)
5. I believe that I will experience discomfort during the treatment	3.00 (1.00)
6. I believe this treatment is likely to result in permanent improvement	3.00 (1.00)
7. I believe this treatment is likely to harm or injure me	1.00 (1.00)
8. I believe it would be acceptable to use this treatment with individuals who cannot choose treatments for themselves	4.00 (1.00)
9. Overall, I have a positive reaction to this treatment	4.00 (1.00)

Table 4. Treatment Adherence/Acceptability Scale item-level results (n=175). Scale ranges from 1=disagree strongly to 7=agree strongly.

Items	Median (IQR)
1. If I began this treatment, I would be able to complete it	6.00 (2.00)
2. If I participated in this treatment, I would adhere to its requirements	6.00 (2.00)
3. I would find this treatment exhausting	3.00 (3.00)
4. It would be distressing for me to participate in this treatment	2.00 (2.00)
5. Overall, I would find this treatment intrusive	2.00 (2.00)
6. This treatment would provide effective ways to help me cope with my chronic pain	5.00 (1.00)
7. I would prefer to try another type of psychological treatment instead of this one	3.00 (3.00)
8. I would prefer to receive medication for my chronic pain instead of this treatment	3.00 (2.00)
9. I would recommend this treatment to a friend with chronic pain	5.00 (2.00)
10. If I began this treatment, I would likely drop out	2.00 (3.00)

XSL•FO
RenderX

Therapeutic Alliance

The WAI-C was completed to gauge the therapeutic alliance between participants and Solace. Overall, participants reported a strong working alliance with Solace (mean 188.03, SD 36.1), with a shared sense of goals rated as the strongest component of the therapeutic alliance (mean 67.86, SD 13.3), followed by agreement on tasks (mean 61.6, SD 12.7), and the therapeutic bond (mean 58.6, SD 12.6). WAI-C individual item scores are presented in Table 5.

Table 5. Working Alliance Inventory-Client Version item-level results (n=175). Scale ranges from 1=never to 7=always.

Items	Median (IQR)
1. I felt uncomfortable with Solace	1.00 (1.00)
2. Solace and I agreed about the things I will need to do in therapy to help improve my situation	6.00 (2.00)
3. I was worried about the outcome of the session	1.00 (1.00)
4. What I was doing in therapy gave me new ways of looking at my problem	5.00 (2.00)
5. Solace and I understood each other	6.00 (2.00)
6. Solace perceived accurately what my goals were	6.00 (2.00)
7. I find what I was doing in therapy confusing	1.00 (1.00)
8. I believe that Solace liked me	5.00 (2.00)
9. I wish Solace and I could have clarified the purpose of our session	2.00 (4.00)
10. I disagreed with Solace about what I ought to get out of therapy	1.00 (1.00)
11. I believe the time Solace and I were spending together was not spent efficiently	1.00 (2.00)
12. Solace did not understand what I was trying to accomplish in therapy	1.00 (1.00)
13. I was clear on what my responsibilities were in therapy	6.00 (2.00)
14. The goals of the session were important for me	6.00 (2.00)
15. I find what Solace and I were doing in therapy were unrelated to my concerns	1.00 (1.00)
16. I feel that the things I did in therapy helped me to accomplish the changes I wanted	5.00 (2.00)
17. I believe Solace was genuinely concerned for my welfare	5.00 (3.00)
18. I was clear as to what Solace wanted me to do in that session	6.00 (2.00)
19. Solace and I respected each other	7.00 (2.00)
20. I feel that Solace was not totally honest about its feelings toward me	1.00 (0.00)
21. I was confident in Solace's ability to help me	5.00 (3.00)
22. Solace and I were working toward mutually agreed upon goals	6.00 (2.00)
23. I feel that Solace appreciated me	5.00 (3.00)
24. We agreed on what was important for me to work on	6.00 (2.00)
25. As a result of therapy, I became clearer as to how I might be able to change	6.00 (3.00)
26. Solace and I trusted each other	6.00 (3.00)
27. Solace and I had different ideas about what my problems were	1.00 (1.00)
28. My relationship with Solace was very important to me	4.00 (4.00)
29. I had the feeling that if I said or did the wrong thing Solace would stop working with me	1.00 (0.00)
30. Solace and I collaborated on setting goals for my therapy	6.00 (2.00)
31. I was frustrated by the things I was doing in therapy	—[a]
32. We had a good understanding of the kind of changes that would be good for me	6.00 (2.00)
33. The things that Solace was asking me to do did not make sense to me	1.00 (1.00)
34. I did not know what to expect as the result of my therapy	2.00 (3.00)
35. I believe the way were working with my problem was correct	6.00 (2.00)
36. I feel Solace cared about me even when I did things it did not approve of	5.00 (3.00)

Clinical Outcomes

Clinically relevant outcomes were completed before and after the conversation with Solace and were analyzed using linear mixed effects models. Descriptive statistics and test results are presented in Table 6. Following Bonferroni correction to account for multiple comparisons, participants reported significant improvement in kinesiophobia, pain resilience, and pain willingness. On the PROMIS-29, participants reported improvement in anxiety and pain interference.

Table 6. Changes in clinically relevant outcomes.

Outcomes	Baseline, mean (SD)	Posttest, mean (SD)	*F* test (*df*)	*P* value
PRS[a]	28.07 (10.6)	30.57 (10.6)	41.62 (1, 193.6)	<.001
PRS-Behavioral Perseverance	11.64 (4.2)	12.1 (3.9)	6.79 (1, 196.8)	.01
PRS-Cognitive-Affective Positivity	16.43 (7.7)	18.48 (7.6)	51.95 (1, 194.1)	<.001
Kinesiophobia	43.4 (7.1)	41.79 (8.0)	24.73 (1, 191.5)	<.001
CPAQ[b]	61.66 (12.6)	62.5 (12.2)	1.71 (1, 201.1)	.19
CPAQ-Activity Engagement	31.71 (8.0)	33.02 (8.1)	16.46 (1,194.05)	<.001
CPAQ-Pain Willingness	29.95 (8.5)	29.48 (9.1)	0.37 (1, 194.05)	.54
PROMIS-29[c]				
Physical Function	15.15 (3.5)	15.0 (3.6)	2.38 (1, 191.7)	.13
Anxiety	10.46 (3.9)	10.0 (4.1)	17.04 (1, 191.2)	<.001
Depressive Symptoms	9.58 (4.6)	9.42 (4.6)	2.82 (1, 192.2)	.09
Sleep	12.87 (4.0)	12.86 (3.9)	0.01 (1, 193.6)	.93
Social Function	13.0 (3.9)	13.08 (3.8)	0.37 (1, 195.1)	.55
Pain Interference	11.60 (4.0)	11.15 (3.9)	10.89 (1, 195.1)	.001
Fatigue	12.95 (4.1)	12.7 (4.4)	3.78 (1, 191.2)	.05

Discussion

This study conducted a feasibility evaluation of Solace, an expert-trained generative AI conversational agent designed to use pain psychology–informed self-management strategies for chronic pain, following the DECIDE-AI framework [40]. Participants reporting chronic pain completed self-report measures before and after at least 25 minutes of conversation with Solace. Broadly, participants rated Solace to have excellent usability, good treatment acceptability, and reported a strong therapeutic alliance. Moreover, participants reported improvement in several clinically relevant domains from before to after the interaction with Solace.

The reported system usability (mean 85.04, SD 13.6) was rated well above the benchmark established for digital health applications (SUS score >65), indicating excellent usability [41,42]. Notably, SUS scores were also higher than those reported for other generative AI tools, such as ChatGPT, when rated by either general users (mean 67.44) or health care professionals (mean 64.52, SD 13.91) [43,44]. Although the SUS has been frequently used to evaluate AI applications [45], the SUS may not capture the nuance of using a generative AI conversational agent such as Solace [41]. Future studies should include more specific measures of usability designed to analyze generative AI conversational agents, such as the Bot Usability Scale [46].

Solace was deemed an acceptable health application for chronic pain and was well-received by participants. Participant responses on the TEI-SF and the TAAS were largely on par with other DHIs for chronic pain [47,48]. Participants responded with agreement to almost all items. This includes statements such as "I believe this treatment is likely to be effective," "I would find this treatment to be an acceptable way of dealing with my chronic pain," and "this treatment would provide effective ways to help me cope with my chronic pain." Participants also endorsed items related to the belief that they could adhere to treatment with Solace, such as "If I began this treatment, I would be able to complete it," and beliefs that Solace is a safe intervention (ie, strongly disagreeing with "I believe this

XSL•FO
RenderX

treatment is likely to harm or injure me"). It is worth noting that participants rarely expressed the strongest agreement with the TEI-SF or TAAS items. This may be due to the noninterventional nature of the evaluation and the lack of set treatment expectations. It will be important to further evaluate acceptability in the context of a treatment trial or clinical practice.

Participants reported developing a strong therapeutic alliance with Solace over the course of the 25-minute conversation. In particular, participants reported a strong shared sense of treatment goals (ie, strongly disagreeing with the statement "I find what Solace and I were doing in therapy was unrelated to my concerns"). Several previous studies have examined the experience of therapeutic alliance with a conversational agent, and have found similarly strong working alliance [15,17]. It is perhaps understandable that participants reported the therapeutic bond as the weakest aspect of the alliance. Items designed to capture this on the WAI-C reflect a personal relationship that might not be relevant for interactions with a conversational agent, such as items asking if participants felt Solace liked or trusted them. New tools might be needed in this area to thoroughly assess therapeutic alliance with nonhuman conversational agents [49]. It is also notable that this study was not presented to participants as a treatment designed to help them with their pain, despite the conversational focus on treatment-related topics. It will be important to replicate these promising indications of therapeutic alliance with Solace in a treatment setting, and to examine if alliance improves with longer treatment duration, an important predictor of treatment success [50,51].

Safety of Solace and other generative AI conversational agents is a critical consideration in their development as DHIs. However, this could not be fully assessed as guardrails designed to manage suicidality, self-harm, medical emergencies, or medication recommendations were developed, but user prompts did not include safety concerns, and therefore, guardrails were not activated in this study. It will be necessary to analyze a much larger volume of interactions to fully test guardrail performance.

After the 25-minute conversation with Solace, participants demonstrated improvement in several meaningful clinical domains, including kinesiophobia, resilience, activity engagement, as well as anxiety and pain interference on the PROMIS-29 measure. Across these factors, there was 4%-9% improvement, with the greatest improvement seen in pain resilience. There are several difficulties in interpreting these changes. Notably, although participants were told Solace was a treatment in development and self-report constructs inherently included reference to treatment, they were also told that this was not a treatment study. There was also a mismatch between the wording on several of the measures and the time frame of the study. In particular, instructions for the subscales of the PROMIS-29 ask respondents to reference how they felt "in the last 7 days," whereas the study might have lasted as little as 25 minutes. Despite these challenges in interpretation, improvements were all in the beneficial direction, held up to statistical correction, and likely reflect the participants' feelings at the time of responding. Although the change was modest in magnitude, this is a promising indication for further treatment-focused research on Solace.

Future research on Solace should take several directions. As described above, a program of clinical research should be undertaken to evaluate the efficacy and effectiveness of Solace, either as a stand-alone program or integrated into the Manage My Pain application, a digital pain self-management application developed by ManagingLife. This will include a fuller test of the effectiveness of the safety guardrails in identifying discussions involving recommendations for medication use, suicidal ideation, and harm to self or others. Further evaluation of the nature of users' interactions with Solace will also be critical. These should focus on both the therapeutic relationship as well as evaluation of safety features of the application. Moreover, algorithmic fairness was not assessed in this study. Subsequent studies reporting on Solace will aim to compare model performance (sensitivity and specificity) across demographic subgroups, including sex, age, and ethnicity, to ensure equitable accuracy and lack of bias. Patient engagement is also needed to more fully address the lived experience of individuals with chronic pain.

There is room to further improve Solace's functionality. In particular, Solace's responses required a reading comprehension level considered roughly equivalent to early-middle high school. Future iterations of Solace should focus on the accessibility of language to improve utility by the general population. More detailed analysis of conversations with Solace is also warranted to ensure that conversational content is adherent to prompting.

There are several notable limitations of this study. First, the study was conducted via an online crowdsourcing platform. Although the sample recruited in this study is similar in several respects (ie, age, sex, and duration of pain) to individuals with chronic pain recruited from community samples [52], there were several notable distinctions, and also limited demographic data collection. In particular, participants in this study were primarily White and working full-time. As such, it is possible that community or treatment-seeking individuals with chronic pain would have a different experience of Solace. Although extensive research on chronic pain has been conducted via the Prolific platform [53,54], future research needs to be conducted in clinical samples with verified diagnoses. Second, the study was not designed as a test of Solace as a treatment. As such, participants did not necessarily have a treatment-related interaction with Solace, which could impact perceptions of acceptability and therapeutic alliance. Third, the sensitivity and specificity of the guardrail system were not fully tested, given the few instances that required guardrail activation. Finally, the short time frame of the study and the lack of a control condition limit the interpretation of the clinical impact of Solace. It is possible that alternative explanations, such as regression to the mean or social desirability, could account for the change associated with Solace use. Subsequent studies should examine prolonged or repeated interactions and feature comparisons to a control condition to enhance internal validity.

In conclusion, participants found Solace to be a usable system and an acceptable treatment for chronic pain after a 25-minute conversation. Participants reported a strong therapeutic alliance

XSL•FO
RenderX

and demonstrated improvement in several clinically relevant domains. Furthermore, examination of safety guardrails for Solace indicated appropriate performance. Solace is a promising therapeutic tool, and clinical trials are needed to fully examine its clinical efficacy as a DHI for chronic pain.

The authors of the publication “Managing Musculoskeletal Pain in Older Adults Through a Digital Care Solution: Secondary Analysis of a Prospective Clinical Study” [1] have introduced further details regarding the exercise component of the intervention to improve transparency and interpretability. To provide a generalized framework underlying the exercise prescription within the digital care program, Multimedia Appendix 2 was added (included here as Multimedia Appendix 1), including representative exercise categories, progression principles, and dosage parameter ranges. Additionally, a detailed description of a condition-specific implementation of digital care programs was reported in a previously published study [2], cited in the Introduction section of the original article. These clarifications do not impact the results or conclusions of the original study.

Multimedia Appendix 1
Overview of the exercise prescription framework, including exercise characteristics, dosage parameters, and progression principles.

KEYWORDS

vestibular rehabilitation; smartphone; crossover trial; digital health; statistical analysis

Kaplan et al [1] evaluated smartphone-supported vestibular rehabilitation in a randomized 2-period, 2-sequence crossover pilot trial and interpreted their findings as suggesting app support conferred an advantage. However, the reported analyses did not directly estimate the incremental effect of the app.

Participants were randomized to app-first or conventional-first sequences, crossed over after 3 weeks, and had no washout period; residual effects may therefore have influenced period 2 [1]. The CONSORT (Consolidated Standards of Reporting Trials) crossover extension emphasizes paired participant-level analyses that account for within-participant correlation [2]. In contrast, Mann-Whitney *U* tests were used to compare sequences, whereas Friedman and Wilcoxon tests were used to compare time points within sequences. A comparison between baseline and week 6 provides an estimate of the total 6-week change, and a between-sequence comparison of that change provides an estimate of the order difference after both sequences received both delivery modes. Neither isolates app support from conventional delivery.

The Instrumented Timed Up and Go Test result illustrates the problem. In the app-first sequence, the only significant post hoc change was from baseline to week 6, spanning both treatment periods, not from baseline to week 3, the app-supported period. The results therefore cannot establish an early benefit of smartphone guidance. Moreover, significance in one sequence but not the other does not establish a difference between treatments or sequences [3].

The Dizziness Handicap Inventory responder analyses have the same limitation. At week 6, 7 of 9 eligible app-first participants and 2 of 8 conventional-first participants exceeded the minimal clinically important difference, but both sequences had received both modes [1]. The period-specific counts (6/17 vs 3/17) are paired outcomes, so discordant-pair counts are needed. Two *P* values also require clarification. For the week 6 table, 7 of 9 versus 2 of 8 yields a likelihood-ratio χ^2_1=4.98 (*P*=.026), whereas the 2-sided Fisher exact test gives *P*=.057; the manuscript reports χ^2_1=4.97 (*P*=.06). For period-specific responders, treating 6 of 17 and 3 of 17 as independent observations yields *P*=.438 with the 2-sided Fisher exact test, not *P*=.057. However, because these are paired outcomes, the appropriate analysis requires the discordant-pair counts, which were not reported.

We recommend reporting period-specific outcomes using a participant-level model that estimates treatment and period effects and considers sequence and carryover. Given the absence of washout and plausible persistence of rehabilitation effects, an exploratory baseline-adjusted first-period comparison preserving randomization may be more interpretable than a full crossover contrast. Until then, the study supports feasibility and overall improvement across 6 weeks, but does not establish an incremental benefit of app support.

To the Editor

We welcome the commentary [1] regarding our publication [2] evaluating the Vestibulon app in vestibular rehabilitation. We appreciate the opportunity to clarify the clinical and statistical considerations guiding our pilot trial and to contextualize our findings.

The author raises a concern regarding the absence of a washout period. The absence of a washout period was a deliberate clinical decision. Vestibular rehabilitation involves central compensation, adaptation, habituation, and motor learning, which may not be reliably reversed by a short interruption. Because participants were symptomatic and receiving clinically indicated care, continuity of rehabilitation was prioritized. We nevertheless acknowledge that carryover from the first period may have limited the interpretation of period-2 comparisons, as noted in our Limitations section [2].

Given the pilot nature of the study and the small sample size, we used prespecified nonparametric methods for the exploratory comparisons. This approach was appropriate for the bounded and potentially skewed Dizziness Handicap Inventory (DHI) and State-Trait Anxiety Inventory scores, which derive from ordinal response categories, and was applied consistently to the continuous Instrumented Timed Up and Go (iTUG) measure. We acknowledge that these tests do not constitute a complete crossover analysis accounting for treatment, period, sequence, within-participant correlation, and potential carryover. This exploratory analysis was not intended to provide definitive evidence of the app's efficacy, but rather to provide initial clinical insights and establish feasibility for future studies.

Across all sections, we explicitly refrained from making definitive claims of superiority, including regarding early iTUG changes, repeatedly framing results as "preliminary trends." Importantly, our Limitations section explicitly outlined the constraints noted by the author: the pilot sample size, potential carryover effects due to the absence of a washout period, and the essential need for a future fully powered randomized controlled trial (RCT).

We thank the author for identifying the typographical error on page 9, where P=.057 was inadvertently reported twice. This P value (.057) corresponds to the 2-sided Fisher exact test for the week 6 comparison of 7 of 9 versus 2 of 8 minimal clinically important difference (MCID) responders. Furthermore, for period-specific responder outcomes (6/17 versus 3/17), a valid paired analysis relied on discordant pairs, with 5 participants achieving the MCID strictly during the app period and 2 strictly during the conventional period (exact McNemar test: P=.453). Therefore, they should not be analyzed as independent samples alone. As a supplementary analysis less affected by carryover, we analyzed period 1 using an analysis of covariance. Baseline-adjusted week 1 DHI scores were 38.82 in the app-first

XSL•FO
RenderX

group and 40.33 in the conventional-first group, a difference that was not statistically significant (F=0.04, P=.840, partial η^2=.002). The DHI MCID was achieved by 5 of 9 versus 1 of 8 eligible participants (55.6% vs 12.5%; P=.131). Although exploratory for definitive inference, these findings provide a useful trend and preliminary data for an RCT.

In conclusion, our pilot trial supports the feasibility of integrating smartphone support into vestibular rehabilitation and observed improvement in functional outcomes over the 6-week rehabilitation program. We agree that establishing definitive incremental efficacy requires a parallel-group RCT, and we thank the author for this constructive scientific dialogue.

Abstract

Background: Digital, smart, and electronic low vision aids (LVAs) have expanded options for visual rehabilitation and functional independence among people with visual impairment. However, adoption of these technologies remains limited, particularly in low- and middle-income countries such as Jordan, where access, affordability, and training resources may be constrained.

Objective: To examine barriers to the adoption of electronic LVAs and identify factors associated with their use among eye care professionals in Jordan.

Methods: A descriptive cross-sectional survey was conducted among 270 eye care professionals working in hospitals, rehabilitation centers, and private clinics across Jordan. The questionnaire assessed awareness, training exposure, institutional support, and perceived barriers related to electronic LVAs. Descriptive statistics and inferential analyses were used to examine adoption patterns and predictors, with statistical significance set at $P<.05$.

Results: Of the 270 participants, 156 (57.8%) were optometrists, 78 (28.9%) were ophthalmologists, and 36 (13.3%) were low vision specialists. The mean age was 36 (SD 8) years, and the mean professional experience was 12 (SD 6) years. Overall, 117 of 270 (42.2%) participants reported current use or recommendation of electronic LVAs. The most frequently reported barriers were high device cost (n=213, 79%), lack of training (n=184, 68.1%), limited institutional support (n=173, 64%), and low patient awareness (n=154, 57%). In multivariable analysis, greater training exposure (odds ratio [OR] 1.82, 95% CI 1.31 - 2.53; $P<.001$), stronger institutional support (OR 1.48, 95% CI 1.12 - 1.96; $P=.008$), and higher awareness scores (OR 1.35, 95% CI 1.05 - 1.72; $P=.02$) were positively associated with aid adoption, whereas high device cost was negatively associated with aid adoption (OR 0.41, 95% CI 0.27 - 0.62; $P<.001$).

Conclusions: Adoption of electronic LVAs among eye care professionals in Jordan remains limited. Cost, training exposure, and institutional support are key factors influencing uptake. These findings suggest that strengthening professional training and institutional support may facilitate broader integration of electronic LVAs into low vision rehabilitation services.

Introduction

Visual impairment affects more than 2.2 billion people worldwide, and at least 1 billion cases could have been prevented or remain unaddressed [1]. Low vision rehabilitation aims to enhance residual vision and functional independence using optical and electronic assistive technologies [2]. Recent advances in portable, digital, and smart low vision aids (LVAs), including magnifiers, wearable displays, and smartphone-based systems, have significantly improved navigation and access to information [2-5]. These devices, collectively termed electronic LVAs, complement traditional optical aids by offering adjustable magnification, contrast enhancement, and speech feedback [6,7].

Despite growing evidence supporting their functional and psychosocial benefits [8-11], adoption of electronic LVAs remains limited globally [12]. Reported barriers include high device cost, inadequate professional training, limited awareness among clinicians and patients, and insufficient institutional and policy support [13-15]. These challenges are particularly pronounced in low- and middle-income countries, where limited service infrastructure, fragmented referral pathways, and absence of sustainable funding mechanisms further restrict access to electronic low vision technologies [2].

In Jordan, visual impairment represents the most prevalent form of disability, affecting approximately 6% to 7% of the population aged 5 years or older, according to national statistics [16]. Although optometric education and eye care infrastructure

XSL•FO
RenderX

have expanded in recent years, integration of structured low vision rehabilitation services within the health care system remains inconsistent [7,15,17]. Available local evidence indicates that assistive and digital technologies are used predominantly in educational or professional contexts, with limited incorporation into formal low vision rehabilitation pathways. Regional studies further suggest that fewer than half of eye care professionals routinely prescribe or recommend electronic LVAs, underscoring persistent gaps in training, access, and service delivery [3,18,19]. Understanding context-specific barriers in Jordan is therefore essential for developing targeted professional training and service-level interventions.

Technology adoption frameworks, including the technology acceptance model and the unified theory of acceptance and use of technology, provide a useful lens for examining these challenges [20]. These models emphasize perceived usefulness, ease of use, and facilitating conditions as key determinants of adoption [21]. In low vision rehabilitation, these constructs translate into clinician awareness, perceived patient benefit, affordability, and availability of institutional support. While prior studies have examined assistive technology use in various contexts, limited evidence exists regarding how these adoption factors interact among eye care professionals involved in low vision care in Jordan. The aim of this study was to examine awareness, training exposure, institutional support, perceived barriers, and factors associated with the adoption and recommendation of electronic low vision aids among eye care professionals in Jordan.

Methods

Study Design

A descriptive cross-sectional study was conducted among eye care professionals working in public and private hospitals, university eye clinics, and vision rehabilitation centers across Jordan. This study was implemented as an online cross-sectional survey and is reported in accordance with the CHERRIES (Checklist for Reporting Results of Internet E-Surveys) guidelines (Checklist 1). Invitations were distributed electronically through established professional networks, including national professional associations, institutional mailing lists, and closed professional communication groups (eg, email lists and secure messaging platforms) commonly used by ophthalmologists, optometrists, and low-vision specialists in Jordan. These networks included clinicians working in public, private, and academic settings across Jordan. Distribution was not stratified by geographic region or sector; therefore, participation depended on individual access to and engagement with these professional channels. Survey items were presented in a fixed order. Completion of all mandatory closed-ended items was required for submission, whereas open-ended questions were optional. Only fully completed questionnaires were included in the analysis.

Eligible participants included optometrists, ophthalmologists, and low-vision specialists currently practicing in Jordan. Inclusion criteria were (1) possession of a valid professional license from the Ministry of Health, (2) at least 1 year of clinical experience, and (3) direct involvement in patient care. Professionals in administrative roles or not directly engaged in patient management were excluded. A total of 300 invitations were distributed electronically, of which 270 completed responses were received (response rate 90%). The response rate was calculated at the overall survey level based on completed questionnaires relative to the total number of invitations distributed. The survey was distributed through professional online groups and networks of eye care clinicians. Because the questionnaire was not sent to a fixed list of individuals, accurate denominators for each professional group were not available; therefore, group-specific response rates could not be calculated. An a priori sample size estimation was conducted using G*Power (version 3.1) [22] for multiple linear regression analysis. Assuming a medium effect size (f^2=0.15), an α level of .05, statistical power of 0.80, and up to 10 predictors, the minimum required sample size was 118 participants. The final sample of 270 respondents exceeded this requirement, providing adequate statistical power for the planned analyses.

A self-administered electronic questionnaire was developed following a review of existing validated surveys on assistive technology adoption [10-12,14,18,23]. The instrument comprised five domains: (1) awareness, (2) training exposure, (3) institutional support, (4) perceived barriers, and (5) adoption of electronic low vision aids (Table 1). Items were rated on a 5-point Likert scale (1=strongly disagree to 5=strongly agree). Optional open-ended questions were included at the end of the survey to allow participants to provide additional comments or perspectives not captured by the closed-ended items. Selected anonymized comments are presented in the Results section to illustrate key quantitative findings; no formal qualitative coding or thematic analysis was performed.

	I routinely demonstrate electronic LVAs in my clinic.	3.4 (0.8)
	I feel confident teaching patients how to use electronic LVAs.	3.6 (0.7)
	I intend to integrate electronic LVAs more frequently in future practice.	3.8 (0.8)
	I believe electronic LVAs improve my patients' quality of life.	4.1 (0.7)

[a]LVA: low vision aid.

The survey was administered in English, as English is the primary language of instruction and clinical documentation among eye care professionals in Jordan. Participants were able to request clarification for any items if needed. The questionnaire underwent expert review by 3 senior vision rehabilitation specialists to establish content validity, followed by pilot testing with 25 clinicians. Pilot data were excluded from the final analysis. Minor linguistic refinements were made to improve clarity and internal consistency. Internal consistency was assessed using Cronbach α for each domain (Table 2). Values ≥0.70 were considered acceptable.

Table . Internal consistency (Cronbach α) of questionnaire domains based on the final survey sample (N=270).

Domain	Cronbach α
Awareness	0.86
Training exposure	0.81
Institutional support	0.83
Perceived barriers	0.88
Adoption behavior	0.79

Data were analyzed using SPSS software (version 29; IBM Corp). Descriptive statistics summarized participant characteristics and mean domain scores. Inferential analyses included chi-square tests to compare aid adoption rates across professional groups, independent-sample *t*-tests to compare training hours between adopters and nonadopters, and multivariable binary logistic regression to identify predictors of electronic low vision aid adoption. Multicollinearity was assessed using variance inflation factors (<2). Model fit was evaluated using the Hosmer-Lemeshow test (P>.05). Statistical significance was set at P<.05 (2-tailed).

Professional experience was assessed using a single self-reported item asking participants to indicate their years of clinical practice in eye care. Awareness of electronic and digital low vision aids was measured using a composite awareness score derived from multiple Likert scale items assessing familiarity with device types, indications, and clinical applications. Training exposure was assessed by asking participants whether they had received formal or informal training related to electronic LVAs (yes or no), as well as the total number of training hours completed.

Internal consistency was calculated using Cronbach α for each domain (Table 2). Values ≥0.70 were considered acceptable. The α coefficients were calculated using responses from the final survey participants. Expert review (n=3) was used solely for content validity and was not included in the final internal consistency analysis.

Ethical Considerations

This study was approved by the Institutional Review Board of Jordan University of Science and Technology (IRB/642) and was conducted in accordance with the principles of the Declaration of Helsinki. Participation was voluntary, and electronic informed consent was obtained from all participants prior to survey initiation. The survey was administered anonymously through a secure online platform. No personally identifiable information (such as names, identification numbers, or contact details) was collected. Data were stored on password-protected devices accessible only to the principal investigator and were analyzed in aggregate form to ensure participant confidentiality. Measures were implemented to minimize duplicate submissions.

Results

A total of 270 eye care professionals completed the survey, representing a 90% response rate. Participants included 156 optometrists (57.8%), 78 ophthalmologists (28.9%), and 36 low vision specialists (13.3%) working across multiple practice settings in Jordan. The mean age was 36 (SD 8) years, and 149 of 270 (55.2%) participants were female. Respondents reported

XSL•FO
RenderX

a mean of 12 (SD 6) years of professional experience, indicating a clinically experienced cohort.

Across all participants, the mean awareness score regarding electronic LVAs was 3.2 (SD 0.7) on a 5-point Likert scale, suggesting moderate familiarity. The mean training exposure time was 18.4 (SD 12.5) hours. However, substantial variability was observed, with many clinicians reporting fewer than 10 hours of formal training. These data are summarized in Table 3.

Table . Participant characteristics (N=270).

Characteristic	Value
Profession, n (%)	
Optometrist	156 (57.8)
Ophthalmologist	78 (28.9)
Low vision specialist	36 (13.3)
Gender, n (%)	
Female	149 (55.2)
Male	121 (44.8)
Age (y), mean (SD)	36 (8)
Professional experience (y), mean (SD)	12 (6)
Awareness score (1-5), mean (SD)	3.2 (0.7)
Training hours, mean (SD)	18.4 (12.5)

Profession-specific analyses revealed that low vision specialists had the highest training exposure (mean 28.5, SD 9.2 hours) and awareness score (mean 3.8, SD 0.6), followed by optometrists (mean 17.6, SD 11.3 training hours; mean 3.3, SD 0.7 awareness score) and ophthalmologists (mean 12.1, SD 8.5 training hours; mean 3.0, SD 0.6 awareness score). Gender and years of experience were not significantly associated with awareness or training exposure (P>.05).

Among all respondents, 117 of 270 professionals (42.2%) reported that they currently prescribe or recommend electronic LVAs to patients. Adoption was significantly higher among low vision specialists (22/36, 61%) than optometrists (69/156, 44.2%) and ophthalmologists (26/78, 33%) (χ^2=9.64; P=.008). Eye care professionals who reported active aid adoption also demonstrated substantially greater training exposure (mean 23.6, SD 11.2 hours) than nonadopters (mean 14.9, SD 9.8 hours), a difference that was statistically significant (t=5.74; P<.001). Additionally, adopters also had higher awareness scores than nonadopters (mean 3.6, SD 0.6 vs mean 3.0, SD 0.7; P<.001) and higher institutional support scores (mean 3.4, SD 0.8 vs mean 2.9, SD 0.7; P=.002).

Overall, these results suggest that professional experience alone does not drive aid adoption; rather, the presence of structured training and institutional support are key determinants of electronic LVA use. The perceived barriers domain comprised 8 Likert scale items representing 8 distinct barriers to electronic LVA adoption (Table 1). Respondents most frequently cited high device cost (213/270, 79%), followed by lack of training opportunities (184/270, 68.1%), limited institutional support (173/270, 64%), and low patient awareness (154/270, 57%; Table 4) as barriers to electronic LVA adoption.

Table . Barriers to electronic low vision aid adoption among Jordanian eye care professionals (N=270).

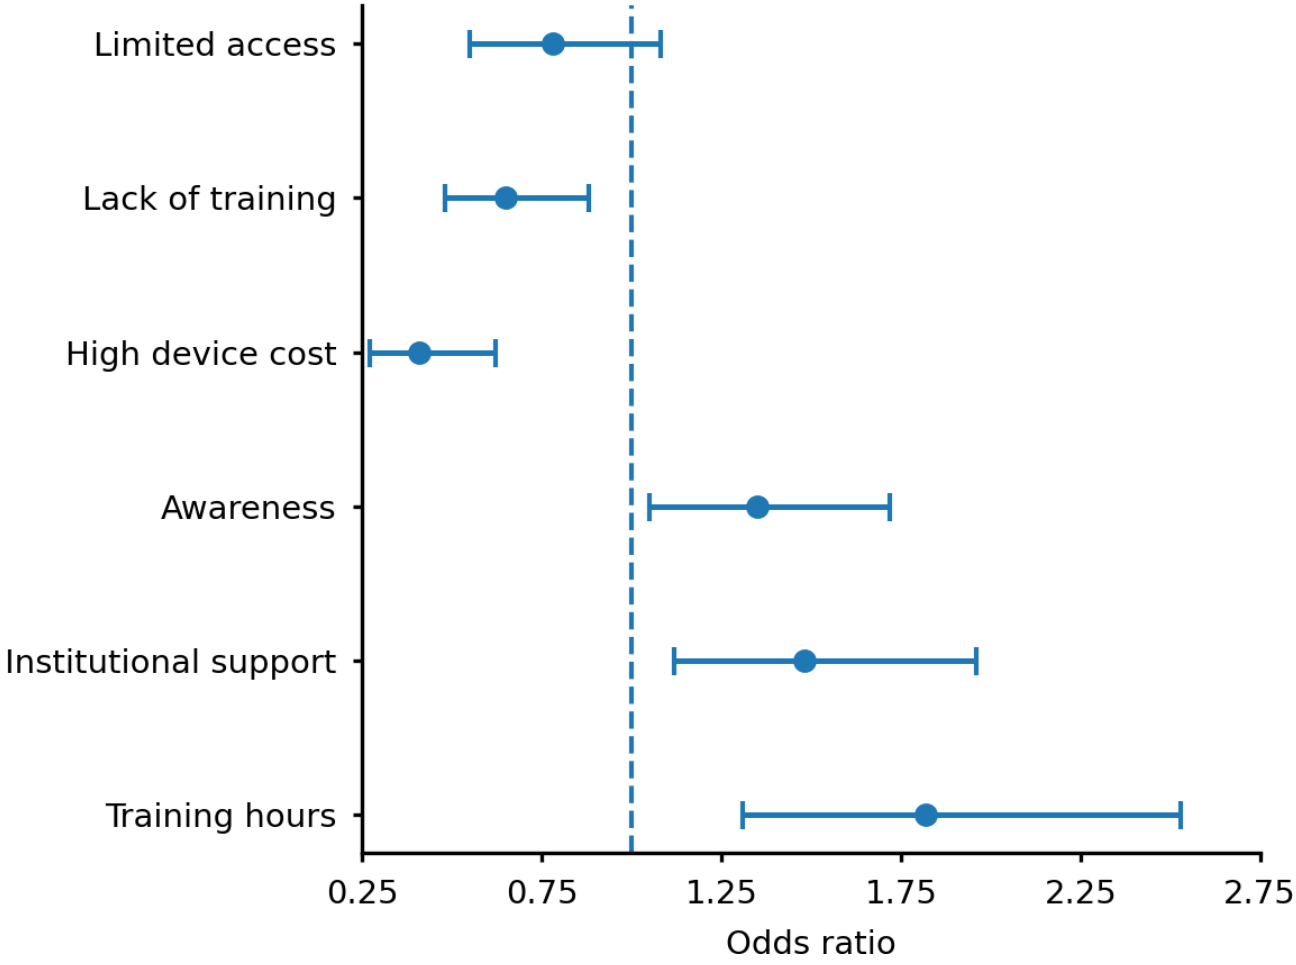
Perceived barriers	Respondents, n (%)
Import regulations make devices unavailable	111 (41.1)
There is limited technical support for device maintenance	124 (45.9)
Devices are difficult to use for older adults or individuals with limited formal education	130 (48.1)
There is a lack of Arabic-language software support	140 (51.9)
Low patient awareness	154 (57)
Limited institutional support restricts adoption	173 (64)
Lack of professional training prevents effective use of electronic low vision aids	184 (68.1)
The high cost of devices limits their use in clinical practice	213 (79)

Subgroup analysis revealed that cost concerns were particularly pronounced among optometrists (131/156, 84.0%), whereas low vision specialists reported greater concern regarding limited patient awareness (22/36, 61%) and lack of Arabic-language

XSL•FO
RenderX

device interfaces (20/36, 56%). In contrast, ophthalmologists more frequently emphasized institutional limitations (56/78, 72%) and unclear referral mechanisms (50/78, 64%) as major obstacles.

One-way ANOVA demonstrated significant between-group differences for lack of professional training ($F_{2,267}$=6.21; P=.002) and limited maintenance or technical support ($F_{2,267}$=4.89; P=.008). Post hoc analyses indicated that optometrists perceived these barriers more strongly than ophthalmologists and low vision specialists. Although cost- and patient-related barriers were commonly reported across all professional groups, no statistically significant between-group differences were observed for these domains (Multimedia Appendix 1). Comments from participants reinforced these findings, as illustrated by the following representative quotes:



> *Even when devices are available, few clinicians are trained to demonstrate them effectively.* [Participant 47, optometrist]
>
> *Cost remains prohibitive for many families, especially without Ministry of Health support.* [Participant 112, ophthalmologist]

These results point to a multifactorial set of barriers (financial, educational, and systemic) that collectively hinder widespread electronic LVA integration into clinical practice.

A binary logistic regression model was fitted to identify predictors of electronic LVA adoption (Multimedia Appendix 2). The model explained 42% of the variance in adoption behavior (Nagelkerke R^2=0.42) and correctly classified 79% of cases. Training hours emerged as the strongest positive predictor of electronic low vision aid adoption (odds ratio [OR] 1.82, 95% CI 1.31 - 2.53; P<.001). Higher institutional support (OR 1.48, 95% CI 1.12 - 1.96; P=.008) and greater awareness (OR 1.35, 95% CI 1.05 - 1.72; P=.02) were also significantly associated with increased adoption. In contrast, high device cost was a strong negative predictor (OR 0.41, 95% CI 0.27 - 0.62; P<.001), while lack of training was associated with a reduced likelihood of adoption (OR 0.65, 95% CI 0.48 - 0.88; P=.006). Limited access was not a statistically significant predictor (OR 0.78, 95% CI 0.55 - 1.08; P=.14).

Figure 1 illustrates the direction and strength of associations, showing that training exposure and institutional support exerted the most substantial positive influence, while high device cost exerted the strongest negative effect.

Figure 1. Forest plot showing adjusted odds ratios (with 95% CIs) for predictors of electronic low vision aid adoption.

Discussion

This study examined barriers to the adoption and recommendation of electronic LVAs among eye care professionals in Jordan. The main findings indicate that high device cost and lack of professional training were significantly associated with a lower likelihood of recommending electronic LVAs, whereas higher awareness and stronger institutional

XSL•FO
RenderX

support were positively associated with adoption. Although overall awareness scores were moderate, fewer than half of respondents reported current use or recommendation of these devices, indicating a persistent gap between awareness and routine clinical implementation. These findings are consistent with reports from other low- and middle-income countries, where cost and training constraints are repeatedly identified as dominant barriers to electronic assistive technology uptake [10-12,14,18,23].

Multivariable regression analysis further demonstrated that training exposure, institutional support, and awareness independently predicted adoption of electronic LVAs, whereas perceived device cost was negatively associated with adoption. Together, these findings suggest that adoption is influenced by both individual-level factors (eg, professional knowledge and perceived benefit) and system-level factors (eg, organizational support and resource availability). This dual influence is consistent with prior research indicating that isolated improvements in clinician awareness are insufficient to promote sustained technology adoption without parallel investment in training and institutional infrastructure.

International studies report similar patterns of underuse. For example, surveys of eye care professionals in high-income settings have shown that fewer than half routinely recommend electronic or digital magnification devices despite recognizing their potential clinical benefit [13]. Studies from the Asia Pacific region and the Middle East likewise highlight limited institutional resources, high device cost, and insufficient professional training as persistent barriers to adoption [2,20]. These parallels suggest that the challenges identified in this study reflect broader implementation issues rather than context-specific resistance to technology.

Interpretation of these findings should also consider broader health system context in Jordan. Reports and policy analyses indicate that low vision rehabilitation services are often fragmented, with limited availability of designated low vision clinics, variable referral pathways, and uneven access to continuing professional education in rehabilitation technologies [1,12,24,25]. Although these system-level characteristics were not directly measured in this survey, they provide important context for understanding why institutional support and training emerged as prominent determinants of adoption. Global guidance from the World Health Organization emphasizes the need for integrated national rehabilitation frameworks to support equitable access to assistive and digital technologies, particularly in resource-constrained settings [3,20]. In this study, clinicians who perceived stronger institutional facilitation and greater patient benefit were more likely to recommend electronic LVAs, consistent with core constructs of the technology acceptance model and the unified theory of acceptance and use of technology framework [21].

The findings underscore the need for coordinated strategies to support electronic LVA adoption. Structured professional training in digital rehabilitation should be incorporated into undergraduate curricula and continuing professional development programs. Health care institutions may benefit from establishing demonstration or referral pathways that allow clinicians to trial devices with patients. In addition, funding mechanisms—such as subsidy schemes or public-private partnerships—may help mitigate cost barriers, particularly for older adults and children with visual impairment. These implications are aligned with international calls to strengthen rehabilitation systems and data collection under the World Health Organization Rehabilitation 2030 initiative [3].

Several limitations warrant consideration. The cross-sectional design precludes causal inference, and adoption behavior was assessed using self-reported measures rather than objective indicators such as prescription records or device use data. In addition, although the survey instrument was informed by established technology adoption frameworks, formal construct validity testing was not undertaken. This study also did not explicitly examine potential regional or socioeconomic variation within the eye care workforce, which may influence access to training, institutional support, and technology availability. These factors may limit generalizability and should be addressed in future research.

Future studies should use longitudinal or mixed methods designs to examine how training interventions, institutional policies, and funding mechanisms influence adoption over time. Incorporating validated measurement instruments, objective adoption indicators, and stratified analyses by region or practice setting would further strengthen the evidence base and inform targeted implementation strategies.

In conclusion, adoption of digital, smart, and electronic LVAs among eye care professionals in Jordan remains limited. Cost, training exposure, and institutional support were the primary factors associated with uptake in this study. These findings suggest that strengthening professional training opportunities, improving institutional facilitation, and exploring sustainable funding mechanisms may support broader integration of digital assistive technologies within low vision rehabilitation services. Greater coordination among clinicians, policymakers, and industry stakeholders may help address persistent implementation barriers and improve access to low vision care.

Acknowledgments

The author thanks the participating optometrists, ophthalmologists, and low vision specialists across Jordan for their valuable contributions. Appreciation is also extended to the statistical support team and research assistants who facilitated data entry and analysis.

Funding

This research received no specific grant from any funding agency in the public, commercial, or not-for-profit sectors.

Abstract

In this cross-sectional study of 300 board-style questions across physical therapy, occupational therapy, and speech-language pathology, we evaluated reasoning types and found high overall accuracy with variation by discipline and reasoning category; the strongest performance was in deductive and analytical reasoning and the lowest accuracy was in evaluative reasoning.

(JMIR Rehabil Assist Technol 2026;13:e91019) doi:10.2196/91019

KEYWORDS

large language model; clinical reasoning; licensing examination; rehabilitation education; GPT-5; semantic similarity; health professions training; artificial intelligence; board-preparation materials

Introduction

Large language models (LLMs) such as ChatGPT (GPT-5; OpenAI) are increasingly used by clinicians and trainees to support learning and licensing examination preparation [1]. Passing licensing examinations ensures practitioner competence and patient safety and is correlated with better patient outcomes [2,3]. However, LLMs' reasoning consistency and conceptual similarity to expert sources remain uncertain [1]. Some prior research has demonstrated that LLMs can achieve passing scores on various professional examinations, but their explanations may exhibit shallow logic or inconsistent reasoning [4]. Recent evaluations of ChatGPT on Chinese national licensing examinations similarly demonstrated failure to meet official pass thresholds, with accuracy varying across examination type and question format [5]. Our study assessed GPT-5's accuracy, reasoning patterns, and semantic similarity to verified board-preparation materials for rehabilitation examinations for physical therapy (PT), occupational therapy (OT), and speech-language pathology (SLP) to assess whether GPT-5 can serve as a reliable study assistant.

Methods

Overview

Three hundred multiple-choice questions (100 each from PT, OT, and SLP validated board-preparation sources that are not publicly available) were entered into GPT-5 (via the ChatGPT web interface) in November 2025 using default settings, without hints or chain-of-thought prompting, to mimic typical learner use. For each discipline, the first 100 sequential questions were included to create a reproducible sample. Difficulty indices and blueprint mappings were unavailable; therefore, items were not stratified.

Selected answers from the model and written rationales were compared with source materials. Accuracy was calculated across items and recorded as correct or incorrect. Rationales were coded by reasoning type: inductive (from specific examples to a general conclusion), deductive (from a general rule to a specific conclusion), analytical (examining parts and their relationships), evaluative (judging something based on criteria), or inferential (drawing a conclusion from evidence). This coding was based on the cognitive process required for the correct answer. Reasoning classifications were predefined within the board-preparation materials and aligned with established educational frameworks.

Semantic similarity was computed using cosine similarity applied to L2-normalized sentence embeddings generated by the all-MiniLM-L6-v2 Sentence-BERT model, and preprocessing was limited to minimal white space normalization, consistent with recommended Sentence-BERT use [6]. Descriptive statistics summarized performance across disciplines. Incorrect responses were qualitatively reviewed to identify recurring conceptual challenges. A single coder (CM-K) conducted inductive content analysis using an emergent coding approach [7] and grouped content by shared subject matter to identify the specific content domains that presented greater

XSL•FO
RenderX

difficulty for GPT-5. Initial codes were developed through iterative review of incorrect responses and GPT-5 rationales using constant comparison. A second coder (MCH) reviewed categories, and disagreements were discussed and resolved. Because coding focused on thematic categorization of recurring errors, formal interrater reliability statistics were not calculated. Consensus review was used to ensure interpretive agreement and consistency of category definitions prior to final theme reporting.

Ethical Considerations

This project used publicly available, non–human participant material and did not require institutional review board approval.

Results

GPT-5 demonstrated strong factual accuracy overall, although performance varied by discipline and reasoning type, with only deductive reasoning in PT receiving 100% (Table 1). Overall accuracy for GPT-5 was 91.0% for PT (95% CI 83.6%-95.8%), 79.0% for OT (95% CI 68.9%-85.5%), and 83.0% for SLP (95% CI 74.4%-89.6%).

Table . Accuracy by discipline and reasoning type.

Reasoning type	Physical therapy (n=100), n/N (%)	Occupational therapy (n=100), n/N (%)	Speech-language pathology (n=100), n/N (%)
Deductive	22/22 (100/100)	11/15 (73.3/100)	31/33 (93.9/100)
Analytical	22/23 (95.7/100)	9/11 (81.8/100)	40/47 (84.8/100)
Inductive	19/22 (86.4/100)	18/21 (85.7/100)	2/4 (50.0/100)
Inferential	22/25 (88.0/100)	26/36 (72.2/100)	6/9 (66.7/100)
Evaluative	6/8 (75/100)	15/17 (88.2/100)	4/7 (57.1/100)
Overall accuracy	(91.0/100)	(79.0/100)	(83.0/100)

Across all questions, the mean semantic similarity between GPT-5 and source-material rationales was 0.707. This indicates semantic alignment between GPT-5 rationales and expert rationales. Deductive reasoning had the highest mean similarity (0.730), followed by analytical (0.714), inductive (0.675), inferential (0.685), and evaluative (0.671) reasoning. The Kruskal-Wallis H test across all 5 reasoning types was also significant: H_4=11.7 (P=.02). This suggests that GPT-5's explanations aligned more closely with reference rationales for deductive reasoning tasks, where rules are applied to reach conclusions, than for tasks requiring generalization, inference, or evaluation.

Qualitative review of incorrect answers identified recurring conceptual challenges. Using inductive content analysis, challenges were grouped by shared conceptual features in GPT-5 rationales. Categories appearing across multiple questions within a discipline are summarized in Textbox 1.

Textbox 1. Summary of missed question-type patterns across disciplines.

Physical therapy

- Functional reasoning (3/9, 33.3%)
- Safety/priority decision-making (3/9, 33.3%)
- Technical recall (3/9, 33.3%)

Occupational therapy

- Functional reasoning (12/17, 70.6%)
- Professional scope and delegation reasoning (3/17, 17.6%)
- Safety-based decision-making (2/17, 11.8%)

Speech-language pathology

- Interpretive clinical reasoning for specialized assessment and instrumental findings (10/22, 45.5%)
- Evidence-based intervention selection (7/22, 31.8%)
- Procedural and ethical decision-making (5/22, 22.7%)

Discussion

In this evaluation of board-preparation materials, GPT-5 reproduced knowledge required for entry-level competence but continued to show deficits in higher-order reasoning. Because reasoning categories reflect examination item demands rather than GPT-5's internal reasoning, findings represent performance patterns across question types. Although semantic similarity to

XSL•FO
RenderX

expert rationales was high, reasoning lapses suggest that the model captures conceptual language patterns without consistently modeling clinicians' inferential logic. These findings reinforce that semantic similarity reflects linguistic alignment rather than equivalence in clinical reasoning. These findings extend previous work showing that LLMs can approach human-level factual performance while still lacking in cognitive depth and explainability [8].

Findings should be interpreted cautiously because board-preparation materials differ from official licensing examinations, which undergo formal psychometric validation, calibrated difficulty scaling, and secure item rotation. Thus, results do not represent performance on live examinations. Although accuracy approached commonly cited passing thresholds [9], comparisons are limited by scoring differences across professions.

Given the shift toward competency-based medical education and assessment frameworks, such as entrustable professional activities (EPAs) [10], the reasoning deficits observed here raise important questions about whether LLMs can support learners' progression toward entrustment. In structured settings, GPT-5 may be used as a formative adjunct, with educators leveraging model rationales to stimulate reflection and compare reasoning against established milestones or EPAs. Such supervised use supports competency development with oversight. While GPT-5 reproduced factual knowledge, its lapses in inferential and evaluative reasoning highlight limitations in supporting competencies related to clinical judgment, prioritization, and ethical decision-making.

This study is limited by its sample size, focus on rehabilitation disciplines only, and absence of learner outcome data. Because reasoning patterns may differ across specialties, future research should evaluate larger question sets, additional medical domains, intermodel comparisons, and performance across LLM models and prompting conditions. Evaluating LLM reasoning in interactive or case-based formats may reflect clinical decision tasks. Finally, longitudinal studies should examine how learners use LLMs during examination preparation to determine whether model reasoning errors influence learner understanding or create opportunities for instructional interventions.

Although GPT-5 reproduced substantial factual content, observed reasoning gaps support supervised integration in examination preparation. Because this study evaluated examination performance rather than clinical outcomes, any safety implications are theoretical. AI tools should complement, not replace, educator-guided reasoning development.

Funding

No funding was provided for this study.

Data Availability

Data can be made available upon reasonable request. The full set of examination questions and answer options cannot be publicly shared because they originate from commercially licensed board-preparation materials that are copyrighted and not authorized for redistribution.

Abstract

This national study found that remote therapeutic monitoring use increased rapidly between 2022 and 2024 but remained low overall, varied by insurance type and clinician specialty, and was concentrated among patients with musculoskeletal conditions.

(JMIR Rehabil Assist Technol 2026;13:e103600) doi:10.2196/103600

KEYWORDS

remote therapeutic monitoring; commercially insured; Medicare Advantage; patients with musculoskeletal conditions; RTM

Introduction

Remote therapeutic monitoring (RTM) enables the collection and monitoring of nonphysiological data, including functional status, treatment adherence, and patient-reported symptoms [1]. Through RTM, clinicians can gain insight into patients' responsiveness to and engagement with prescribed therapies outside of traditional clinical settings. This information can help identify changes in clinical status that require early intervention, particularly for patients with musculoskeletal, respiratory, and oncologic conditions [2-5]. However, despite the potential for RTM to support proactive care and improve clinical outcomes, studies regarding its use remain limited. Therefore, the aim of our nationwide study was to describe RTM use nationwide among commercially insured and Medicare Advantage (MA) patients.

Methods

Overview

We used 2022 - 2024 Merative MarketScan data, which contain longitudinal commercial and MA insurance claims in the United States, and identified RTM using Current Procedural Terminology codes (98975, 98976, 98977, 98980, 98981). Separately for commercial and MA claims, we assessed the total number of months of RTM use and median number of months of RTM use per patient. Patients were included if they had at least 1 month of RTM use and were enrolled in insurance for at least 11 out of 12 months in a calendar year.

We described the number and characteristics of patients using RTM with respect to age, sex, region, clinical complexity (ie, Charlson Comorbidity Index), and insurance plan type (eg, preferred provider organization, health maintenance organization) [6]. *International Classification of Diseases, Tenth Revision, Clinical Modification* codes were used to identify patient diagnoses for RTM use then grouped using Clinical Classification Software Refined categories (Multimedia Appendix 1) [7]. Lastly, RTM use was stratified by clinician and facility type as follows: primary care physicians (eg, internal medicine and family medicine providers), medical subspecialists (eg, cardiologists and pulmonologists), surgeons (eg, orthopedic and neurological surgeons), other physician specialists (eg, neurology and pain medicine specialists), advanced practice providers (eg, physician assistants and nurse practitioners), other clinicians (eg, therapists and nurses) and facilities (eg, rehabilitation or specialty care facilities) [8].

Ethical Considerations

As this study used deidentified data and did not involve human subjects as defined by federal regulations, it was determined to be exempt by the institutional review board of the University of Texas Southwestern Medical Center.

Results

Between 2022 and 2024, RTM was used by 16,116 patients (n=12,951 commercially insured and n=3165 MA patients; Table S1 in Multimedia Appendix 2). Use of RTM increased from 2089 months (n=1528 commercial and n=561 MA) in

XSL•FO
RenderX

2022 to 24,494 months (n=18,368 commercial and n=6126 MA) by 2024.

Commercially insured patients used RTM a total of 26,936 months, with a median of 1 (IQR 1 - 2) month of RTM use per patient. With over 48 million patients enrolled during the study period, this equated to approximately 5.6 RTM months per 10,000 commercially insured patients. Most (12,280/12,951, 94.8%) used RTM during a single calendar year, while a minority (671/12,951, 5.2%) used RTM during multiple years. The majority of the 12,951 patients were female (8061/12,951, 62.2%), enrolled in a preferred provider organization (7855/12,877, 61%), and had low clinical complexity (12,801/12,951, 98.8%). Additionally, a plurality of patients were between the ages of 55 and 64 years (4116/12,951, 31.8%) and from the US South (6112/12,951, 47.2%).

Comparatively, MA patients used a total of 9551 RTM months, with a median of 2 (IQR 1 - 3) months of RTM use per patient. With nearly 4 million patients enrolled between 2022 and 2024, there were about 24.3 RTM months per 10,000 MA patients. A large majority (2949/3165, 93.2%) used RTM during a single calendar year, and a minority (216/3165, 6.8%) used RTM across multiple years. Among the MA patients, the majority were 75 years or older (1654/3165, 52.3%), female (1982/3165, 62.6%), from the US North Central region (1775/3165, 56.1%), enrolled in a preferred provider organization (2619/2999, 87.3%), and had low clinical complexity (2768/3165, 87.5%).

Among patients with commercial insurance, 48.7% of RTM was delivered by other clinicians (eg, therapists, nurses), followed by other physician specialists (16.5%) and then advanced practice professionals (10.1%; Table 1). The predominant diagnosis category for RTM was diseases of the musculoskeletal system and connective tissue (56.3%). The next most common categories were diseases of the nervous system (17.2%), and factors influencing health status and contact with health services (5.5%).

Among MA patients, RTM was most frequently delivered by primary care physicians (37.8%), other clinicians (23.9%), and other physician specialists (21.3%; Table 2). The primary diagnosis category associated with RTM was also diseases of the musculoskeletal system and connective tissue (45.0%), followed by diseases of the circulatory system (14.2%) and nervous system (10.9%).

Discussion

In this nationwide study, RTM use grew during the first 3 years after the billing codes were introduced, overall use remained low, and different use patterns were observed between commercially insured and MA patients. These early findings provide several observations to build on in future studies.

First, despite a smaller sample for MA versus commercial patients during the study period, RTM use was approximately 4 times higher among MA patients (24.3 versus 5.6 months per 10,000). Because MA patients are older with more comorbidities (12.5% for MA vs 1.2% for commercially insured patients with a Charlson Comorbidity Index of ≥2), it might be expected that RTM was used more among MA patients. Given that MA's goal is to improve longitudinal outcomes through managed care, future work should assess whether more frequent RTM use among MA patients is associated with improved patient outcomes and lower spending. How such results combine with the findings of this and prior studies (eg, remote monitoring use for several months mostly among older female patients) remains within the purview of future work [9,10].

XSL•FO
RenderX

Second, RTM use among both commercial and MA patients was dominated by diseases of the musculoskeletal system and connective tissue, underscoring the role of therapeutic monitoring in supporting rehabilitation and functional monitoring. However, our results showed differences in those delivering RTM. Among commercial insurance patients, RTM was most frequently delivered by clinicians such as therapists and nurses, while among MA patients, RTM was more frequently delivered by primary care physicians. Future studies could evaluate the underlying incentives, approaches, and effectiveness of RTM when delivered through different clinician approaches.

Study limitations included the descriptive design and the inability to evaluate associations between RTM use and clinical outcomes. Although our study period included over 50 million patients, our analysis does not reflect RTM use among traditional Medicare patients. Nonetheless, we believe our study provides valuable observations of patterns in RTM use and, in turn, foundational insights for future research.

Abstract

Background: An increasing number of rehabilitation technologies are being developed to support upper limb rehabilitation after stroke, with smart textile solutions for surface electromyography (sEMG) emerging as a promising approach. Early end-user involvement is crucial for developing user-friendly and clinically valid rehabilitation tools.

Objective: This study aims to refine and evaluate the prototype design and usability of a smart textile biofeedback system for self-administered upper limb training after stroke.

Methods: The training system includes a knitted smart textile sleeve with integrated electrodes over the forearm muscles, an sEMG unit, and tablet-based biofeedback software. An iterative co-design process was followed, including initial testing, demonstration sessions with end users (9 clinicians and 10 individuals with stroke), and a final evaluation of the co-design process. Participants' experiences were gathered through semistructured interviews, analyzed using content analysis, and the User Experience Questionnaire. The co-design team included experts in stroke rehabilitation, textile engineering, biomedical engineering, software development, and human factors, as well as a research partner with lived experience after stroke.

Results: The perspectives of the end users and the expert team were collectively integrated into prototype refinements of the sleeve and training software to meet the needs of the intended target group. The experiences of end users formed 2 main categories: "This could be an exciting new training tool for stroke rehabilitation" and "The tool works well, but some changes could enhance independent training." End users found the smart textile sleeve and biofeedback system easy to use and saw potential for integrating it into their training routines. Both end-user groups rated the system as attractive, stimulating, and novel.

Conclusions: The results of this study establish a necessary ground toward the development of a smart textile sEMG biofeedback system for self-administered upper limb training after stroke. Findings from the co-design process support the continued development and evaluation of the system as a self-administered upper limb training tool for individuals living with stroke.

Introduction

Regaining upper limb function is a primary goal for individuals after a stroke [1]. In the acute phase, about 50% to 70% of individuals experience impaired arm and hand function, and in the long term, only a smaller percentage fully recover their previous level of function [2-5]. Upper limb impairment often leads to difficulties in performing daily activities and limitations in participation [6,7]. Most improvements occur early in recovery, with slower progress continuing into the chronic phase [5,8]. To follow this recovery pattern, rehabilitation programs are mostly concentrated in the acute and subacute phases, while in the chronic phase, the responsibility for continued training often falls on the individuals themselves [9,10]. To support long-term rehabilitation [1], various rehabilitation technologies have been developed to facilitate independent home-based training, ultimately aiming to improve functioning [11,12].

Surface electromyography (sEMG) biofeedback is a rehabilitation technology that provides real-time visual feedback on muscle activity, thereby supporting motor learning mechanisms for more effective movement execution [13,14]. Previous research in stroke populations indicates that sEMG biofeedback interventions can increase upper limb muscle strength, active range of motion, and awareness of the paretic arm [15-18]. sEMG biofeedback systems commonly use disposable pre-gelled Ag/AgCl electrodes [19]. As an alternative to these traditional electrodes, smart textile solutions with integrated textile-based electrodes offer improved comfort, easier application, and a reduced risk of skin irritation [20-24]. Textile solutions enable prolonged, repeated use, which makes them suitable for self-administered rehabilitation in both clinical and home settings. However, smart textile solutions for sEMG applications in upper limb stroke rehabilitation are in the early stages of development, with existing studies limited to controlled research environments and/or small sample sizes [25-27].

A challenge in developing new rehabilitation technologies is their implementation in real-world settings [12,28,29]. A failure to meet the needs of end users (patients and clinicians) and underestimating the complexity and costs of implementation in clinical practice are common reasons for limited clinical uptake [30-32]. Adopting collaborative co-design methodologies that involve end users in the development process can help identify and address specific user needs early on. This ensures better alignment among the technology, its intended use, and context and has been shown to improve the applicability and acceptance of rehabilitation technologies [30,33,34].

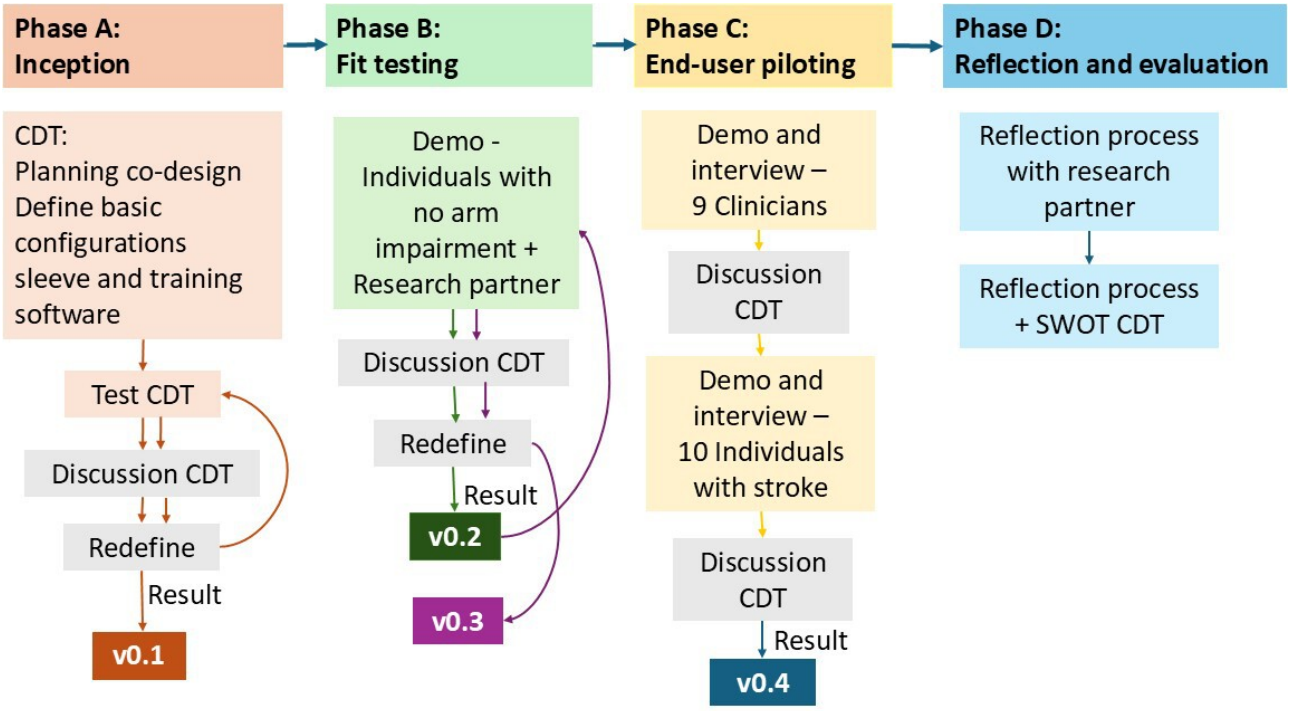
This study aims to refine and evaluate the prototype design and usability of a smart textile biofeedback system for self-administered upper limb training after a stroke, using a co-design approach.

Methods

Ethical Considerations

The study was approved by the Ethics Review Authority (reference 2019-00450/1074-18 and amendment 2024-01703-02) and follows the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist (Checklist 1) [35]. Before entering the study, all participants completed an approved informed consent form, as authorized by the Swedish Ethics Review Authority, including information about the possibility to withdraw from the study at any time without providing a reason. All collected data were anonymized and safely stored accessible only to the research team. No compensation was given for participation.

Co-Design Process



The participatory action research model [36] and the Medical Research Council framework for complex interventions [37] were used to guide the iterative and reflective co-design process, which included 4 phases (Figure 1). Each phase involved iterative cycles of problem definition, planning, acting, observing, reflecting, and redefining the problem [36]. At the end of the codesign process, a strengths, weaknesses, opportunities, and threats analysis [38] was conducted to evaluate the co-design process. The aims, procedures, and actions of each co-design phase are detailed in Table 1.

The co-design team included 7 experts from various fields, including stroke rehabilitation, biomedical engineering, textile engineering, signal processing, software development, and human factors. Most team members had over 15 years of experience in their respective areas, including 1 industry representative with a background in commercial product development. The team also included 2 junior researchers, each with approximately 5 years of experience.

A research partner with a university degree and over 5 years of lived experience with stroke was also included in the co-design team to provide end-user insights during the co-design process. Following the iterative approach of the co-design process, regular physical and digital meetings were held within the co-design team between December 2023 and February 2025.

XSL•FO
RenderX

Table . Co-design process and refinements of the training system.

Phase	Aim	Procedures	Actions
A: Inception	To set priorities for the co-design process and discuss basic configurations for the training system.	• The CDT[a] met several times to set priorities and define the initial configuration of the training system. • The CDT also tested the first version of the sleeve and software.	• Version 0.1: a conically shaped, circularly knitted sleeve with 2 electrode pairs (wrist flexors and extensors) and a reference electrode at the elbow was developed. The electrodes were connected via snap-button connectors to a wireless sEMG[b] acquisition unit (Shimmer3 EMG, Shimmer Sensing) with an external band. To enhance signal quality, water was applied by 3 finger strokes to each electrode prior to use. Biofeedback was delivered through a tablet using a custom-made application (iOS and Android compatible). Real-time sEMG signals from 2 channels (wrist flexors and extensors) were used during a calibration period to set training thresholds. For training, a vertical bar (presented next to the sEMG signals) turned green when the user reached a target threshold.
B: Fit testing	To test the training system with individuals without upper limb impairments and refine its design for improved fit and usability.	• Individual demonstration sessions with the research partner and with 11 participants without arm impairments. • Refinements and production of the sleeve.	• Version 0.2: sEMG signals were obtained from all participants, although the comfort of the sleeve varied across participants. Based on their feedback, medium and large sizes were produced, and a reference line following the middle finger was added to facilitate electrode alignment during donning. • Version 0.3: a second feedback round led to further refinements, including a knob for easier elbow alignment, a Velcro strap to attach the sEMG unit to the sleeve (replacing the external band), and the addition of a small sleeve size. Software updates included adding a separate window for visualizing the bar activity, tracking repetitions exceeding the threshold, and implementing calibration with a manual stop.

XSL•FO
RenderX

Phase	Aim	Procedures	Actions
C: End-user piloting	To assess usability and investigate perceptions and experiences of the training system from clinicians and individuals with stroke.	• Individual demonstration sessions with 9 stroke rehabilitation clinicians and 10 individuals with stroke. • Semistructured interviews and the UEQ[c] with end users at the end of the demonstration sessions.	• Version 0.4: on the basis of the collected feedback by end users, an additional Velcro strap was added to the sleeve to secure cables and simplify donning and doffing. The medium-sized sleeve was also downsized for a better fit. Software improvements included: fewer and larger buttons, naming of channels, adding a calibration countdown, larger size of the bars with repetition counts, higher color contrast, and a performance report.
D: Reflection and evaluation	To reflect on and to evaluate the co-design process.	• SWOT[d] analysis and reflection workshop with CDT. • Individual reflection session with research partner.	• Reflections from the CDT highlighted strengths such as strong collaboration, research partner involvement, and interdisciplinary expertise. Weaknesses included lack of an external facilitator and limited access to in-house software developers. Opportunities and threats related to future implementation were discussed. The research partner provided additional insights on her experience and valued her active role throughout the co-design process.

[a]CDT: co-design team.

[b]sEMG: surface electromyography.

[c]UEQ: User Experience Questionnaire.

[d]SWOT: strengths, weaknesses, opportunities, and threats.

Participants and Data Collection

In phase A, the co-design team defined the basic configuration of the training system (version 0.1). A textile sleeve with 2 pairs of integrated textile electrodes, placed over the wrist extensors and flexors, and a reference electrode placed on the elbow was produced. The sleeve was connected to a 2-channel wireless sEMG system (Shimmer3 EMG, Shimmer Sensing). The biofeedback software provided visual feedback of the sEMG signals displayed on a tablet from the wrist extensor muscles (eg, extensor carpi radialis brevis) and flexor muscles (eg, flexor carpi ulnaris). The sEMG signals from specific muscle activation were used to calibrate muscle activity thresholds, which were then visualized during training through a vertical bar display. This provided real-time feedback and allowed for adjustments to individualized muscle activity threshold settings.

In phase B, an initial test demonstration session was conducted with the research partner, followed by individual sessions with 11 participants without arm impairments. Convenience sampling was used, and age, gender, and anthropometric data were collected from this sample (Multimedia Appendix 1).

In phase C, individual demonstration sessions were conducted with 2 end-user groups: 9 clinicians (6 physiotherapists, 2 occupational therapists, and 1 rehabilitation doctor) and 10 individuals with stroke (Tables S1 and S2 in Multimedia Appendix 2). Participants were recruited through purposive sampling. Clinicians were recruited from stroke rehabilitation units in hospitals and primary care centers, while individuals with stroke were recruited through advertisements at rehabilitation centers in the Gothenburg urban area. Inclusion criteria for individuals with stroke were as follows: aged over 18 years, upper limb impairment after stroke, and detectable sEMG signal from the paretic arm. Exclusion criteria for all participants included open wounds, other conditions affecting arm function, uncorrected visual impairment, and inability to understand or follow instructions in Swedish or English. Demographic data, prior sEMG experience, and familiarity with using technologies (eg, smartphones, tablets, and computers) were collected from all end users. For individuals with stroke, additional information was gathered on stroke type and time since stroke, while for clinicians, data on years of experience and work setting were collected.

All demonstration sessions were conducted at Gothenburg University and led by a physiotherapist experienced with the training system (MM-N). In these sessions, the participants were first instructed on how to use the sleeve and software and

XSL•FO
RenderX

then asked to try it independently, with additional support provided as needed. At the end of the sessions, the participants were interviewed for about 30 minutes and asked to fill in the User Experience Questionnaire (UEQ) [39,40]. Additionally, in the demonstration sessions with individuals with stroke, upper limb function and spasticity were assessed using the Fugl-Meyer Assessment of Upper Extremity [41] and the Modified Ashworth Scale [42], respectively. From the demonstration sessions with end users, 1 clinician tested only the sleeve due to technical issues with the software and 1 individual with stroke provided limited feedback due to aphasia.

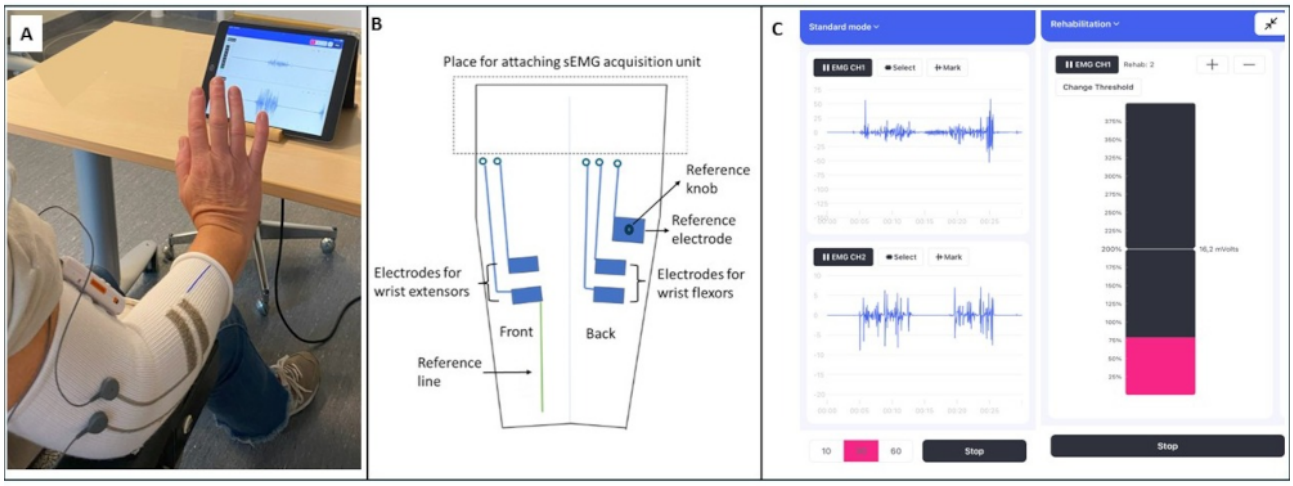
Evaluations and Data Analysis

Semistructured Interviews

The semistructured interviews included questions about the end users' perceptions and experiences using the sleeve and training software during the demonstration sessions, as well as their opinions on the training tool's potential for independent use in clinics or home settings. For clinicians, questions were adapted to explore how they would foresee using the training system in stroke rehabilitation (Multimedia Appendix 1). All interviews were led by the same physiotherapist who conducted the demonstration sessions (MM-N, with more than 5 years of research experience in stroke rehabilitation), unless a participant was not fluent in English, in which case the interview was conducted in Swedish by another physiotherapist (MAM, with more than 20 years of experience in stroke rehabilitation). All interviews were audio-recorded, transcribed verbatim by 2 researchers from the co-design team (MM-N and AB), and stored securely, with access restricted to the authors. The field notes and spontaneous feedback collected from participants during the demonstration sessions were also used to complement the interview data.

Content analysis using the approach described by Graneheim and Lundman [43] was used to analyze the interviews [44]. The analysis involved extracting meaning units, condensing them, coding, and sorting codes into categories and subcategories (Multimedia Appendix 1). Since the interviews were conducted following a single demonstration session, the analysis focused on manifest content, emphasizing explicit and observable elements [43,44]. Interviews conducted in Swedish were translated into English and checked for accuracy by a native Swedish speaker (AB). The analyses were conducted in English. Initial coding was carried out by a member of the co-design team (MM-N), while a second researcher (AB), a research engineer with over 5 years of experience in textile technology who was not involved in data collection but was familiar with the data, participated in the review and refinement of the codes. Interviews with clinicians and individuals with stroke were analyzed together, but coding was grouped separately for each participant type using different colors to facilitate category development while distinguishing differences between the groups. Two researchers (AB and MM-N) independently developed initial categories, followed by an iterative process of discussions with a third researcher (MAM) to refine and resolve conflicts until final categories were agreed upon. The research partner was also included in the final stages of the analysis, providing additional input on the selected categories and subcategories.

User Experience Questionnaire



The UEQ captures a broad range of user experience aspects, helping to identify both strengths and areas for improvement [39,40]. It consists of 26 items rated on a 7-point scale, with each item presented as a pair of opposite terms. The questionnaire evaluates 6 dimensions: attractiveness (overall impression), perspicuity (ease of use), efficiency (task completion without unnecessary effort), dependability (feeling in control), stimulation (excitement and motivation), and novelty (innovation and creativity) [39,40]. The UEQ benchmark [45] was used to interpret the results on 5 levels: excellent, good, above average, below average, and bad.

Results

The specific refinements of the training system during the iterative phases (A-D) of the study are detailed in Table 1. The setup of the training system, the smart textile sleeve configuration, and the biofeedback software used in the demonstration sessions (version 0.3) are shown in Figure 2.

XSL•FO
RenderX

Figure 2. The smart textile sleeve biofeedback training system version 0.3. (A) Demonstration session setup, (B) smart textile sleeve configuration, and (C) biofeedback software (left panel: real-time sEMG signals from extensor [CH1] and flexor [CH2] channels; right panel: muscle activity bar visualization with adjustable threshold settings for training). CH1: channel 1; CH2: channel 2; sEMG: surface electromyography.

End Users' Experiences and Perceptions

From the interviews with clinicians and individuals with stroke, 2 main categories and 5 subcategories emerged, as illustrated in Textbox 1. Quotes are presented below each subcategory, where "S" indicates individuals with stroke and "C" refers to clinicians.

Textbox 1. Categories and subcategories emerging from content analysis.

Categories and subcategories

- This could be a new exciting training tool for stroke rehabilitation.
  - Rewarding and motivating to see muscle activity.
  - Use will be determined by individual needs.
  - Instructions and guidance will help independent use.
- The training tool works fine, but some changes could enhance independent training.
  - It can be difficult at first, but it is possible to find a way to make it work.
  - More is needed for independent long-term use.

This Could Be a New Exciting Training Tool for Stroke Rehabilitation

Participants with stroke and clinicians found the training system to be novel, exciting, and potentially useful for upper limb rehabilitation after stroke. Both groups expressed interest in incorporating the training system into their routines.

Rewarding and Motivating to See Muscle Activity

The real-time visual feedback on muscle activity was described as intuitive, useful [2], and rewarding by most participants. Individuals with stroke liked seeing their muscle activity, especially during training with the bar visualization, as many had thought they had little or no muscle activity due to their impairment. Some participants reported feeling more "connected" to their affected arm when seeing the activity visualized on the screen [3,4]. They described the feedback as not only giving them a sense of control over their arm but also possibly making the training more engaging, interesting, and motivating. Clinicians also highlighted the benefits of visual feedback, particularly for patients with limited muscle activity, as it could help them recognize their remaining muscle function and visualize their progress over time. Participants with stroke and clinicians also noted that visual feedback could enhance motivation and engagement and increase awareness of the affected arm, ultimately supporting and empowering independent training.

> ***S5:*** *That's, for me, [seeing the muscle activity] is something good to see, because then I see that something actually happens…I mean, it's boring to just sit like that, but if you see something happening, then I know my muscles are generating that kind of activity.*

> ***C3:*** *I like the visual feedback you get, even though we just do like a slight movement, you see the graph is changing. And if I put it on stroke patients, I think it's really good because sometimes when you tell a stroke patient, "Oh, can you do this movement?" They are quite sad, because they can't do the movement, but [with this training] you can see, "Oh, they are initiating the movement."*

XSL•FO
RenderX

Use Will Be Determined by Individual Needs

Most participants considered the training system more suitable for the chronic or subacute phases after a stroke. In the acute and subacute phases, individuals with stroke felt it could be overwhelming due to the many other challenges they faced at that stage, a concern shared by the clinicians. Some clinicians also noted that cost, time, and technical constraints could limit its use in clinical settings, while others described the tool as a complement to other training in the subacute phase. Both groups saw it as feasible and beneficial for home training in the chronic phase, especially considering that the available training opportunities are fewer compared to the subacute phase. However, they noted that some level of upper limb function in the paretic arm would be necessary, as high spasticity or limited elbow and finger control could make it difficult to don and doff the sleeve independently. Clinicians also emphasized that a certain level of cognition is required to handle and manage the training without therapist or carer support. Both groups mentioned that limited prior experience with technology could be a potential barrier to using the software.

> ***S6:*** *I think it's a very good idea [the training tool]. Eh, it's a problem for people like me [individuals with stroke], in the winter, to get out to training places when it's snowy, so it's very nice to make it possible to train home as well.*
>
> ***C7:*** *I think if you have one arm [functional arm], you could do it. You still need good cognitive abilities. Maybe not being too old. Some patients who are old are afraid of technological things because they feel uncertain. Even though they can manage… they don't think they can. It is very different from person to person.*

Instructions and Guidance Will Help Independent Use

Individuals with stroke, as well as clinicians, viewed independent home training positively, with individuals with stroke especially finding it exciting and convenient. However, both groups emphasized that clear instructions and support are essential for successful independent use. While they appreciated the simple and clear guidance provided during the demonstration session, they felt additional help with software navigation and sleeve placement would be required. Individuals with stroke generally believed they could train independently or with partial caregiver assistance at home after initial guidance. However, they desired more structured support, including written training protocols, visual and written instructions, in-software reminders, and clinician follow-ups (in person or online) to ensure success. Clinicians also stressed the need for clear, repeated instructions in multiple formats to facilitate adherence. Additionally, clinicians highlighted the importance of hands-on training for patients and caregivers, along with in-person or online follow-ups to monitor tool usage and progress.

> ***S2:*** *It was difficult [to place the sleeve independently]. I think it can be even more difficult if you, kind of, get it [the training system] home and don't get to try it on first.*
>
> ***C1:*** *...They [individuals with stroke] need guidance, as it is right now [the tested version], I think...but otherwise, I think it's quite easy to use with guidance.*

The Training Tool Works Fine, but Some Changes Could Enhance Independent Training

Overall, individuals with stroke and clinicians described the sleeve as functional and easy to use, noting that further improvements to the software were needed to promote independent training.

It Can Be Difficult at First, but It Is Possible to Find a Way to Make It Work

Most participants found the sleeve easy to use and comfortable, and they appreciated the provided instructions as well as the reference line and elbow knob for guidance. Individuals with stroke and more severe arm impairment experienced some difficulties with getting the hand inside the sleeve, rotating the sleeve into the correct position, and/or pulling the sleeve up on the arm. However, many found strategies by themselves during the demonstration session and believed that, with practice, it would not be a major problem. Another challenge was locating the reference electrode at the elbow and applying water to the reference and flexor electrodes due to a limited range of arm movement and/or sensory impairment. In the end, all participants with stroke were able to place the sleeve correctly, although some needed more time and minor assistance.

Perceptions of the software varied. Younger participants in both groups found the software easier to use, while others described it as a bit complicated and not intuitive. The buttons on the screen were too small and difficult to see for many. In general, most individuals with stroke and clinicians liked that a tablet was used for feedback, as it is larger than a phone but also portable compared to a computer screen. They emphasized that initial guidance and clear instructions on the software would be essential to ensure successful use.

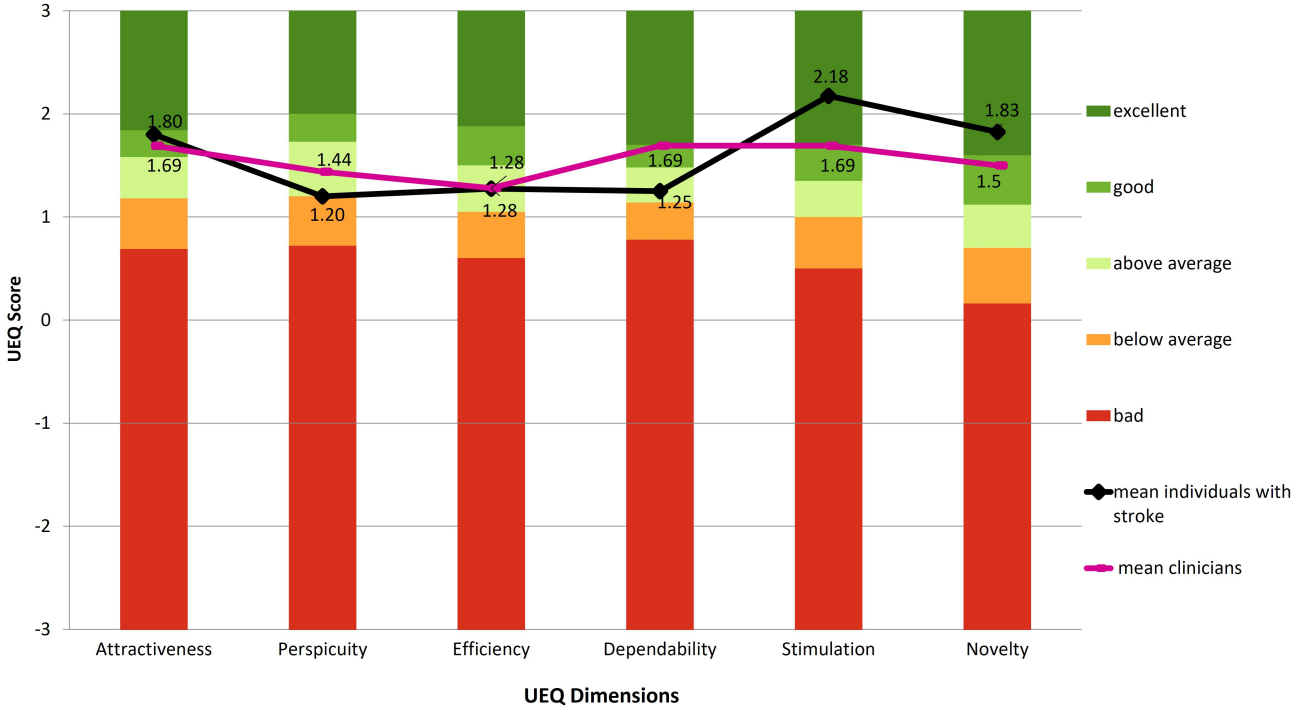
> ***S7:*** *Yes, it was difficult to begin with [to put on the sleeve], but I think it's something you get used to.*
>
> ***C6:*** *To me, it was easy and fine. I don't know if a patient with a paresis would have difficulties having it drawn up on the middle of the arm …and also, placing it correctly on the elbow might be difficult.*

More Is Needed for Independent Long-Term Use

Independent home use was a possibility that many described as feasible, but they suggested improvements for better usability and long-term adherence. To simplify sleeve placement, participants recommended using a mirror or tablet webcam to better view the electrodes on the dorsal side of the arm and the reference electrode. Additional reference points, shorter electrode cables, and a pull strap for easier placement were also suggested. Regarding the software, both participants with stroke and clinicians desired a more user-friendly, engaging, and intuitive interface, with suggestions including games, videos, and motivational elements to make training more engaging. Clinicians emphasized adding functional, goal-oriented tasks and applying resistance to enhance engagement and facilitate training. Fewer and larger clickable buttons, simpler calibration

XSL•FO
RenderX

procedures, and adding more colors and contrast were other proposals for software improvements. Clinicians also suggested incorporating audio feedback to guide training and augment visual feedback. Additionally, both groups highlighted the need for customizable training parameters to facilitate sessions, such as calibration time and the number of repetitions, as well as the ability to track progress, which is particularly important for independent training. When considering home training, participants thought that a short daily training session of about 15 minutes would be feasible—short enough to avoid mental fatigue. A clinician also suggested using a bag to keep the sleeve clean between training sessions and noted that multiple sleeves might be needed if one requires cleaning or washing.



> ***S10:*** *On the tablet, I think it's too many knobs [buttons] to press on…It should be easier. One or two presses.*

> ***C2:*** *I'm thinking this [the training tool] was easy to use. But maybe adding some extra, like instructions... instructions like how fast you will do the exercise, how many repetitions, how long will I keep it. Maybe adding…like an audio, like a voice, [for example] if you have bad vision.*

User Experience Questionnaire

The UEQ was completed by all individuals with stroke and all but 1 clinician, who did not have the opportunity to try the software. Both groups rated *attractiveness* as "good" and *efficiency* as "above average." Clinicians rated *perspicuity* as "above average," while participants with stroke rated it lower, between "above average" and "below average." *Dependability* was rated "good" by clinicians and "above average" by individuals with stroke. Participants with stroke rated *stimulation* and *novelty* as "excellent," while clinicians rated them as "good" (Figure 3).

Figure 3. The results from the User Experience Questionnaire (UEQ) in relation to the standard UEQ benchmark levels. Scores range from −3 (very negative evaluation) to +3 (very positive evaluation), with 0 representing a neutral response. Line plots indicate the mean responses from individuals with stroke (black line; n=10) and clinicians (pink line; n=8).

Reflection and Evaluation of the Co-Design Process

The strengths of the co-design process identified by the co-design team were strong collaboration, effective communication, and research partner involvement, ensuring an end-user perspective. Flexibility, team commitment, and optimal facilities were also highlighted. Not having access to an external facilitator and software developers within the co-design team was identified as a weakness, with the latter contributing to delays in communication and iterative development. Opportunities included creating visual simulations before user involvement, direct contact with clinicians and patients, and a positive view of the training tool's potential value. Threats such as overdevelopment, uncertainty about real-world applicability, and challenges with commercialization and regulatory approval were also identified.

At the end of the co-design process, a reflection session with the research partner revealed that she enjoyed the experience and was pleasantly surprised by how much she liked it, as it was her first time in this role. She appreciated being involved not only in testing the training system but also in the reflective process. Overall, she found the experience fun and felt good about contributing to the research.

Discussion

Principal Findings

Supported by collaboration between experts from different fields and end users, the iterative co-design process provided valuable

XSL•FO
RenderX

insights into the technical, clinical, and user-centered aspects of the training system, highlighting its potential usability, acceptability, and areas for improvement based on end users' needs. The participants with stroke were able to independently, or with minor assistance, don and doff the sleeve and operate the training software on the tablet. Both clinicians and individuals with stroke recognized the training tool's potential for self-administered training. This study provides a starting point for the ongoing development and improvement of the training system.

The structured co-design process in this study, grounded in the participatory action research model [36] and the Medical Research Council framework [37], provided a strong foundation for the development of the training system and the shared understanding necessary for its continued refinement. This approach supported a systematic and iterative development of the training system and may serve as a useful model for future rehabilitation technology development [46,47]. The interdisciplinary nature of the co-design team enriched the process through diverse perspectives. However, differences in disciplinary knowledge and workflows, as reported in previous studies [48-50], may have prolonged the decision-making process. The co-design team suggested that adding a neutral facilitator to the team could have helped to advance the process further [33,51]. Integrating end-user feedback on design improvements with development constraints and limited available resources is a complex but well-recognized challenge in rehabilitation technology development [36,52]. This challenge was addressed through regular co-design meetings and systematic documentation, which enabled balanced prioritization of modifications based on both end-user feedback and practical constraints. Even though not all suggestions from the end users were integrated, they offered valuable insights for future improvements to the training system.

The overall positive perceptions of the smart textile biofeedback training system among individuals with stroke and clinicians underscore its potential as a possible solution for self-administered rehabilitation at home and in clinical contexts. Initial difficulties with donning and doffing the sleeve, particularly among participants with more severe upper limb impairments, highlighted the importance of user-centered design and individualized support during the development of the training system [30,33,34]. All participants were ultimately able to use the system independently or with minimal assistance, suggesting its accessibility across varying levels of motor function. The integration of textile electrodes simplified the donning process, possibly reducing barriers associated with conventional electrode placement and supporting independent use [20-24], especially for individuals with limited fine motor control. Although the system was evaluated in single sessions, the positive perceptions and willingness to incorporate it into daily training routines indicate promising initial usability and acceptability. Further longitudinal studies are needed to assess sustained engagement and rehabilitation outcomes over time.

The visual feedback, consistent with previous evidence [53-56], was perceived as intuitive and helpful in increasing awareness of muscle activity. The participants also found that being able to see and control their muscle activity increased their engagement and motivation. Future iterations, as suggested by the end users, will include more engaging interactive games and/or virtual environments, to facilitate long-term use [57-60]. Additionally, more advanced signal processing techniques, such as myoelectric pattern recognition, could be valuable for detecting specific movement patterns and enabling more intuitive control [14,61]. Ease of use and engaging designs have been identified as key factors in increasing treatment adherence [50,62,63] and will therefore be prioritized in the continued development of the training system for self-administered rehabilitation.

The participants also emphasized the need for structured support from the therapist, including regular follow-ups and adjustments to the training program. They highlighted the importance of clear instructions, in written or video formats, to support independent use and long-term adherence. Clear guidance, personalized feedback, and ongoing clinician support are essential for the successful use and sustained engagement with home-based rehabilitation technologies [50,63-65]. Both participants with stroke and clinicians found the training tool suitable for individuals with limited upper limb function but raised some concerns for individuals with limited cognitive capacity or experience with digital tools. On the basis of these insights, future iterations of the training system will focus on incorporating therapist support, clear instructional materials, the potential integration of a virtual coach, and appropriate user targeting to promote effectiveness and broader adoption in home-based rehabilitation.

Strength and Limitations

The ongoing input from the research partner was a strength of this study, offering valuable feedback that kept the co-design team focused on end users' needs. The iterative co-design process, supported by the triangulation of interviews, field notes, and questionnaires, as well as ongoing reflexive discussions within the team, strengthened the study's credibility, transparency, and overall trustworthiness [46,47]. Additionally, interviews, field notes, and a UEQ provided a broader understanding of participants' experiences.

A strength that also posed a limitation was that some participants were recruited through professional networks and, in many cases, the first author conducted both the sessions and the interviews. While this facilitated access and trust, it may have introduced sampling bias and relationship bias, as prior familiarity could have influenced participants' responses and the researcher's interpretation, potentially limiting the diversity and representativeness of perspectives.

The end users' perceptions were primarily used to inform the design and perceived usefulness of the training system, rather than to evaluate its practical application in clinical settings. The brief, single-session exposure further limited feedback to initial impressions rather than long-term use. Future studies are needed to evaluate the usability, feasibility, and potential effectiveness of the system in people with stroke after a longer training period.

Conclusions

This study developed and evaluated the usability of a smart textile sEMG biofeedback system designed for self-administered

XSL•FO
RenderX

upper limb rehabilitation after stroke. The co-design process, involving a multidisciplinary team of experts and end users, played an important role in identifying users' needs and preferences, contributing to a more targeted and user-centered design. Individuals with stroke and clinicians found the training tool useful and relevant for rehabilitation. The findings will guide ongoing development and clinical evaluation, but further research is needed to determine the system's effectiveness as a home-based rehabilitation tool for people with stroke.

Acknowledgments

The authors thank all the participants, including individuals with stroke, clinicians, researchers, and individuals with no arm impairment, for their time and effort in joining this study. The authors give special thanks to their research partner, Johanna Persson, for her invaluable guidance in the co-design process and to Elin Gustafsson for assisting with participant recruitment. The authors also acknowledge Bola AB for producing the textile prototypes used in this study and Katharina S Sunnerhagen for her support throughout the process.

Funding

This study was funded by the Promobilia Foundation (A23169); KK-Stiftelsen (20220222); Strokeförbundets Stiftelser och Fonder (S-10119402024-09-15); Norrbacka-Eugeniastiftelsen (837/24); Stiftelsen Hjalmar Svenssons (HJSV2024058); Swedish Society for Medical Research (S19-0074); and the Swedish state under the agreement between the Swedish government and the county councils, the ALF-agreement (ALF-GBG-932697, ALF-GBG 965508, and ALF-GBG 1006050).

Abstract

Background: While smart speakers are emerging as a novel health care technology, people with Parkinson's Disease (PwPD) and speech and language therapists (SaLTs) have reported difficulties using smart speakers with speech and voice impairments in research. To date, PwPD have identified frustration with having to repeat themselves to be understood, devices timing out before they had finished speaking, and being unable to have a conversation with smart speakers. SaLTs have reported technical and practical challenges in implementing voice-assisted technology tools. Both PwPD and SaLTs indicated a lack of knowledge about what smart speakers could do, as well as concerns about privacy and the listening nature of the devices.

Objective: This study aims to co-design solutions that support the use of smart speakers for speech and voice difficulties experienced by PwPD.

Methods: Based on the Design Thinking framework, a multistage design process was conducted, involving a lay steering group and 2 online co-design workshops. Twenty participants, including PwPD, carers, SaLTs, design and technology experts, and third-sector staff, collaborated during the co-design workshops. The ideate phase included brainstorming and ranking, and conventional content analysis was used to specify prototypes.

Results: Two main prototypes were created: (1) education and guidance, including privacy and therapeutic usage guides for PwPD and SaLTs to address troubleshooting and delivery considerations; and (2) new speech and language therapy (SLT)–specific features for smart speakers. Participants provided feedback on their experiences of co-design, highlighting feeling valued, the balance of perspectives, and making improvement suggestions. Feedback aligned with the UK standards for public involvement.

Conclusions: Smart speakers could enhance accessibility, therapy engagement, and long-term speech outcomes, offering scalable, cost-effective solutions to support SLT services, patient independence, and reduced service demand. Smart speaker solutions with a SLT focus enable PwPD to self-manage speech and voice difficulties at home and reinforce therapy gains between clinic visits. Co-designed with users, these prototypes are intended to address health disparities and relieve pressure on SLT services, offering a scalable and sustainable solution that enhances efficiency and supports ongoing rehabilitation within health care systems.

Introduction

Background

Voice-assisted technology (VAT) is defined as a device that uses natural language processing or automatic speech recognition (ASR) to interpret spoken language and translate it into actionable requests.

Smart speakers are commercially available VAT devices that are controlled using voice commands and are usually connected to the internet (current examples include Amazon Alexa and Google Assistant). They can feature built-in control systems for tasks on demand, including smart home automation, providing general information (not limited to weather, recipes, or health information), person-to-person calls, sending and receiving messages, and playing music. New models with screens can also support audio and video streaming. Smart speakers are readily available for purchase and use by the general public [1].

It has been reported that VAT prompts some participants with speech difficulties to modify their speech to enable interaction with VAT [2-6]. People with Parkinson's disease (PwPD) have reported adapting their speech by speaking more slowly, loudly, and clearly when interacting with a smart speaker [4]. Considering that 90% of PwPD present with reduced speech intelligibility and limited vocal loudness [7], VAT may hold potential as a therapeutic adjunct in speech and language therapy (SLT). This prior evidence indicates that VAT may enhance access to therapy [8].

Some therapists have reported using VAT to promote improved volume, clarity, and intelligibility of speech [9]. In addition to offering biofeedback on speech clarity, these tools have provided structured opportunities for home-based practice, fostering self-awareness and supporting the self-management of dysarthria and other speech difficulties [9,10]. PwPD have reported increased clarity of speech and volume when using VAT, and have used VAT as a communication partner to practice their speech and rebuild confidence in using their voice [11]. Both speech and language therapists (SaLTs) and PwPD agree that the objective nature of VAT is key to promoting interaction and providing feedback on speech. Textbox 1 presents a hypothetical vignette illustrating how a person with speech or voice difficulties may interact with smart speakers. This vignette is informed by the understanding and findings of previous research [11].

Textbox 1. Case study

1. Case

John is 65 and has had Parkinson's disease for 5 years. His phonation is impacted by poor breath support, resulting in a breathy, hoarse voice with low volume. His articulation is reduced, resulting in imprecise speech production, which reduces speech clarity and intelligibility. His speech is also hypernasal, and nasal emissions are noted. He has hypokinetic dysarthria. At home, his family can understand him, but he is frequently told that they "can't hear him" and that he "needs to speak up." This is frustrating for John, as he reports that "he feels like he is shouting," which suggests impaired self-awareness of his speech.

2. Use

John uses his smart speaker daily. When he speaks to the smart speaker, it replies with "Sorry, I didn't get that" approximately 50% of the time. As a result, John raises his volume and repeats his request. Often, he uses a loud voice, overarticulates his words, slows down, and speaks as soon as he takes a breath. The smart speaker responds when he uses these strategies. This demonstrates that smart speakers provide feedback on volume and clarity of speech in the form of an external cue: "Sorry, I didn't get that." This can encourage increased self-awareness of speech volume and intelligibility, and result in the use of LOUD, clear speech strategies. As John's smart speaker can time out before he has finished speaking, he uses *adaptive listening mode* (available on Amazon devices), which is found in the accessibility settings and gives him longer to speak.

John also plays the game "Word Tennis" on his smart speaker. He has to think of words within a semantic category quickly and remember to use a LOUD, clear voice when answering. This task focuses on a word-level activity within the speech hierarchy and adds a cognitive load to increase difficulty, which aligns with Lee Silverman Voice Treatment (LSVT) LOUD principles [12]. He also enjoys sport and cooking and uses his smart speaker to search for recipes. Common functional requests include "Add cheese and potatoes to my shopping list," "Show me my cooking library," and "What was the Man United score today?" Sometimes, he even uses his smart speaker like a diary: "Leave a sticky note for...", where he records a voice note on his smart speaker to remind someone to feed their dog.

3. Summary

Overall, interacting with his smart speaker allows John to practice a LOUD, clear voice at home, with external feedback on speech volume and clarity that may help improve his self-awareness.

Despite the facilitators discussed in Textbox 1, several barriers to the effective use of VAT among PwPD and SaLTs remain [9,11]. For example, PwPD have reported feeling frustrated by needing to repeat themselves to be understood, by devices timing out before they had finished speaking, and by being unable to have a conversation with their smart speaker [11]. SaLTs also indicated that they faced technical and practical challenges in implementing VAT tools [9]. Both PwPD and SaLTs reported a lack of knowledge about smart speaker capabilities and concerns surrounding privacy and data security.

Addressing these challenges is essential to enable the integration of VAT into SLT practice. Design Thinking is a user-centered innovation framework used to guide the development of new health care technologies, often utilizing co-design approaches [13-15]. It offers a structured approach to identifying problems and generating solutions through empathy, collaboration, and iterative prototyping and testing. This study is informed by the define, ideate, and prototyping phases of the Design Thinking process. Figure 1 outlines the Design Thinking process, and Table 1 shows the connections between the phases of the Design

XSL•FO
RenderX

Thinking framework, the specific research questions to be addressed, and the methods used.

Co-design has been used to foster collaboration that stimulates new ideas, clarifies concepts, and creates solutions that prioritize the needs and lived experiences of end users [16]. Co-design workshops have been used in SLT, health technology research, and with older adult populations [17-19], with improved outcomes for technology adoption compared with noncollaborative design processes [17,19]. Co-design is critical when developing technologies for SLT [18] and has value in engaging people with communication difficulties [20-22]. We set out to follow the co-design cycle and principles, meeting the criteria for true co-design under the ladder of co-production [23-25], through the identification and development of recommendations from participants with communication difficulties [26,27].

Figure 1. The Design Thinking stages [13] from empathize to prototyping, which can be used during the development of new health care technologies [15].

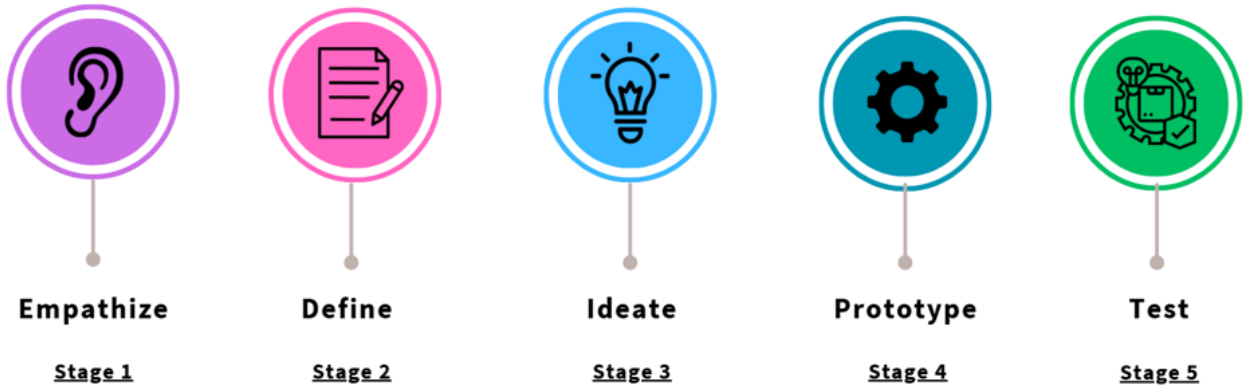

Table 1. Ways in which existing barriers to the therapeutic use of VAT[a] by people with Parkinson's can be solved.

Objective	Objective 1: To consider and select problem statements from the perspectives of experts by experience.	Objective 2: To create solutions to problem statements associated with VAT usage, alongside people with Parkinson's, carers, SaLTs[b], technology and design experts, and third-sector representatives.	Objective 3: To prioritize co-designed solutions to inform prototype VAT interventions.	Objective 3: To prioritize co-designed solutions to inform prototype VAT interventions.

[a]VAT: voice-assisted technology.

[b]SaLT: speech and language therapist.

This research is intended to address previously noted barriers to VAT use [9,11] and aims to co-design solutions to previously identified challenges with VAT by working with PwPD, carers, SaLTs, charity representatives, and technology and design experts. This approach was taken to ensure that new technologies can be used in ways that meet end user needs. We sought to create solutions by using commercial technology, without coding or modifying VAT devices. This ensures that solutions are low cost and accessible, enhancing the potential for wider adoption of VAT in SLT contexts.

Aim

We set out to co-design solutions to support the use of smart speakers in SLT to improve volume and intelligibility for PwPD, using a Design Thinking framework. The research addressed the following question: "How can we facilitate the therapeutic use of VAT by people with Parkinson's Disease?"

Our study objectives (mapped onto Design Thinking stages) are as follows:

- To consider and select problem statements from the perspectives of experts by experience (Define).
- To co-create solutions to problem statements associated with VAT usage, alongside PwPD, carers, SaLTs, technology and design experts, and third-sector representatives (Ideate).
- To prioritize co-designed solutions to inform prototype VAT interventions (Prototype).

Methods

Participatory Co-Design Approach

Participatory methods such as co-design allow interventions to be designed around end user needs. This study co-designed solutions to previously identified barriers regarding the use of VAT when speech and voice difficulties were present. This results in technology that more readily meets user needs [28] and helps to avoid digital exclusion [29]. Workshops were held online, removing geographical and physical barriers and

XSL•FO
RenderX

enabling SaLTs from throughout the United Kingdom to share their experiences.

Ethical Considerations

Ethical approval was granted by the Ulster University Research Ethics Committee in January 2025 (approval number FCNUR-24-078-A). This study is part of a larger PhD project using Design Thinking. Previous phases of work aligned with the empathize stage, and the current co-design phase aligns with the define, ideation, and prototyping stages. All participants provided informed consent before the workshops. Participant outputs were anonymous, and ground rules were agreed upon to maintain confidentiality. Participants did not receive payment or financial incentives.

Patient and Public Involvement

A patient and public involvement (PPI) steering group was established to provide a voice for key stakeholders and ensure their active role in shaping the research. This group included a SaLT with firsthand experience using VAT in clinical settings, a person living with Parkinson's, and a caregiver. These 3 experts by experience coassessed the barriers to VAT usage identified in previous research [9,11] and co-decided the top 5 problems that reflected their experiences, in keeping with the cycle of coproduction [24].

Study Recruitment

PwPD and carers were recruited via a third-sector organization (Parkinson's UK) using advertisements on the Parkinson's UK research portal, Research Support Network monthly emails, and flyers at local Parkinson's support groups in Northern Ireland. SaLTs were recruited through the Royal College of Speech and Language Therapists, including the Parkinson's Clinical Excellence Network. In addition, Parkinson's UK staff and technology or design experts were recruited through the lead author's (JM) professional network. Some participants had established a relationship with the lead researcher through work with the local branch of Parkinson's UK in Northern Ireland.

Previous research was used to determine the number of participant collaborators invited to share their experiences during the workshops (n=20) [30,31]. Participants were asked to contact the research team to express interest in the study and were screened according to predefined criteria (Table 2). Potential participants were sent study information and consent forms by email or post, depending on preference, and were asked to indicate their availability. Once consent was obtained, participants completed a demographic survey and received links for the online workshops. This enabled interaction between diverse experiences. Participants were placed into smaller, experience-diverse groups of 4-5 participants to encourage idea generation in a safe and supportive environment.

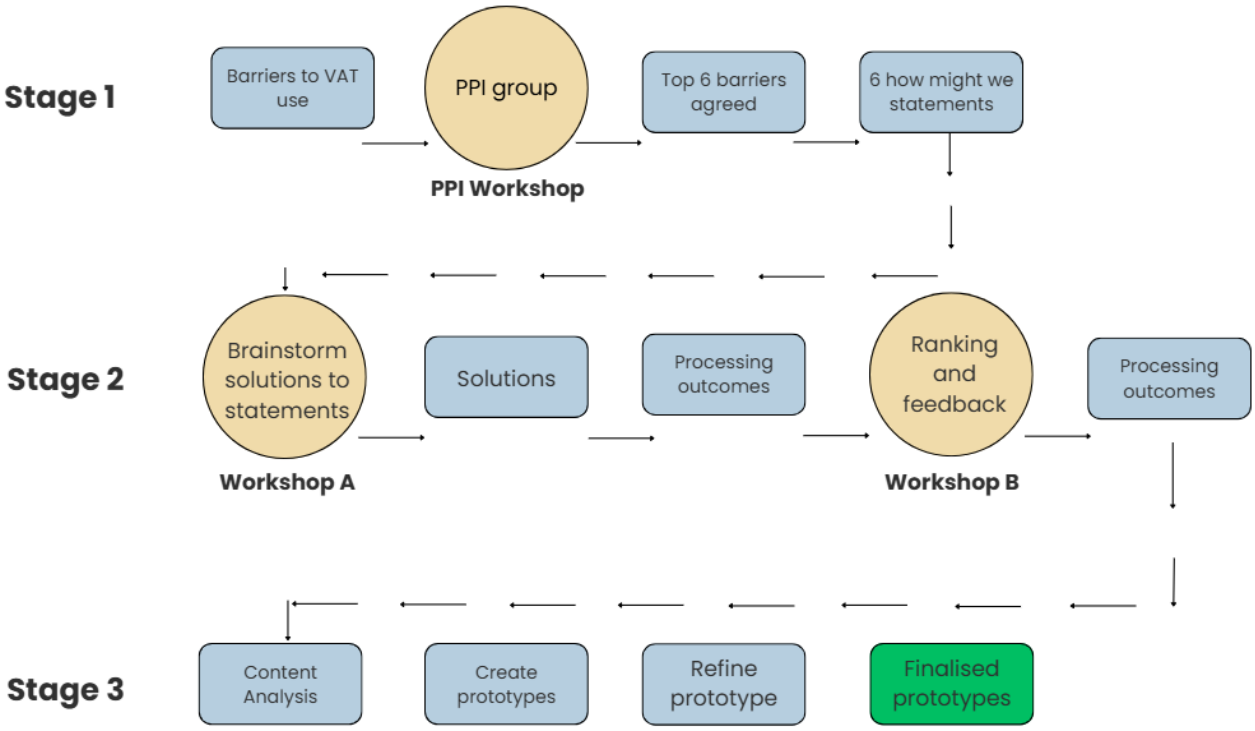
Table 2. Inclusion and exclusion criteria for people with Parkinson's, carers, speech and language therapists, third-sector representatives, and technology or design experts.

Participant group	Inclusion	Exclusion
People with Parkinson's	• Adults over 18 years old • Mild to moderate dysarthria/voice difficulties (to include users of augmentative, alternative communication) • Diagnosis of Parkinson's disease • Current or previous use of VAT[a] • Have access to a laptop, with a camera, that facilitates videoconferencing software	• Moderate or severe cognitive impairment • History of other neurological disorders
Carers	• Adults over 18 years old • Live with or care for a PwPD[c] or both • Experience of facilitating the use of VAT with a PwPD • Have access to a laptop, with a camera, that facilitates videoconferencing software	N/A[b]
Speech and language therapists	• Adults over 18 years old • Who currently have/have had a clinical caseload of PwPD in the past 5 years • Who have used VAT in practice and have basic knowledge of the devices • Have a laptop, with a camera, that facilitates videoconferencing software	N/A
Third-sector staff	• Adults over 18 years old • Currently working in a third-sector organization for PwPD • Involvement and relationships with the local Parkinson's community • Basic knowledge of speech and voice difficulties in Parkinson's disease • Have a laptop, with a camera, that facilitates videoconferencing software	N/A
Technology/design experts	• Adults over 18 years old • Experience of VAT and detailed knowledge of its capabilities or relevant experience in designing or developing health care technologies	N/A

[a]VAT: voice-assisted technology.

[b]N/A: not applicable.

[c]PwPD: people with Parkinson's disease.



Procedure

Overview

Using principles underpinned by Design Thinking and Participatory methodology, a series of 2 co-design workshops were undertaken, informed by insights gained from previous research [30-32]. The 3-stage co-design procedure is outlined below (see Figure 2) and aligns with the define, ideate, and prototype phases of the Design Thinking framework, as presented in Figure 1.

XSL•FO
RenderX

Figure 2. The co-design process from the development of problem statements, through workshop completion, analysis, prototype creation, and refinement. PPI: patient and public involvement; VAT: voice-assisted technology.

Stage 1: Define Phase

Barriers identified by PwPD, their carers, and SaLTs during an earlier stage of the research [9,11] were reviewed by the PPI group, ensuring that the research was shaped by lived experience. Researchers JM and OD were present during the workshop. The group identified and agreed on the top 6 problems to be brought forward to workshop A, and, as per Design Thinking guidance, these were reframed into "How Might We" statements. These "How Might We" statements are used in Design Thinking to help people reframe a problem-focused perspective into solution-focused thinking [33], and previous research highlights the value of shaping research based on lived experience, as this ensures that the problems being solved are meaningful to end users [34]. The final 6 "How Might We" statements are presented in Table 3.

XSL•FO
RenderX

Table 3. Procedures and outcomes for stages 1, 2, and 3 of the co-design process.

Stage	Design Thinking framework stage	Procedure	Outcomes
1	Define	**PPI[a] workshop** • The PPI group was presented with all barriers from previous research [9,11]. • JM shared her screen via videoconferencing, using Canva PowerPoint software to present the barriers identified in previous research and to assist with live decision-making. This acted as contemporaneous notes. OD also took field notes. • PPI group identified 6 top problems—felt to be a reasonable number of barriers to brainstorm solutions to within an hour. • 6 problems reframed into "How Might We" statements.	• The following "How Might We" statements were used in workshop A: • How might we help people understand smart speaker privacy and reduce their fears? • How might we help people when smart speakers do not work? • How might we help people to have a conversation with a smart speaker? • How might we help people to know what smart speakers can do? • How could we deliver this information? • How could smart speaker technology be adapted?
2a	Ideate	**Co-design workshop A** • A document with problem statements and examples of the problems was emailed to the participants before the workshop. • Welcome and introduction PowerPoint, which presented an overview of previous research, problems experienced by people using smart speakers, and an overview of the co-design process. • Two example brainstorming activities completed. • Smaller groups discussed 6 problem statements, rotating after 10 minutes on each problem statement. All groups completed different problems at the same time. • Facilitators shaped discussions and noted contributions on a live Word document. Each problem statement had a separate Word document. • Participants were invited to share solutions to the problem statements around using VAT[b] with a speech or voice difficulty. • Participants were thanked for their time and the workshop ended.	• Solutions to each problem statement were reviewed. Similar solutions for each problem statement were grouped together and combined. No content was removed, while ensuring there was a feasible number of ideas to rank. • Ideas are presented fully in Multimedia Appendix 1, as they appeared during the workshop. • A reduced number of solutions were placed into tables for each group to rank in workshop B.
2b	Ideate	**Co-design workshop B** • Welcome and recap of solutions generated in workshop A. Participants received a document of the solutions ahead of the workshop to aid their preparation. • Each facilitator worked through 3 solutions documents with their group and ranked their top 5 priorities for each solution. • A similar procedure to workshop A was followed: each solution was captured in a separate Word document, and groups rotated after 10 minutes on each problem statement, inputting to the same solution document. • Each participant was asked a short series of questions about their experience of the co-design workshops. Questions were based on the UK standards for public involvement. • Participants were thanked for time, next steps were explained, and the workshop ended.	• Lead researcher (JM) collated solutions and rankings and removed any solutions that were not ranked. • Solutions ranked and their rankings taken forward to stage 3 (prototyping).

XSL•FO
RenderX

Stage	Design Thinking framework stage	Procedure	Outcomes
3	Prototyping	**5 stages of inductive content analysis conducted for solutions and rankings from workshop B** • Initial and final codes were discussed for refinement and agreement with the research team and broadly grouped into themes. • Themes were mapped into 2 prototypes.	• Two prototypes were created, namely, prototype 1 (education and guidance) and prototype 2 (developing new SLTc-specific features for smart speakers). • An overview of the link between workshop 2 outputs and final prototypes is available in Multimedia Appendix 2. • Participant feedback was collated.

[a]PPI: patient and public involvement.

[b]VAT: voice-assisted technology.

[c]SLT: speech and language therapy.

Stage 2: Ideate Phase

Co-design workshops were facilitated by 2 qualified SaLTs (JM and OD), 2 health care professionals (KP and RB), and an academic (GK), with participants working in smaller groups during the workshops. Facilitator guidance and training before the workshops ensured methodological consistency when participants worked within the groups (Multimedia Appendix 3). Co-design principles of valuing lived experience, sharing power, and respect were presented at the beginning of each workshop, aiming to reduce power imbalances between researchers and participants. Both workshops lasted approximately 1 hour and were conducted via videoconferencing to enable data collection across a wider geographical area [35], avoid travel, and facilitate workshops in the evenings.

Data collection was recorded as notes in live Word (Microsoft Corporation) documents. By recording content-only contributions, participant anonymity was ensured from the outset, as no identifiers were associated with the contributions. Although participants may have been known to other group members, they were asked to respect everyone's right to confidentiality by not sharing contributions outside the group setting. Additionally, workshops were not audio- or video-recorded, in keeping with co-design principles. Although this may have contributed to some data loss, the live recording of workshop contributions helped to mitigate this risk.

In workshop A, participants brainstormed solutions to the "How Might We" statements shown above. The process for this workshop is shown in Table 3. Following workshop A, these solutions were refined by combining similar ideas and removing duplicates (Multimedia Appendix 1) in preparation for workshop B. In workshop B, participants reviewed the solutions to the 6 problem statements created during workshop A and were asked to rank the top solutions for each problem statement from 1 (top priority) to 5 (lower priority). Ranking is regarded as a way to prioritize and reach an agreement [36]. To ensure priorities accurately reflected participants' lived experience, each problem statement was ranked by 2 groups; however, this meant that not every group ranked every problem statement. The workshop procedure is outlined in Table 3, and the solutions are presented in the "Results" section. At the conclusion of the workshop, participants were asked by facilitators to provide feedback on their experiences of the co-design process. Following workshop B, the lead researcher (JM) collated the rankings and removed any solutions that were not ranked.

Stage 3: Prototyping

Outcomes from the workshops were analyzed using content analysis and used to create prototypes, in line with the Design Thinking process. Conventional inductive content analysis, following 5 stages, was used to allow categories to emerge directly from the workshop outputs and to reduce the volume of information [37].

The lead researcher (JM) read through the workshop outputs and any associated field notes several times to become immersed in the data. This supported note-making on initial ideas in a reflexive journal, allowing consideration of connections, similarities, and differences within the data. This process also highlighted that participants generally lacked knowledge about smart speakers, were fearful of hackers, and wanted speech-accessible smart speakers. These insights challenged the lead researcher's confirmation bias, encouraging empathy with the experiences of PwPD and allowing the research to be shaped by user needs. This highlighted the importance of creating new features for smart speakers that better meet users' needs, as well as utilizing existing features. Reflexivity also allowed the lead researcher to reflect on her multiple roles as a SaLT, facilitator, and analyst, and the potential for these roles to introduce interpretation bias toward a clinical perspective. As a result, an audit trail was developed to demonstrate the analysis process and enhance trust in decision-making during analysis [38].

Following data immersion, the lead author created a mind map to inductively group ideas and develop initial codes for analysis. Initial codes were shared with OD, KP, and GK for discussion and refinement, enhancing credibility through investigator triangulation and peer debriefing. The final codes were both descriptive (eg, "privacy concern") and interpretative (eg, "need to increase motivation for speech practice"), and the meaning of each code was documented to ensure reliability during coding.

XSL•FO
RenderX

Subsequently, the workshop outputs were coded. This was conducted by hand, using graph paper and colored pens to assign meaning to each output.

Coding was conducted 3 times on separate days by 1 coder (JM) and was presented to the research team for discussion, redrafting, and agreement. It is acknowledged that coding by a single researcher may introduce bias, and, upon reflection, the involvement of 2 coders may have enabled data triangulation and enhanced data credibility. Despite this, peer debriefing helped to minimize potential impacts on the analysis of results. Similar codes were grouped into broader themes to capture meaning across the outputs. This process was also completed by hand, using colored pens to illustrate relationships between codes. Reflexive notes were recorded, discussed with coauthors (OD, KP, and GK), and refined accordingly. Finally, themes were conceptually mapped into 2 prototypes, in keeping with the Design Thinking Framework.

The content analysis process described above, from ranked ideas to the creation of prototypes, is available in Multimedia Appendix 2 as an audit trail, enhancing the credibility of the outputs [39]. All solutions that were ranked in workshop B were included in the prototypes to ensure that the prototypes reflected the wants and needs of participants. Furthermore, direct quotations, where available, from participant feedback are presented to provide a direct voice and to link outputs with interpretations [32]. Findings were sent to all participants for member checking to ensure that the written findings reflected their lived experiences and to enhance the rigor of the research.

Results

Study Participants

A total of 20 participants were recruited; 19 participated in co-design workshop A, and 16 in co-design workshop B. Overall, 15 participants took part in both workshops (Tables 4 and 5).

Table 4. Makeup of breakout rooms in workshop A.

Group number	Number of participants, n	Participants				
		People with Parkinson's disease	Carer	Speech and language therapist	Third sector	Technology/design
1	4	✓	✓	✓	N/A[a]	✓
2	3	✓	✓	✓	N/A	N/A
3	4	✓	✓	✓	✓	N/A
4	4	✓	✓	✓	N/A	✓
5	4	✓	N/A	✓	N/A	✓

[a]N/A: not applicable.

The ranking of solutions aligned with the 6 problem statements is outlined in Multimedia Appendix 4. For problem statements 1, 2, 4, and 6, 3 solutions were ranked by both groups, and 4 solutions were ranked by 1 group. For problem statement 3, 2 solutions were ranked by both groups, and 5 solutions were ranked by 1 group. For problem statement 5, all 4 solutions were ranked by both groups, as only 4 options were presented. Solutions that were not given a rank by any group were removed from the results presented below. The full list of ideas available for ranking during workshop B is provided in Multimedia Appendix 1.

Stage 1: Prototyping Results

Rankings were collated into 2 main prototypes by the primary researcher and agreed upon by the team: (1) educational guidance on the therapeutic use of smart speakers, and (2) developing new SLT-specific features for smart speakers (Multimedia Appendices 5 and 6). These prototypes present the results outlined above, emphasizing cross-cutting themes. Participants' experiences of the co-design process are also presented. The process from solutions to prototypes is fully detailed in Multimedia Appendix 2.

XSL•FO
RenderX

Prototype 1: Education and Guidance

Guides for PwPD and SaLTs, detailing how to use smart speakers to improve volume, intelligibility, and clarity of speech, were unanimously agreed upon by participants. The contents of these guides are described in Multimedia Appendix 5. Participants highlighted a gap in knowledge between the traditionally available features of smart speakers and an understanding of how these features could be repurposed to benefit speech and voice in Parkinson's disease. The suggested skills catalog for therapy would create a repository of standard smart speaker features and skills that could be utilized with therapeutic intent by SaLTs and PwPD. Suggestions included integrating prompts and positive reinforcement by building routines, for example: "Could you speak louder?" or "Well done, great practice today." PwPD felt that verbal prompts to speak louder or clearer, along with positive reinforcement from smart speakers, would replicate cuing provided by SaLTs during direct therapy and motivate home practice.

Participants indicated that routines could be used to practice scripted conversations, and that these should be personalized, include prompts to help sustain conversations, and contain only personal information that users felt comfortable sharing with their smart speaker.

It was evident that not all participants were aware of these accessibility features, which are designed to maximize engagement with smart speakers, and that education in this area may help to encourage more natural conversational reciprocity. For example, the conversation mode available on Amazon Alexa devices.

Participants also indicated that education about privacy relating to smart speaker use was required. It was reported that education for both PwPD and SaLTs would help to alleviate fears regarding personal data storage and General Data Protection Regulation (GDPR) concerns.

Prototype 2: Developing New SLT-Specific Features for Smart Speakers

Participants indicated that an Alexa skill could be created to support speech therapy, as shown in Multimedia Appendix 6. Suggestions included delivering LSVT through a smart speaker or developing a speech therapy game to support speech and voice practice. Participants suggested that this could include increased feedback, such as visual cues on a screen for volume and speech clarity and live transcription of speech that repeats back what was heard, to support self-awareness in PwPD. It is acknowledged that newer Amazon Alexa models, such as the Echo Show 10, already offer subtitling features within the settings, which provide live captioning of speech or video calls.

Additionally, participants were excited about the potential for artificial intelligence (AI) integration within smart speakers and suggested that this could be used to enable more intelligent conversations with the device. Many participants indicated that current smart speakers lacked this capability. Although intelligent conversation has not yet been integrated as a core functionality across Amazon Alexa devices, skills such as ChatGPT were perceived to facilitate live, functional conversation. Furthermore, Alexa Plus, a paid feature for Amazon devices, uses generative AI to remember previous interactions and continue conversations over time. It also offers 5 personalities, which may help users feel as though they are conversing with a person rather than a device. However, Alexa Plus is not yet available in Northern Ireland, where this research was conducted. Additionally, the *follow-up* mode within Alexa accessibility settings prevents users from having to repeat the device wake word, which Amazon suggests supports a more conversational interaction with smart speakers.

Participants also indicated that extended listening time for smart speakers would prevent mid-sentence interruptions. It is acknowledged that Amazon Alexa devices currently offer an *adaptive listening* feature in the accessibility settings, which extends input time and accommodates speech differences. Although a few participants were aware of this feature, they did not indicate its impact on their smart speaker interactions.

Furthermore, enhanced privacy features were suggested. Again, it is understood that, under Alexa privacy settings, voice commands can be enabled to clear Alexa voice history; for example, "Alexa, delete everything I've ever said." Additionally, although Alexa cannot be trained to respond only to certain voices, there is an option to set up a voice profile to receive more personalized content and prevent unauthorized voice purchases.

Although participants acknowledged that adapting smart speakers to better recognize dysarthric speech could hamper their therapeutic value, they felt that this would improve accessibility for the devices more generally. They sought devices that could gradually learn their speech patterns over time, as well as deal effectively with regional accents. Notably, there is currently no research exploring the impact of improved speech recognition in smart speakers on therapy outcomes in SLT.

In addition to ranking solutions, participants were asked about their experience of co-design using questions based on the UK standards for public involvement. Overall, participants valued the online workshop format, which facilitated engagement for those with limited mobility. They felt the workshops were informal yet professional and found the tasks interesting, positively challenging them to think of solutions. Small groups were reportedly the right size for supported discussions, and participants felt this was an effective way to gather substantial information. Participants discussed their expectations and involvement in co-design, describing feeling included and respected:

> *I had some experience of delivering co-design, so I had an idea of how it should be done...I felt valued, and felt everyone has been really equally valued, no matter how you're coming at it; person with Parkinson's, speech therapist, whatever. We've all been treated equally, with respect.* [Person from Parkinson's UK]

> *I felt heard and respected throughout and you did a good job of facilitating conversations for us to feel heard.* [SaLT]

> *The carer and patient are heard. So often in NHS setting they are the last ones to be heard y'know, what*

XSL•FO
RenderX

> *would they know. But here, they were put front and centre.* [Carer]

Participants also felt that the right people were involved in the co-design process and that there was a good balance between perspectives:

> *It's involved so many stakeholders that come from that same place of making improvements for people living with Parkinson's. It was great to see various individuals are spoken to and included.* [PwPD]

> *There was a really good balance of people from different backgrounds...It absolutely worked and its so important to get everyone's view; it's mostly important to hear people with Parkinson's, carers you work alongside. You get a really holistic picture of what is the most important thing from different perspectives.* [SaLT]

> *It was useful to be able to discuss together in a group and helpful to consider all views: SaLTs, patients and tech experts.* [PwPD]

Participants provided feedback on engagement challenges and future improvements. Some PwPD or carers felt that a bridging workshop between creating and ranking solutions would be helpful. This could have included a session to discuss all brainstormed solutions and integrate them with real-world examples. Although elements of this were included in the workshops, they felt that a third workshop would have given them time to digest the large number of solutions and some more complex ideas before ranking them. One clinician who was unable to attend the first brainstorming workshop felt that this would have helped orient her more fully before the ranking task. Others suggested that color grouping or collapsing solutions for each problem statement by themes may have made it easier to rank statements. Participants also indicated that more prompts were required to remind them to think creatively and that "anything was possible."

Participants also discussed the project's focus on smart speakers, as well as their advantages and disadvantages. A few participants felt that it would be easier to create an app, as many are available for smartphones, and most people use these devices. However, most participants felt that the voice interaction of smart speakers offered advantages over smartphones, particularly for people with a tremor. Additionally, participants felt that smart speakers could remind and motivate users to practice, whereas with an app, users often have to self-motivate or remind themselves.

Discussion

Principal Findings

This study aimed to co-produce solutions to support smart speaker use for speech and voice difficulties and to inform a future intervention. PwPD, carers, SaLTs, Parkinson's UK staff, and technology and design experts collaborated during 2 online co-design workshops to brainstorm and prioritize solutions to problems identified in prior research [9,11]. Two prototypes were developed: (1) education and guidance on the therapeutic use of smart speakers and (2) the development of new speech therapy–specific features for smart speakers. By incorporating collaborators' priorities and needs, the study offers a foundation for a future smart speaker–based intervention for speech and voice therapy in PwPD.

Impact of Co-Design

This project recognizes the need to involve end users early and meaningfully when designing health care interventions [40,41], contributing to the quality and relevance of co-designed outcomes [42]. This aligns with the Design Thinking framework, specifically the ideate and prototyping phases. While co-production with people with aphasia is increasing, there is limited evidence on co-design in SLT, especially for motor speech disorders [21,32,43]. Therefore, this research continues to contribute to and develop the evidence base regarding co-design in SLT, particularly for people with dysarthria. This study is unique, as it is believed to be the first co-design study with PwPD who have speech and voice difficulties that co-designs solutions to problems experienced when using commercial VAT technology.

Participants described personal benefits of co-design, including gaining knowledge, social interaction, and feeling heard and validated, echoing previous co-production findings [32,44] and aligning with public involvement standards [45]. These benefits are particularly relevant for PwPD, who often experience reduced participation due to speech and voice issues [46], highlighting how co-design can empower participants. Power sharing and partnership can enhance engagement and lead to more patient-centered outcomes [47], and involving SaLTs may also improve future implementation of such tools into clinical practice [48]. In wider co-design research in SLT, participants with communication difficulties report improved confidence, motivation, and sense of well-being [27], and their involvement can lead to more and better-quality outcomes [43]. Overall, this demonstrates how co-production can allow participants, such as PwPD, to feel in control, empowered, and validated. For PwPD, this co-design study both physically and metaphorically provided them with a voice, building on current evidence. Despite this, wider research also acknowledges that relinquishing power in research can be challenging for researchers, requiring an active effort to make the co-design process truly collaborative [18].

Additionally, collaborator feedback highlighted the importance of skilled facilitation in enabling communication during workshops. Although evidence on co-design facilitation strategies for people with speech and voice difficulties is limited, facilitators used clinical experience and evidence-based strategies [32] to support PwPD. These included allowing preparation time before workshops, building rapport, giving extra time to speak, screen-sharing key points, regularly checking understanding, and summarizing discussions [43,49,50]. Such approaches are crucial for inclusive and accessible co-design. Some collaborators suggested improvements, such as offering more workshops and using multimedia formats to make tasks easier, which extends the evidence base on co-design with PwPD who have speech and voice difficulties. This balance of positive experiences and suggested improvements reflects the range of participants, lived experiences, and heterogeneous needs. Advantages and

XSL•FO
RenderX

disadvantages of co-design methods should be evaluated from a range of perspectives to achieve a balance between the needs of a diverse group of PwPD.

Participants indicated that training for SaLTs in the therapeutic use of smart speakers for speech and voice difficulties was a priority. Wider research supports this finding, showing that education and guidance are required to support therapeutic adoption by SaLTs and PwPD [4,9-11], and that digital health interventions for older adults should include education in effective device use, digital literacy skills, and technical support throughout [51,52]. Tailored education and guidance may contribute to PwPD and SaLTs successfully adopting and using smart speakers to support speech and voice difficulties. As such, this study begins to advance understanding of how to support VAT adoption into clinical SLT practice. While smart speaker features make them valuable tools for chronic health management among older adults [53,54], older people in particular can struggle to comprehend the full range of smart speaker functions [11,54].

Guidance should clearly link device features to SLT goals to promote understanding and demonstrate how devices can help people achieve their SLT practice and related goals [55,56]. This may positively impact digital literacy for PwPD, supporting device adoption and regular use [56], again contributing to advances in knowledge regarding the clinical adoption of VAT. Similarly, SaLTs in our earlier research made several content suggestions for guidance to empower them to use VAT [9], including sample therapy plans, scripts, goal-setting frameworks, and evidence-based practice. However, this is the first study to collate these elements into an education and guidance prototype for SaLTs. Simplified guidance is particularly important, as clinicians often discontinue technologies they perceive as overly complex for clients [57]. Similar requirements for implementation guidance have been reported in SLT research using commercial technologies, such as virtual reality (VR) [19,58,59]. These studies highlight that therapeutic usage guides should promote the ease of use and usefulness of commercial technologies to support clinical adoption and provide opportunities to trial the devices. However, it is important to note that although commercial VR technology was used, the VR program itself was specifically created by researchers. This suggests that guidance must explain how smart speakers' out-of-the-box "Alexa skills" are relevant to SLT, given that the commercial use of the technology is not intended to be therapeutic. Unlike custom VR programs, smart speakers are off-the-shelf products not originally designed for health care. Therefore, guidance must explicitly link commercial features to therapeutic aims and support clinicians in adapting features to individual client needs, ultimately contributing to the adoption of VAT into clinical practice.

Furthermore, privacy and data protection are significant barriers to the adoption of smart speakers [60]. Common concerns include the recording of conversations and data misuse, which can deter both clinicians and clients [51,61-63]. To address this, usage guides for PwPD should include clear, accessible privacy information, support informed consent, and clearly explain how devices handle user data [64]. Given SaLTs' responsibility for safeguarding client data, guidance should map VAT's GDPR compliance and potential risks to SLT governance policies, such as Data Protection Impact Assessments. This study, therefore, begins to answer questions posed by previous research [10] regarding how VAT may be implemented in accordance with clinical governance requirements. Previous findings highlight that many SaLTs lack clarity on which technologies meet governance and GDPR standards [57]. Reassuring both clinicians and PwPD about privacy may improve confidence and facilitate adoption [65]. Future evaluation of guidance acceptability and usability could apply frameworks such as the Technology Acceptance Model or Unified Theory of Acceptance and Use of Technology 2.

Delivery

Participants suggested delivering training through Royal College of Speech and Language Therapy–led webinars, live demonstrations, and group sessions led by trained SaLTs. While previous research has not identified optimal delivery formats [4,10], this study provides new insights into practical implementation and contributes to the evidence base regarding the therapeutic use of VAT in SLT clinical practice. The literature indicates that older adults often prefer hands-on, task-based learning supported by written instructions [66,67]. A training program using VAT as a tool for activities of daily living with adults with cognitive communication disorders indicated a need for written, easy-to-follow instructions, with hands-on support to overcome low technological literacy [67]. Group-based workshops can offer a supportive, low-pressure environment for exploration and skill-building with in-person support [52]. This is particularly important for users with limited experience or confidence in digital tools.

Findings indicate that SaLTs are central to introducing and supporting smart speaker use in therapy. When clinicians demonstrate relevance and ease of use, PwPD may be more likely to adopt the technology [67]. By increasing perceived usefulness and reducing concerns, training can enhance performance expectancy and digital engagement. Additionally, previous research on integrating commercial technologies in SLT has highlighted the importance of multifaceted training approaches, including device trials, workshops, clinical manuals, and information technology support [58,68]. Additional methods, such as guided observation and co-delivered interventions, may be necessary to bridge the gap between knowledge and practice [58,69]. As such, this study begins to address gaps in knowledge regarding the implementation of VAT as a therapeutic tool for speech and voice difficulties associated with Parkinson's disease.

Participants highlighted the need to develop SLT-specific features for smart speakers, designed for therapeutic use. For example, Cassano et al [70] described a SaLT building a custom skill. At the time of publication, at least three speech therapy Alexa skills existed: Speech Therapy Practice, Speech Device Practice, and Let's Talk. Additionally, 2 further speech therapy skills were identified but are no longer publicly available on the Amazon Skills store: Speech Doctor, as discussed by Makin et al [71], and Speech Therapy by Cathal Killeen. Notably, Speech Therapy Practice is a live Alexa skill developed by a SaLT that enables people with aphasia to practice very basic

XSL•FO
RenderX

words and phrases, such as colors, opposites, who/what questions, and yes/no questions. While this may potentially act as a starting point for SaLTs, the skill lacks applicability to practicing phrases and sentences and, in its current state, is unlikely to meet the speech practice needs of PwPD. To date, there are no specific Alexa skills for adults with Parkinson's or targeting dysarthria, and our research highlights the potential for future development. Future research may seek to work with developers to create an Alexa skill for this population that can be used to support home practice of speech therapy exercises. Features may include prompts for loud, clear speech; increased feedback on volume and intelligibility with suggestions for improvement; the ability to monitor progress; visual displays and biofeedback; reminders to complete therapy tasks; and LSVT-style exercises with gamification [9,11]. Such features align with wider studies integrating technology into SLT and related areas, including apps using Google Glass [72], smart speaker–based physical activity interventions [73,74], and social engagement tools for people with disabilities [75]. Development platforms like Alexa Skills Kit and Alexa Blueprint may offer scalable, cost-effective options, enabling a focus on increasing motivation, engagement, and potential adherence to intervention programs. A curated hub of Alexa skills that can be used for SLT goals may also support clinical implementation. For example, Esquivel et al [76] developed a repository of Alexa skills and recommendations for people with disabilities, by people with disabilities. Future research may explore the acceptability of a speech therapy–specific Alexa skill and its implementation within clinical practice.

Given the commercial nature of smart speakers, it may be beneficial to first assess their current therapeutic value before creating bespoke skills. As our study focused on co-design processes and did not include a formal evaluation of intervention usability, effectiveness, or acceptability, future research may consider testing the current prototypes to determine real-world clinical impact and user outcomes. This study establishes the rationale for a future feasibility study to examine the effectiveness of VAT as a therapeutic tool for speech and voice difficulties in Parkinson's disease. At the time of writing, no studies have been conducted in this area using commercial VAT. Emerging SLT research shows benefits for speech clarity in populations with intellectual disabilities and speech sound disorders [5,71], citing immediate rewards, spaced practice, enhanced autonomy, intrinsic motivation, and reduced social barriers as mechanisms of change in speech. However, these interventions do not follow established SLT intervention protocols [5,71]. Therefore, future studies should evaluate the effectiveness and usability of smart speakers for PwPD using principles of neuroplasticity and motor learning from SLT protocols, such as LSVT LOUD or Speak Out!

Despite this, the challenges surrounding the therapeutic use of smart speakers cannot be ignored. Smart speakers rely on evolving ASR models, a type of AI, which are continually being improved. ASR models can change without warning, presenting a risk to the reliability of baseline measurements and the measurement of therapy goals [77]. Furthermore, ASR errors are often higher than expected for dysarthric speech, speakers of minority languages, and those with regional accents [78-80]. Without clear and specific feedback on device or speech errors, both PwPD and SaLTs are left without information about where the "error" lies, whether it is speech- or device-related. These risks may reinforce maladaptive speech behaviors if speech practice is based on inconsistent or misleading responses from the device. It may also damage client motivation and confidence, with PwPD blaming themselves for technological errors. Research demonstrates that speakers can attribute ASR errors to themselves and link this to their sense of identity, including racial, regional, and locational identity [77]. To mitigate this lack of transparency, it is essential that SaLTs educate potential VAT users on strategies for adapting speech, managing frustration, and correctly interpreting VAT errors, as well as raising awareness of the limited ASR training on dysarthric speech and some minority or foreign languages [9,11]. This highlights the importance of a therapeutic usage manual for smart speakers for people with speech and voice difficulties and for SaLTs, as indicated in the current findings.

However, it should be noted that projects such as Voiceitt, Google Euphonia, and Project Relate aim to improve ASR accuracy in recognizing dysarthric speech, and Accessible Voice Interaction Technology for Aphasia (AVITA) aims to improve the accessibility of smart speakers [81], which may have the unintended consequence of limiting certain therapeutic applications of smart speakers in SLT. When smart speaker recognition is improved, speech difficulties no longer affect recognition, meaning all speech is easily recognized. This can be problematic, as speech that may not be intelligible in real life is recognized by devices. Consequently, this hampers therapeutic applications, because positive biofeedback provided by smart speakers does not reflect the speaker's intelligibility to unfamiliar listeners in everyday contexts. Indeed, participants in this research indicated that future adaptations of smart speakers, outside of therapeutic contexts, should aim to better recognize dysarthric speech and regional accents. Future smart speaker designs may bridge the gap between standard out-of-the-box devices and fully customized skills. For example, smart speakers could allow users to set recognition thresholds, enabling both increased accessibility for users and therapeutic usage for clinicians. Given the rapid pace of innovation, continued review of emerging literature and technologies is recommended throughout the development and implementation stages.

Limitations

This co-design study offered valuable insights into developing VAT tools for PwPD with speech and voice difficulties; however, limitations are evident.

Participants suggested an additional workshop between the ideation and prioritization phases, that is, between workshops A and B. A bridging session could have allowed more reflection and improved understanding, potentially leading to rankings that more accurately reflected lived experience. Furthermore, although recruitment was successful, there was some participant dropout between workshops A and B. This necessitated merging groups in workshop B, which may have influenced group dynamics and limited continuity of discussion.

XSL•FO
RenderX

Despite efforts to recruit a diverse group, the sample was small (n=20), and certain perspectives, such as those of people with advanced Parkinson's or severe dysarthria, were underrepresented. This may limit the generalizability of the findings.

Finally, given the rapidly evolving technology landscape in AI and ASR, some recommendations may become outdated by the time of implementation. This includes changes in smart speaker capabilities, privacy policies, and integration with large language models (eg, AI conversational agents).

Conclusions

This study highlights the value of co-designing smart speaker interventions with PwPD, carers, SaLTs, third sector representatives and technology and design experts to address challenges in using VAT for speech therapy. Using a participatory Design Thinking approach, user-centered solutions were generated to improve the accessibility, usability, and therapeutic potential of smart speakers.

Two prototypes were developed: (1) education and guidance for PwPD and SaLTs, and (2) speech therapy–specific smart speaker features.

The outputs balance commercial technology with clinical needs, focusing on privacy, troubleshooting, and feedback for home use, while reinforcing co-design as a powerful method for developing digital health tools. Co-design also ensured that interventions reflected lived experience and clinical insight, enhancing the likelihood of adoption and sustained use. This research strengthens the evidence for co-design in SLT and supports smart speakers as tools to enhance therapy access, promote self-management, and reduce pressure on SLT services. Future work should develop and evaluate these prototypes to assess their real-world impact and scalability.

Acknowledgments

We thank Rory Bradley for his contributions to the co-design workshops in this research. The authors would also like to thank Donna McGuckin, Emmet Leyden, and Dr Marc Parker for their contribution to this research as members of the patient and public involvement (PPI) group.

Abstract

Background: Youth with persisting symptoms after concussion (PSaC) can experience ongoing physical, cognitive, and emotional challenges, and their caregivers experience increased stress. There are currently limited interventions that support youth with PSaC or their caregivers. *Move&Connect* is a virtual group program with 2 parallel interventions: *Move&Connect-Youth* (*M&C-Y*) and *Move&Connect-Caregivers* (*M&C-C*). *M&C-Y* includes concussion education, active rehabilitation, and goal setting. *M&C-C* uses psychoeducation and practical tools to promote family communication and problem solving.

Objective: Within the context of a broader pilot study of *M&C-Y* and *M&C-C*, we completed a fidelity and engagement evaluation with the objectives of (1) evaluating intervention fidelity and (2) exploring facilitators and barriers to youth and caregiver engagement.

Methods: *M&C-Y* and *M&C-C* were delivered virtually using Zoom Healthcare and ran in parallel. Youth with PSaC and caregivers were recruited from a children's rehabilitation hospital in Ontario, Canada. Intervention fidelity was evaluated according to the 5 principles of fidelity from Bellg et al: design, training, delivery, receipt, and enactment. Intervention delivery, attendance, and engagement ratings were monitored through weekly logs and field notes. Participants completed exit satisfaction surveys, and a subset of youth and caregivers completed semistructured interviews to understand facilitators and barriers to engagement. Descriptive statistics were used to analyze logs and surveys. Directed content analysis, guided by a motivational framework, and inductive coding to identify barriers and facilitators to engagement were applied to qualitative data.

Results: A total of 34 youth (age: mean 15.1, SD 2.28 years) and 36 caregivers (age: mean 48.9, SD 5.92 years) participated in 10 *M&C-Y* and 9 *M&C-C* groups, respectively. Most youth identified as girls (24/34, 71%), and most caregivers identified as mothers (30/36, 83%). Clinician facilitators adhered to the components of the intervention protocols between 92% and 97% of the time in *M&C-Y* and 82% and 93% of the time in *M&C-C*. The majority of youth (22/34, 65%) and caregivers (24/36, 67%) attended 5 or more sessions. In addition, 82% (28/34) of youth and 94% (34/36) of caregivers agreed they would recommend the interventions to others. Qualitative findings revealed youth engagement was supported by motivation, comfort in the virtual setting, interactive intervention components, feelings of trust, and diverse and modifiable exercises. Barriers to youth engagement included ongoing symptoms, discrepancies between exercises and physical abilities, and previous knowledge of education. Caregiver engagement was facilitated by perceived benefits of *M&C-C*, emotional connection and validation, and comfort and

XSL•FO
RenderX

convenience of the virtual setting. Barriers to caregiver engagement included stress, competing scheduling demands, and limited reminders or access to intervention materials.

Conclusions: The pilot study of *M&C-Y* and *M&C-C* was conducted with high delivery adherence. Exit satisfaction surveys combined with qualitative data revealed high levels of caregiver satisfaction and engagement, whereas youth satisfaction and engagement had some variability, particularly related to the exercise. Findings demonstrate important implications for delivering virtual group interventions for youth with PSaC and their caregivers.

Introduction

Background

After a concussion, youth can experience an array of physical, cognitive, and emotional and behavioral symptoms [1]. Although most youth recover relatively quickly from concussion, up to 30% continue to experience persisting symptoms after concussion (PSaC) for months or even years [2,3]. PSaC can negatively impact youths' quality of life [4,5] and lead to ongoing mental health challenges [6,7]. Youth with PSaC also experience feelings of isolation and a lack of social support and understanding from peers [8].

An interdisciplinary approach is recommended to support youth with PSaC [9,10], and active rehabilitation (ie, subthreshold aerobic exercise, coordination exercises) [11] and psychoeducation are considered standard best practices in the treatment of PSaC [12]. Active rehabilitation has been shown to reduce symptoms and improve mental health outcomes in youth with PSaC [13-16]. Psychoeducational intervention about recovery expectations and treatment recommendations is important for youth with PSaC and their caregivers [17,18]. In addition to these approaches, emerging research has explored the feasibility and impact of providing concussion care in a virtual model [19-21] and virtual active rehabilitation to youth with PSaC [22-25]. These virtual approaches are safe and tolerable for youth with PSaC and provide comfort and convenience for families [19,21-23,26].

Caregivers play a critical role in managing their child's PSaC and describe burden [27] and elevated stress regarding their child's recovery [28]. Caregiver and family functioning may have an important bidirectional association with PSaC after pediatric concussion [29]. Providing caregivers with psychoeducation and therapeutic support can help to navigate challenges after concussion [30]. Caregivers report a need for clear and reliable information about concussion recovery [31], and caregiver education on concussion signs and symptoms has been linked to reduced recurrence rates [32]. Despite this, there is a dearth of interventions tailored to caregivers of youth with PSaC and a clear need to develop support that targets caregivers' well-being during concussion recovery [33,34].

Move&Connect

The *Move&Connect* program was designed to support youth with PSaC and their caregivers and consists of 2 parallel intervention arms: *Move&Connect-Youth* (*M&C-Y*: for youth with PSaC) and *Move&Connect-Caregivers* (*M&C-C*: for caregivers of youth with PSaC). *M&C-Y* and *M&C-C* are 6-week virtual group interventions with 1-hour sessions that were developed using the intervention mapping framework [35] and codesigned with youth, caregivers, and clinicians. The detailed design and development processes of these interventions are described elsewhere [36,37].

Delivering rehabilitation interventions such as *M&C-Y* and *M&C-C* via virtual platforms (eg, Zoom Healthcare) can enhance access to services, support participation, and promote continuity of care [38,39]. The virtual group model in *Move&Connect* is particularly appropriate for youth with PSaC and their caregivers due to geographic inequities accessing specialized concussion care [40-42], family burden navigating appointments [43,44], and engagement of individuals who may become symptomatic with travel or in-person appointments [42]. The *Move&Connect* program differs from existing virtual concussion and group rehabilitation programs [25,45-48] due to the parallel youth and caregiver intervention design, theory driven development, and interdisciplinary delivery.

M&C-Y is guided by the biopsychosocial model [49] and includes psychoeducation, active rehabilitation, and goal-setting. Each week, the intervention begins with an ice breaker followed by an education or discussion topic (eg, headache management, managing stress, advocacy). Youth then complete exercises (ie, cardiovascular, balance, coordination, strength) with the goal of improving their confidence and tolerance to different physical demands. All exercises are designed to be completed at home with no equipment required. In-session music during exercise and weekly polls are used to engage participants. At the end of the session, youth set a weekly goal, often related to the psychoeducation topic or exercise, which is reviewed and discussed in a solution-focused manner [50] the following week [36].

M&C-C is guided by the family-directed approach to brain injury (FAB) model [51] and includes psychoeducation and active skill development to promote family communication and problem-solving. Psychoeducation, discussion, and activities are completed as a group and are related to weekly themes: the ripple effect, school advocacy, considering your child's well-being, family and you, stress and daily challenges, and parenting is hard. Weekly take-home reflection activities are

XSL•FO
RenderX

introduced at the end of each session, and caregivers share their insights during the group discussion the following week [37].

Initial testing of *M&C-Y* [36] (n=10) and *M&C-C* [37] (n=9) revealed that the interventions were feasible based on the key domain areas (recruitment, acceptability, and evaluation of participant responses) from Orsmond and Cohn [52] and our a priori criteria. Youth indicated that *M&C-Y* was enjoyable and they were able to form meaningful peer connections [36]. Caregivers indicated that *M&C-C* was a safe space to share personal experiences and they valued receiving advice from facilitators and their peers [37].

Intervention Fidelity and Engagement

Following establishment of feasibility, it is important to consider intervention fidelity, which is the ongoing assessment, monitoring, and enactment of the reliability and internal validity of a study [53]. Intervention or treatment fidelity (herein referred to as intervention fidelity) is a critical part of intervention research as it increases confidence that changes in the study outcome of interest (dependent variable) are due to the intervention (independent variable) [54]. A rigorous fidelity plan should include study design, training, and quality and consistency of delivery [54,55]. Importantly, recent studies have emphasized moving beyond only assessing intervention delivery to including a greater focus on the understanding of participants' receipt and enactment (collectively called engagement) of intervention activities [53,56,57]. Understanding intervention engagement is especially important as it is multifaceted and may be influenced by numerous contextual factors [57] (eg, virtual delivery, group setting, multiple intervention components). Engagement has previously been described by King and colleagues [58] as the affective (expecting positive outcomes), cognitive (believing that therapy will be effective), and behavioral (actively participating in therapy tasks) involvement or investment in a therapy session [58]. Using engagement-promoting strategies is recommended to improve adherence to interventions [59-62]. Additionally, family members being actively engaged in their child's rehabilitation journey is associated with better outcomes [63]. Thus, exploring intervention fidelity and participant engagement are vital steps in delivering an intervention study.

Objectives

Based on the aforementioned promising feasibility findings, we conducted a pilot study of *M&C-Y* and *M&C-C*. Within the context of the broader pilot study, the goal of this paper was to (1) evaluate intervention fidelity and (2) explore facilitators and barriers to youth and caregiver engagement.

Methods

Study Design

This paper describes a multimethod fidelity and engagement evaluation of *M&C-Y* and *M&C-C*. Between November 2022 and June 2025, 10 *M&C-Y* and 9 *M&C-C* groups were delivered. Group interventions were delivered virtually using Zoom Healthcare. Two trained clinician facilitators delivered each *M&C-Y* (occupational therapists and/or physiotherapists) and *M&C-C* (neuropsychologist, neuropsychology trainee, and/or social worker) session. A research staff observer attended all *M&C-Y* and *M&C-C* sessions to record observations and support any technological challenges. Youth were allocated to groups by age/grade, when possible (ie, elementary and high school), to account for developmental differences. Caregivers were also allocated to groups for those with elementary or high school–aged children. Participants were provided with weekly reminder emails of upcoming sessions including any supplies and weekly handouts or materials in advance of each session.

To ensure safety and personalization during *M&C-Y*, modifications to make each exercise more or less challenging were provided, breaks were encouraged, and clinicians monitored participant symptom changes. Consistent with concussion best practice guidelines [12], if youth experienced >2-point change in their symptoms on a symptom severity scale ranging from 0 to 10, they were instructed to stop the activity until their symptoms had returned to their baseline level. Virtual breakout rooms were utilized for 1-on-1 conversations regarding symptom monitoring. Reminders about participant privacy and group confidentiality were provided at the beginning of each session. The study's principal investigator randomly audited intervention sessions. No adverse events occurred during the study.

Youth and caregiver participants also completed outcome measures before (T_0), immediately following (T_1), and 3 months following (T_2) intervention completion. Clinical outcome results will be described in subsequent publications, as the primary contribution of this paper is the evaluation of intervention fidelity and engagement. Intervention fidelity evaluation involved data collected during intervention delivery and at the T_1 follow-up. Engagement evaluation involved optional youth and caregiver exit interviews completed at T_1. The qualitative components of the study follow guidelines outlined in the Consolidated Criteria for Reporting Qualitative Studies (COREQ) checklist [64] (see Checklist 1).

Recruitment and Eligibility Criteria

Youth were included if they were between the ages of 8 years and 21 years, had a diagnosis of concussion, and had been experiencing PSaC for >4 weeks at intervention onset. Youth were excluded if they had a physical condition that would impact participation (eg, requiring a mobility device), a disorder of social cognition or communication (eg, intellectual disability, autism spectrum disorder), a functional neurological disorder (eg, conversion disorder, somatization), or an acute psychiatric condition that resulted in a recent hospital admission. Given the pilot nature of the study, youth with these conditions were excluded as they may have unique support and safety needs. Caregivers were included if they had a child (aged 8 - 21 years) who was diagnosed with a concussion and had been experiencing PSaC for >4 weeks at intervention onset. Youth and caregivers had to be able to read and understand English, be willing to engage in weekly sessions, and have access to a reliable internet connection. Youth and caregivers could enroll as a dyad (ie, both youth and caregiver enroll) or independently (ie, youth could enroll without caregiver; caregiver could enroll without youth). Recruitment predominantly occurred via convenience sampling through concussion services at Holland

XSL•FO
RenderX

Bloorview Kids Rehabilitation Hospital (HBKRH) [10], but community participants were also eligible.

Ethical Considerations

Ethics approval was obtained from HBKRH (REB #0513). All procedures complied with the ethical principles outlined in the Declaration of Helsinki. Youth and caregivers were informed that their decision to participate in the study would not affect the care that they received at HBKRH. A capacity assessment (ie, a formal assessment of decision-making capacity) [65] was performed for all youth participants, and all participants (youth and caregivers) provided informed written consent.

Study Measures

Intervention Fidelity Assessment

This pilot study used the framework by Bellg et al [55] for assessing the fidelity of the *M&C-Y* and *M&C-C* interventions, which describes 5 key domains to ensure optimal intervention fidelity: (1) intervention design, (2) provider training, (3) intervention delivery, (4) intervention receipt, and (5) intervention enactment. Rather than define strict a priori fidelity thresholds, we used triangulation to evaluate intervention delivery, receipt, and enactment. Multiple data sources and approaches were used for each domain to allow for triangulation and reduction of potential bias [57] (Table 1).

Table . Intervention fidelity components and assessment approaches. Table adapted from Ginsburg and colleagues [57].

Intervention fidelity component [55]	Our approach to fidelity assessment
Fidelity of design	
Intervention is defined and operationalized consistent with its underlying theory	• Intervention approach and components designed with incorporation of underlying theory; see Scratch et al [36] and Al-Hakeem et al [37] for details
Fidelity of training	
Clinician facilitator training	• Research and institutional orientation • Clinicians provided with intervention manuals and materials • Train-the-trainer approach including session shadowing and discipline specific peer debriefing • Feedback provided by trainees to inform train-the-trainer approach
Fidelity of delivery	
Adherence to protocol (components, timing) and consistent delivery	• Clinician delivery checklist completed after each session • Debriefing after each session with clinicians and research staff observer • Bi-weekly research team meetings • Clinician consultation with study principal investigator, as needed
Fidelity of receipt	
Participants understood/can use intervention components	• Participant attendance tracking • Research staff observer field notes
Fidelity of enactment	
Engagement in Move&Connect activities	• Participant engagement rating • Exit satisfaction survey • Research staff observer field notes • Semistructured interviews[a]

[a]Used in objective 2 to further explore barriers and facilitators to engagement.

Intervention Fidelity Tools

All fidelity tools, with the exception of the semistructured interviews, were captured using REDcap [66].

Clinician Delivery Checklist

To monitor adherence to the components and timing of the intervention delivery, 2 clinician facilitators completed the clinician delivery checklist weekly after each session. The *M&C-Y* clinician delivery checklist asked if the education, exercise, and goal setting components of the program were delivered as intended (3 yes/no questions). The *M&C-C* clinician delivery checklist asked if the education, activity, and take-home reflections were delivered as intended (3 yes/no questions). An open-ended text box allowed clinicians to explain any deviations from intervention delivery or additional contextual information.

Attendance Tracking Log

Youth and caregiver attendance for each session was monitored in an attendance tracking log completed by the research staff observer. The attendance tracking log contained information regarding session number (1-6), attendance (yes/no), and if a participant was late for the session (yes/no). An open-ended text box allowed for any additional contextual information related to attendance (eg, if a participant emailed that they were unable to attend).

XSL•FO
RenderX

Research Staff Observer Field Notes

A structured field note template was used by the research staff observer in all *M&C-Y* and *M&C-C* sessions to capture behavioral observations, participant goals, and any feedback on the intervention provided by participants throughout the sessions.

Participant Engagement Rating

The research staff observer completed the participant engagement rating for each participant that attended each *M&C-Y* and *M&C-C* session. The participant engagement rating was developed by the research team to provide an exploratory measure of participation and engagement and was based on insights and observations from initial feasibility testing [36]. The 1 - 3 rating asked, "how would you rate the participant's overall engagement and participation during this session?" For *M&C-Y*: 1-Fair (Participant demonstrated reduced engagement; did not share thoughts, experiences, or goals without considerable prompting; and did not engage or attempt exercises.), 2-Good (Participant was engaged for the duration of the session; shared their thoughts, experiences, and goals with prompting; and participated in the exercise activities.), or 3-Excellent (Participant was engaged during the session and shared their thoughts, experiences, and goals in detail with minimal prompting and completed and engaged with exercises.). For *M&C-C*, the same 3-point rating structure was used, with the omission of the exercise component. An average engagement score was calculated for each participant (sum of scores/number of sessions attended) and at the group level (sum of participant scores/number of participants in the group). The *M&C-Y* and *M&C-C* groups were observed by 3 different research staff members. The primary study coordinator (AL) conducted 1-on-1 observer training on the participant engagement rating, incorporating didactic instruction and case review from the initial feasibility study [36,37]. Questions or uncertainties from alternate observers were discussed with the main study coordinator (AL).

Exit Satisfaction Survey

Youth and caregivers were invited to complete an exit satisfaction survey after the interventions were complete (T_1). The survey asked about satisfaction with intervention components, the group setting, group size and timing, clinician facilitators, and future intent to implement strategies (5-point Likert scale; youth: 20 items; caregivers: 17 items). It also included 3 open-ended questions about the structure and delivery of the intervention, the best feature of the intervention, and what participants would like to see changed or improved.

Semistructured Interviews

Youth and caregivers had the opportunity to participate in an optional semistructured interview after the interventions were complete (T_1) to better understand participants' experiences with the interventions. All youth and caregivers who participated in the interventions were invited to participate in the interview through email. Toward the end of recruitment, the team focused on inviting families from underrepresented backgrounds, including fathers, boys, and participants from diverse ethnic backgrounds. Consistent with the concept of information power, sample adequacy was considered in relation to the study aims and the range of participant perspectives represented in the qualitative sample [67]. Interviews were completed virtually using Zoom Healthcare by a member of the research team who did not facilitate the intervention. Interviews were audio-recorded, transcribed verbatim, and checked for accuracy. Of note, the quotes presented in this paper were lightly edited to remove dysfluencies (eg, um) and repeated words for clarity and conciseness [68] and were labeled using data codes. See Multimedia Appendix 1 for the complete interview guides. Note that this interview guide was used in the broader pilot study and not all questions align with the scope of the research questions addressed in this manuscript. Additional qualitative findings will be presented in subsequent publications.

Data Analysis

Overview

Results of the clinician delivery checklist, attendance tracking logs, and participant engagement ratings were reported using frequencies and descriptive statistics. Exit satisfaction survey Likert-scale question responses were collapsed into 3 groups: (1) favorable response (strongly agree, agree), (2) neutral response (neither agree nor disagree), and (3) unfavorable response (strongly disagree, disagree). They were then reported descriptively. Responses to open-ended exit satisfaction survey questions were grouped into initial codes by 2 members of the research team (AH, AL). Codes were then grouped into broader categories, and the frequency of responses in each category was reported. Two researchers (AH, AL) coded observer field notes descriptively, grouped related codes into categories, and presented categories related to engagement. Any discrepancies in the coding process were resolved through discussion. Findings from checklists, logs, field notes, surveys, and interviews were triangulated by assessing consistency and identifying complementary insights (eg, did observations align with participants' reported experiences?) [57].

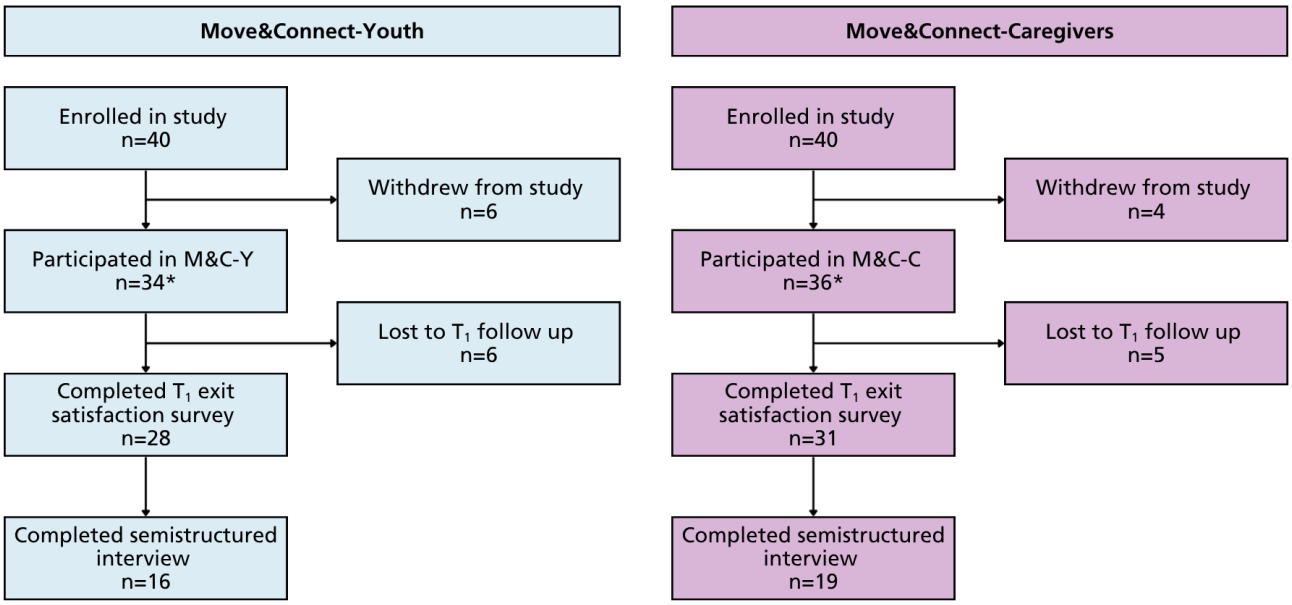
Interviews

Content analysis was used to examine the interview data, following both directed and inductive approaches. Pre-identified codes were derived from the multifaceted motivational framework of engagement [58]. Inductive coding was used to generate additional codes from the interview data to capture facilitators and barriers to engagement across both interventions. Facilitators were defined as factors that supported participants' ability to engage, whereas barriers reflected factors that hindered their engagement. An initial codebook informed by the multifaceted motivational framework of engagement [58] and the concepts of facilitators and barriers to engagement was developed collaboratively by 2 coders (HAH, SMN) prior to coding. The 2 coders then independently applied the codebook to the interview transcripts and met regularly to discuss coding decisions, resolve discrepancies through consensus, and iteratively refine the codebook by clarifying existing codes and incorporating additional inductively derived codes. The analytic process involved (1) identifying topics or patterns, (2) gathering examples of topics from the transcripts, and (3) examining connections and relationships among codes to refine categories. This process included organizing examples of engagement using

XSL•FO
RenderX

the predefined codebook and developing categories that reflected key facilitators and barriers. Quirkos software was used to apply codes and organize relevant excerpts [69].

Reflexivity



Interviews were conducted by AL (male research coordinator with a master's degree in human health and nutritional sciences), HAH (female graduate student in clinical neuropsychology), and SMN (female research assistant with an undergraduate degree in neuroscience and psychology). Some interviewers had limited prior contact with participants through onboarding procedures. Interviewers did not conduct interviews with participants from a group if they acted as a clinician facilitator for that group. The broader study team has expertise in brain injury rehabilitation and experience with the *M&C-Y* and *M&C-C* interventions, which may have influenced the interpretation of the findings. To support reflexive practice and enhance trustworthiness, data analysis was completed by 2 individuals (HAH, SMN), and analytic memos documenting coding decisions and interpretations were maintained throughout the analytic process. Interpretations were also shared with the broader research team to encourage reflection and dialogue [70].

Results

Participants

Youth and caregiver participant progression throughout the study is outlined in Figure 1.

Figure 1. Youth and caregiver participant flow throughout the study, including participant numbers for enrollment, withdrawals, intervention participants, lost to T_1 (immediately following invervention completion) follow-up, T_1 exit satisfaction surveys, and semistructured interviews. *Demographics, attendance, and engagement ratings are reported for all participants who participated in the interventions.

Youth Participants

A total of 40 youth enrolled in the study (32 as dyads with parent/caregiver participants; 8 independents): 4 youth withdrew before the intervention began, 2 youth withdrew from the intervention due to scheduling demands, and 6 youth participants attended group sessions but were lost to T_1 follow up.T_1 follow-up procedures were completed by 28 youth. At the time of enrollment, youth participants completed a demographics form (see Table 2 for youth characteristics). All youth who attended T_1 follow-up (n=28) were invited to an optional semistructured interview: 16 youth completed an interview (10 identified as girls, 5 identified as boys, and 1 identified as gender fluid), and 12 youth declined. All 6 *M&C-Y* sessions were attended by 7 of the 16 youth who were interviewed, and interviews lasted from 4 minutes to 27 minutes (mean 18 minutes). For clarity, this leaves the following sample sizes: demographics, attendance, and engagement ratings: n=34, 27 dyads, 7 independents; exit satisfaction survey data for fidelity of enactment: n=28, 21 dyads, 7 independents; and interviews: n=16, 11 dyads, 5 independents).

Objective 1: Intervention Fidelity Assessment

This section describes the results of the intervention fidelity assessment for *M&C-Y* and *M&C-C*.

Fidelity of Design

An intervention mapping framework [35] was applied to the intervention design process for *M&C-Y* and *M&C-C*. Scratch and colleagues [36] and Al-Hakeem and colleagues [37] described the detailed intervention development process, alignment with theory, and feasibility testing results. The perspectives of youth, caregivers, and clinicians were incorporated throughout the development process. To ensure fidelity of the intervention design, an intervention manual was created that outlined the intervention purpose, format, and protocols required to complete *M&C-Y* and *M&C-C*. This was provided to clinician facilitators and research staff.

Fidelity of Training

Four occupational therapists and 2 physiotherapists were trained to deliver *M&C-Y*, and 2 social workers, 2 neuropsychologists, and 2 neuropsychology trainees were trained to deliver *M&C-C*. Our train-the-trainer model was underpinned by best practices and frameworks within the training field [71,72]. Train-the-trainer frameworks are commonly used to update health care professionals' knowledge and skills and implement evidence-based interventions [71]. The training protocol used a blended learning approach, consisting of didactic and interactive methods, and was intended to ensure that all clinician facilitators delivered *M&C-Y* and *M&C-C* correctly, consistently, and safely to youth and caregivers. Feedback was also provided by the trainees (ie, individuals who were trained) about the training, which also informed the train-the-trainer approach. All clinician facilitators received institutional research training (eg, Tri-Council Policy Statement: Ethical Conduct for Research Involving Humans [TCPS-2], Collaborative Institutional Training Initiative [CITI]), orientation to the study protocols and procedures, and a study manual with all intervention materials (eg, slides, REDcap access) [66]. All clinician facilitators observed group sessions prior to facilitating the intervention independently and participated in 1-on-1, discipline-specific, peer debriefing throughout this process. Weekly debrief meetings were held between the clinician facilitators and the research staff observer to resolve any logistical or operational issues. Individual consultation with the study principal investigator occurred, as needed (eg, to review the mental health safety protocol).

Fidelity of Delivery

The *M&C-Y* intervention protocol was consistently delivered as intended across all 10 groups (discussion: 58/60, 97% sessions; exercise: 55/60, 92% sessions; goal setting: 57/60, 95% sessions). Reasons for modifying or deviating from the *M&C-Y* intervention protocol included sessions being canceled or modified due to only 1 participant attending (n=2), youth declining to participate in the exercises due to illness or being symptomatic (n=2), and discussions that were so productive that the exercise or goals setting components of the program needed to be shortened to accommodate session timing (n=2). The *M&C-C* intervention protocol was also consistently delivered as intended across all 9 groups (psychoeducation: 50/54, 93% sessions; activity: 50/54, 93% sessions; take home reflection [weeks 2 - 6 only]: 37/45, 82% sessions). Reasons for modifying or deviating from the *M&C-C* intervention protocol included shortening the activity component because caregivers had questions and thoughts to share about the psychoeducation (n=3) or moving directly to the psychoeducation if caregivers did not complete the take home reflection (n=5). See Multimedia Appendix 2 for the detailed group breakdown of the clinician delivery checklist for *M&C-Y* and *M&C-C*.

Fidelity of Receipt

Attendance rates were as follows: all 6 sessions: 14/34 youth, 41% and 17/36 caregivers, 47%; 5 sessions: 8/34 youth, 24% and 7/36 caregivers, 19%; 4 sessions: 6/34 youth, 18% and 5/36 caregivers, 14%; 3 sessions: 4/34 youth, 12% and 4/36 caregivers, 11%; 2 sessions: 2/34 youth, 6% and 2/36 caregivers, 6%; 1 session: 1/36 caregivers, 3%. Participants frequently emailed the research team in advance when they were unable to attend a session (ie, due to scheduling conflicts or illness). In terms of fidelity receipt (ie, that participants understood and could use the intervention content), the research staff observer field notes revealed that participants frequently asked questions related to weekly topics (verbally and using the meeting chat function). Additionally, youth and caregivers were observed attending sessions with previously circulated educational materials and referring to them during group discussions. Participants completed weekly polls and discussions related to goal setting (youth) and take-home reflections (caregivers). Youth also frequently came to the sessions with the required supplies for the exercises (ie, running shoes, water bottles) that were provided in the weekly email reminders.

Fidelity of Enactment

For *M&C-Y*, the average exploratory participant engagement rating score was 2.72 (SD 0.36; range 1.5 - 3.0), and the overall group engagement scores ranged from 2.37 to 3.0 (mean 2.73, SD 0.21; see Multimedia Appendix 2). Overall, youth participants were satisfied with the *M&C-Y* intervention, indicated by favorable responses across the exit satisfaction survey (Table 4). In addition, youth responses on open-ended questions in this survey revealed that youth perceived the best feature of *M&C-Y* to be connection with other participants (10/34, 36%), the weekly exercises (7/34, 25%), the weekly goal setting (6/34, 21%), and learning strategies that they could apply outside the sessions (2/34, 7%). In terms of changes or opportunities to improve *M&C-Y*, some youth recommended moving the intervention from a virtual to an in-person format (4/34, 14%), providing more opportunities for connection between participants (4/34, 14%), making the exercises easier or harder (4/34, 14%), and including different educational topics (4/34, 14%).

[a]1 missing youth response (n=27).

[b]1 missing caregiver response (n=30).

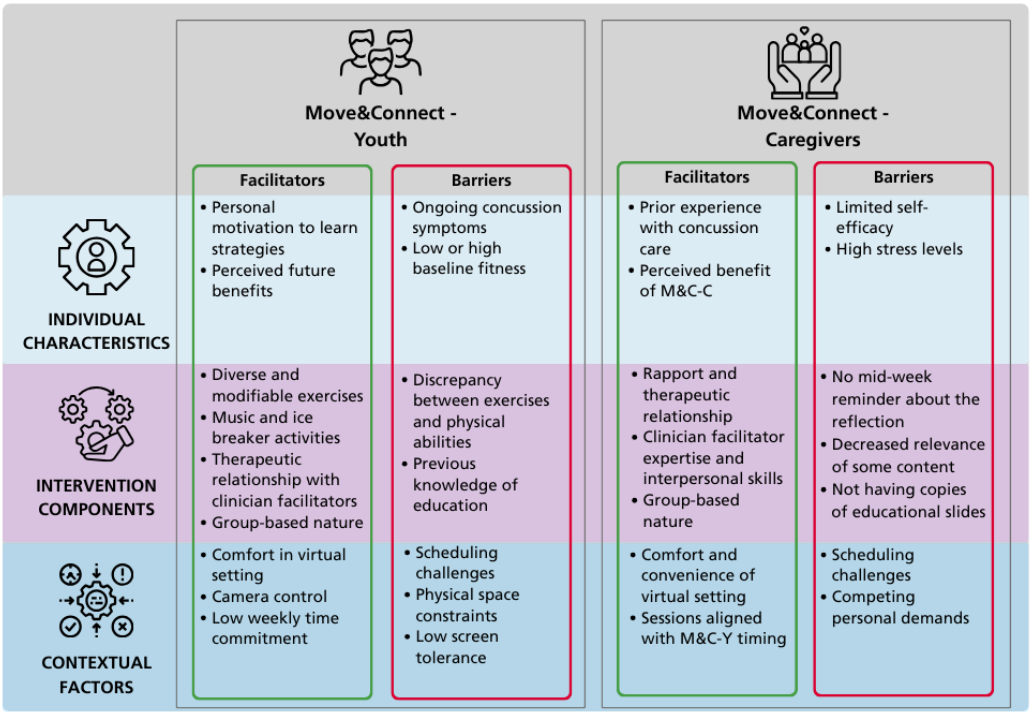
For *M&C-C*, the average exploratory participant engagement rating score was 2.79 (SD 0.27; range 2.0 - 3.0), and the overall group engagement score ranged from 2.5 to 3.0 (mean 2.8, SD 0.17; see Multimedia Appendix 2). Caregiver participants were also satisfied with the *M&C-C* intervention, with favorable responses indicated across the exit satisfaction survey (Table 4). Through open-ended questions on this survey, caregiver participants also indicated that they enjoyed the convenience of the virtual format (7/31, 23%) and that the best features of *M&C-C* were connecting with other caregivers with similar experiences (19/31, 61%) and the education and strategies provided (11/31, 36%). Suggestions to improve *M&C-C* included providing different educational topics and resources (6/31, 16%), additional reminder emails with program content (5/31, 16%), allowing more opportunities for connection between participants (4/31, 13%), modifying the timing of sessions (3/31, 10%), and increasing the number of participants in each group (2/31, 7%).

Examples of how youth and caregivers (Table 5) engaged with the interventions are outlined using the motivational framework from King et al [58], followed by an examination of the individual, intervention-related, and contextual factors that influenced these experiences of engagement (Objective 2). Behavioral engagement in both interventions centered around taking part in intervention components (eg, discussions and group activities) and participants' confidence in their ability to perform intervention tasks. Affective engagement involved the

XSL•FO
RenderX

positive feelings and attitudes participants had toward the interventions. Cognitive engagement included participants' interests, ways they felt inspired, and an appreciation of the structure and utility of *M&C-Y* and *M&C-C*.

Table . How youth and caregivers engaged with *Move&Connect-Youth* (*M&C-Y*) and *Move&Connect-Caregivers* (*M&C-C*), with each example of behavioral, affective, and cognitive engagement presented with an illustrative participant quote.



Examples	Quotes
M&C-Y	
Behavioral (participation/confidence in ability to do intervention tasks)	
Group discussions	We would talk about topics, and it would be nice to hear people's opinions and ideas on how to help […] it helped sometimes, it is not bad at all (Y01, age 11 years).
Goal setting	I was sharing my goals with everyone and they were also, they also had goals for themselves, kind of was a motivation to continue out for that, that goal. And... so I can come back next week and say that I accomplished it (Y09, age 17 years).
Exercising	I thought it was really cool to do all the exercises and have good discussions (Y10, age 16 years).
Beliefs about self-efficacy	I think I'll be able to. Uh, if you know a goal comes up that I think I will be able to follow it and accomplish it pretty well (Y16, age 17 years).
Affective (emotional investment and attitude towards intervention)	
Comfort and keenness	It made me feel like if I can do it, they can do it. If they can do it, I can (Y01, age 11 years).
Active and energized	I think it made me feel less tired, uh, just like yeah just less tired and more felt better, yeah, just like more active (Y11, age 16 years).
Cognitive (conviction of intervention appropriateness)	
Inspired by peers	It was inspirational to see them [the other participants] getting better throughout the weeks (Y14, age 17 years).
Belief in utility and structure	It was really educational, I think, and it was really good to talk to other people that were like experiencing the same thing as me. I think that was the most beneficial part for me (Y12, age 16 years).
M&C-C	
Behavioral (participation/confidence in ability to do intervention tasks)	
Emotionally vulnerable discussions	We were all a part of a group that was sharing information and relating to each other (C17).
Active listening and verbal participation	When I would make a comment and the other parent would respond by saying, "yeah, I get that, I get that I have that too." And then I, you know, the reciprocal was there (C02).
Application of strategies outside of sessions	It brought a heightened awareness about that might be what the children have been going through, right, and, and just being more aware and understanding about everything that is going on (C12).
Affective (emotional investment and attitude towards intervention)	
Validation and connection	It was great connection and kind of, it's nice to be able to talk about it with people who are going through similar experiences (C03).
Relief	I don't know how else to say it but it was it really was umm liberating. I don't know if that's the right word, but I just felt like a huge relief of saying, okay, I'm not the only one. I'm not going crazy when my kid is actually experiencing this, and you know somebody else actually finally understands me (C04).
Cognitive (conviction of intervention appropriateness)	
Relevance and benefit of *M&C-C*	I'm actually learning something, the presentation is good, you know? This is knowledge coming to me that I didn't have before, so yes (C11).
Positive perceptions of *M&C-C* structure	I thought it was just, really well run. It was just enough of everything like do you know what I mean like, um, education versus, um, chatting, um, yeah, I just thought it was done really well (C12).

XSL•FO
RenderX

Objective 2: Facilitators and Barriers to Engagement

This section describes factors that influenced participant engagement within *M&C-Y* and *M&C-C*. Facilitators and barriers to intervention engagement are organized across 3 overarching categories: (1) individual characteristics, (2) intervention-related components, and (3) contextual considerations (Figure 2). Findings for *M&C-Y* are presented first, followed by those for *M&C-C*.

Figure 2. Visual representation of key barriers and facilitators to engagement in *Move&Connect-Youth* (*M&C-Y*) and *Move&Connect-Caregivers* (*M&C-C*), organized by individual characteristics, intervention components, and contextual factors.

Facilitators of Engagement in M&C-Y

Individual Characteristics

Individual motivation and personal interests facilitated engagement. With respect to motivation, youth described joining *M&C-Y* to improve health, manage symptoms, and return to valued activities. Some also noted an interest in contributing to research and helping others.

Intervention Components

A lighthearted, comfortable, and nonjudgmental environment was reported to drive engagement in *M&C-Y*. Youth described *M&C-Y* sessions as friendly and positive, with a lighthearted tone that included laughter and playful moments among participants and clinician facilitators:

> *We have like those like ball throwing or sock throwing things, and things would just fly everywhere. [We would] like poke fun at each other but like in a positive way that made you feel like you can like laugh at yourself and not feel so bad if you're not good at something.* [Y15, age 17 years]

Creative icebreaker activities and conversation prompts were reported to ease nerves and encourage engagement. Youth noted that the personalized music played in the session supported the active rehabilitation exercises. Youth also emphasized that seeing their peers being open and transparent regarding their symptoms and challenges made it easier to participate in discussions and relate the intervention content to their own situations:

> *They [the other participants] were really open to sharing, which I really appreciated. And they shared some similar things. And so it was kind of like, I can share something like this. I felt comfortable sharing, some of the stuff that I was dealing with, because they were also sharing some of the stuff they were dealing with and it was similar.* [Y12, age 16 years]

Clinician facilitators were consistently described as supporting youth engagement. Youth commented that the clinician facilitators' style felt relatable, and they offered encouragement and validation. Clear reminders about confidentiality or "what's said on the call stays on the call" (Y01, age 11 years) reinforced trust and made disclosure feel appropriate within the group. Further, youth emphasized that the clinician facilitators taking part in activities and exercises themselves, alongside participants, enhanced engagement and comfort.

Most youth described the educational content as helpful and relatable when it linked concussion information to their own symptoms, daily routines, and recovery goals. They identified the variety of exercises and flexibility as supportive and appreciated that the exercises were tailored to different abilities and broken down into manageable blocks:

> *There were a lot of options, so even if I did not want to do one, if I was doing an exercise for a long time*

XSL•FO
RenderX

> *and could not do it anymore, I could move to an easier version.* [Y15, age 17 years]

Youth also valued that the exercises were challenging enough to feel meaningful without being overwhelming:

> *They [the exercises] were not too hard where I would be sore the next day, but they were hard enough that I would be tired in the end. That helped my physical and mental health, and they were fun to do.* [Y11, age 16 years]

Youth noted that watching peers share openly encouraged their own participation and improved feelings of connection. More specifically, having others in the group of similar age with comparable concussion experiences was helpful:

> *Everyone was always smiling, um, like there was never any criticism or anything, any questions were answered like there was kind of always a solution, like yeah it was just a nice environment. And again, with the age like being so close and similar in age and experiences too that it just it was a comfortable environment.* [Y16, age 17 years]

Importantly, the group format supported accountability and follow-through with setting and achieving goals. Youth indicated that the clear expectation to set goals, return the following week, and report on progress to the group promoted accountability. Others described how hearing peers' goals provided ideas for their own targets and a sense of shared effort:

> *I did set goals [before M&C-Y], and I tried to stick to them, but I just, I found I really wasn't sticking to them at all. And then within the group, it really helped me to stick to them because […] I was sharing my goals with everyone and they were also, they also had goals for themselves, kind of was a motivation to continue […] so I can come back next week and say that I accomplished it.* [Y09, age 17 years]

A small group size was also a facilitator to engagement. Youth described that a smaller group made it easier to speak, reduced stress levels, and increased the sense that individual contributions would be heard. It also allowed for more direct check-ins and time from the clinician facilitators supporting the sessions:

> *There weren't many people, and I felt like my voice was heard a lot of the time.* [Y04, age 16 years]

Contextual Factors

Broader environmental and technological factors also facilitated *M&C-Y* engagement. Youth were able to attend sessions more regularly when they had fewer extracurricular and school-related commitments. The virtual format supported comfort and engagement for some youth, particularly in their ability to control the camera and position themselves at a comfortable distance from the camera:

> *You don't actually have to see people like super close up. You can kind of move away from your camera and just focus on yourself instead of, oh, what are other people doing? Or what are other people thinking about watching me exercise.* [Y06, age 16 years]

Barriers to Engagement in M&C-Y

Individual Characteristics

Ongoing concussion symptoms (eg, headaches, fatigue, dizziness) were barriers to full participation in the exercises or made it harder to attend sessions. One youth described that where they were in their concussion recovery affected their participation and did not feel that the exercise component aligned with their needs:

> *I don't think exercises are really on par with my recovery. Because I've noticed that exercise is actually in fact making my symptoms worse. Even if it's just light exercises like walking. So, I wouldn't say that it was bad. Once again, I would say it just wasn't for me per se.* [Y05, age 17 years]

Intervention Components

Having exercises that felt too easy or too difficult was a barrier to engage fully in the session, particularly when youths perceived a mismatch between their current abilities and the session of intensity. For example, 1 youth who competed in track and field wanted "more challenging exercises," noting that even the harder options felt easy at times (Y08, age 15 years). However, the availability of modifications often mitigated some of these barriers:

> *I liked how they had very different variations depending on whether you could do it or not. I cannot really jump a lot because I get dizzy, and they have different alterations to some of the exercises.* [Y06, age 16 years]

Several youth reported that portions of the education content did not feel new nor relevant to their stage of recovery and were described as repetitive. For some, prior exposure to concussion resources or longer recoveries meant they had previously received education, which impacted how they engaged with the material. Others noted that, although the education was acceptable, it did not provide additional ideas for self-management beyond what the participant was already doing:

> *If people who are starting to realize what [concussion] is and what to do. And to me, I feel like I was a little bit of a step ahead. So I had to learn all this stuff already by myself, but it was still a good kind of process.* [Y03, age 15 years]

Youth offered suggestions to improve relevance and depth of education materials, including expanding topics such as sleep hygiene (Y01, age 11 years), brain anatomy, and nutrition (Y05, age 17 years). They also suggested integrating interactive elements or games into the education to increase engagement with younger youth. Some requested additional time for open-ended and peer-to-peer discussion to share experiences more fully:

> *I do wish I had more time to kind of have like more open-ended discussions like between like everyone. Just a bit more like time like specifically for having*

XSL•FO
RenderX

> *the discussions between all the kids. And like how they feel and their experiences…* [Y15, age 17 years]

A barrier to group participation involved social comparison, with 1 participant commenting that they evaluated themselves against others in terms of their recovery:

> *It was kind of like, ughh, you know, 'wow I'm so much worse than everyone else here.' It was kind of like a little not nice but yeah, whatever, like again it doesn't really affect me whether they're better than I or not as good, so yeah.* [Y16, age 17 years]

Contextual Factors

Scheduling demands, physical space, and screen tolerance were noted as barriers to engagement. Scheduling commitments related to schoolwork and extracurricular activities impacted attendance. One youth also commented that physical space in their home was a barrier to participating in the exercises:

> *I was doing it in my room, and I'm tall, my ceiling's a bit low, so it was a bit difficult at times.* [Y04, age 16 years]

Some youth noted limited screen tolerance made paying attention harder during the session. One youth, however, noted gradual improvement in screen tolerance over the course of the intervention:

> *At first, I was like 'how can I get on a Zoom call because screens hurt my eyes?' [yeah] but I tried it the first time. I wasn't feeling well that first week, but, I felt better as we got into the exercises. And then I also wasn't as afraid of going on to screens anymore, so yeah.* [Y14, age 17 years]

Facilitators of Engagement in M&C-C

Individual Characteristics

Individual characteristics that facilitated caregivers' engagement in *M&C-C* were motivation, perceived benefit of the intervention, and prior experiences with concussion care. Participants were motivated to join *M&C-C* to gain practical strategies to support their child's recovery, enhance their own well-being, and increase their understanding of concussion. Many caregivers were also interested in connecting with others in similar situations. Their frustration with previous concussion care also motivated them to join *M&C-C*:

> *I think we were at our wit's end right? And […] no matter where we were going, the doctors… we, we just felt like we weren't being heard, right?* [C04]

Intervention Components

Elements of the intervention that promoted engagement in *M&C-C* were having a dedicated space to connect and receive validation from other group members; clinician facilitator expertise; and a small, cohesive group format. Caregivers shared that the group provided a unique opportunity for open discussion with others who understood the challenges of supporting a child through prolonged concussion recovery, as a caregiver stated "No one judged me here" (C17). Connecting with other caregivers, exchanging stories, and hearing about others' coping strategies were among the most helpful aspects of the sessions. Similarities among members also supported engagement, with caregivers highlighting that their group happened to include parents in similar caregiving roles with similar aged children as them, which appeared to ease sharing among one another:

> *Just recognizing things that I was like oh yes I, I've got that too, and, and so, you know, recognizing the commonalities that are there and kind of then kind of what they're going through and how they deal with it was really nice.* [C18]

Caregivers reported feeling listened to and encouraged to participate, noting that the facilitators maintained a steady pace, balanced education with support, and created space for discussion. Sessions were described as well-structured and smoothly run, with facilitators who were personable, responsive to questions, experts in their fields, and clear in presenting material:

> *[The clinician facilitators] were just phenomenal. Besides the fact of being very personable, I think just the ability to ask some questions and the way they took us along the program. You know it, they were just really well-handled, well-structured sessions.* [C04]

Small group size was consistently mentioned as an important facilitator of engagement in *M&C-C*. Participants reported that fewer members increased connection, made communication easier, and fostered a sense of responsibility to attend and contribute. One caregiver shared:

> *This was the smallest group I've been involved with, and I think that the benefits of these small numbers really… they can't be ignored. […] I found, like I said, the level of intimacy was very beneficial and not only did it drive engagement, it really helped me make a full commitment to the program.* [C02]

Contextual Factors

Caregiver engagement was also facilitated by environmental and technological considerations. Caregivers highlighted that it was helpful to have both sessions (*M&C-Y* and *M&C-C*) run at the same time, as their children were occupied and not listening in on the caregiver group. The virtual format was widely viewed as convenient by caregivers. They emphasized that the virtual format reduced travel time and fit more easily into busy schedules. The ability to join from home was described as feasible and manageable:

> *I wouldn't have been able to do those [the sessions] if it wouldn't have been over Zoom because being so far away there, there's no way I would have been able to go for an hour and spend 3 hours getting there and back, wouldn't have made it work.* [C17]

Barriers to Engagement in M&C-C

Individual Characteristics

Some caregivers had initial doubts about their ability to understand the intervention content:

XSL•FO
RenderX

> *You're thinking, oh god, you know, is this going to be, uh, a really science-y thing, and I don't understand science.* [C19]

Others noted that stressful life demands made it challenging to fully engage in sessions or implement strategies between sessions:

> *It's still been hard to implement some of this only because I'm being pulled in so many different directions.* [C04]

Intervention Components

Although information shared was generally viewed positively, caregivers identified practical barriers in how materials were delivered by facilitators. Some requested receiving the full slide deck in advance to review and save for later use, as well as accessibility improvements such as larger font to make slides easier to read. Several caregivers also suggested sending additional reminders to complete the optional reflection activities:

> *I was remiss at not doing my first week's homework. And the reason why is because I couldn't remember what it was. And you know, had too many distractions on…* [C06]

Caregivers acknowledged that a limitation of the group model is that not all content resonated equally with all participants, with some material feeling less applicable to their circumstances:

> *Some weeks are maybe like a little bit longer or more dull if you want to say but that's always the way, right. You're going to latch on to like, some of the other parents latched on to things that I was like, I don't see myself or my kid in any of this. And then, so those weeks seem a little bit less connecting but that is the nature of different people being different.* [C07]

Contextual Factors

Time and logical constraints were common barriers to engagement. Caregivers described feeling stressed and overwhelmed with other life demands, which made it difficult to attend consistently, complete between-session activities, or implement new strategies. Scheduling the sessions during the evening (ie, 5 PM or 6 PM) was described as challenging due to appointments and family routines. Caregivers proposed alternative scheduling to improve engagement, such as later evenings, weekend options, or condensed workshop formats to broaden access. Some suggested that weekend sessions might attract caregivers who were underrepresented in the groups:

> *So, if it was a weekend workshop, maybe you'd get some of those dads out. Maybe they could go for a weekend. I could see them being like, okay, let's get those done in a one-er, you know?* [C06]

Despite the virtual convenience, a few caregivers also expressed a preference for at least one in-person touchpoint, such as a closing session or celebration, to strengthen personal connections.

Discussion

Principal Findings

Within the context of a broader pilot study, we used a multimethod approach to assess the fidelity of the *M&C-Y* and *M&C-C* interventions in terms of intervention development, training, delivery, receipt, and enactment. Second, we explored barriers and facilitators to youth and caregiver engagement with the interventions at the individual, intervention, and contextual levels. A rigorous approach to fidelity monitoring ensured high adherence to our theory-driven intervention protocols, quality of virtual delivery, and participant satisfaction and engagement. Caregivers showed consistent and high levels of satisfaction with *M&C-C*, whereas youth satisfaction with *M&C-Y* had some variability, particularly related to exercise difficulty. Both youth and caregivers expressed that clinician facilitators established a supportive, nonjudgmental environment that was central to building feelings of comfort and supported engagement. The group format provided important validation of youth and caregiver experiences and supported accountability to apply strategies outside of the interventions. Barriers to youth engagement included concussion symptoms, baseline fitness, and previous knowledge of education, whereas barriers to caregiver engagement included stress, scheduling demands, and limited access to intervention materials. Results provided important implications for delivering virtual group interventions for youth with PSaC and their caregivers.

Comparison With Prior Work

Our approach to fidelity assessment aligned with the framework from Bellg and colleagues [55] and best practices for evaluating intervention fidelity [53,54] by using multiple methods to allow for triangulation and reducing the chance of biases associated with any one approach [73]. Triangulation recognizes that each individual will have a unique perspective on a shared phenomenon [57]. We used clinician facilitator checklists and research staff observer logs and field notes and provided multiple mediums for youth and caregivers to provide their feedback. There is heterogeneity in what constitutes "good" attendance of an intervention [74]; however, it is promising that the majority of participants in this study attended at least 5 of 6 sessions. As recommended by Toomey and colleagues [75], our approach extended beyond intervention delivery to include an evaluation of fidelity receipt and enactment. Opportunities to assess fidelity receipt and enactment were also built directly into the interventions to reduce administrative burden [57]. A rigorous approach to fidelity assessment is especially important in complex interventions like *M&C-Y* and *M&C-C* that likely have multiple potential active components, and this fidelity evaluation can enhance replicability and help ensure that future outcomes can more confidently be attributed to the interventions [53,57,75].

Virtual videoconferencing technology (eg, Zoom Healthcare) enables access and scalability of pediatric rehabilitation interventions [76,77], and families report that virtual care offers benefits such as convenience, flexibility, and comfort in the home environment [78]. Similar to findings reported by Shore and colleagues [26], where youth with PSaC and parents

XSL•FO
RenderX

appreciated the convenience and comfort of engaging in individual virtual rehabilitation from home, participants in this study described the virtual setting as a facilitator of attendance and felt comfortable completing the interventions from home. Although participants appreciated the benefits provided by the virtual setting and almost all participants felt supported by the other members of the group, some felt that they did not connect with other members of the group. The discontinuous nature of cyberspace or the "loss of shared space" in virtual therapy has been identified as a threat to group engagement and relational processes in virtual groups [79,80]. To increase connection and engagement, some participants requested an in-person component or more time for unstructured or open-ended conversations between participants. The virtual nature of *M&C-Y* and *M&C-C* may lack the informal opportunities for connection that happen in the waiting room or parking lot before and after the weekly sessions. Indeed, there seems to be a trade-off between convenience and connection in the virtual group setting for youth with PSaC and caregivers.

The findings from this study have important implications for providing virtual group-based education and active rehabilitation to youth with PSaC. Active rehabilitation and education are recommended in the treatment of PSaC [12], and virtual active rehabilitation interventions are emerging as feasible approach to care [22,23]. The educational and exercise components of *M&C-Y* were delivered as intended in the majority of sessions, which is especially important as intervention personalization and deviations have been poorly reported in previous exercise interventions for concussion [81]. Although most youth agreed the education was beneficial and relevant to their personal experiences, some youth described that the education was repetitive, with information that they had already received from other health care providers or strategies that they had to previously learn on their own. Importantly, youth in this study had many risk factors for prolonged recovery [2,82] and were an average of almost 1 year postinjury (mean 327 days). As such, perspectives of these youth and their caregivers, as well as their responses to the interventions, could be different than youth injured more recently. Consistent with current clinical care guidelines [12], this suggests that education should be provided earlier in the recovery process.

The *M&C-Y* program aligns with a recent call-to-action to develop concussion interventions that do not require expensive gym-based equipment (eg, stationary bike) and to implement home exercise programs via virtual care that only require accessible and affordable materials [83]. Interestingly, both high and low levels of baseline fitness were identified as a barrier to engagement in the exercise portion of *M&C-Y*. The intervention uses a predetermined set of exercises, and clinician facilitators provided modifications for each exercise to make it easier or more challenging, which was viewed as a facilitator to engagement for participants. Even with these modifications, some youth felt that the exercise component was not the right level of difficulty. This is consistent with previously identified challenges with personalizing exercise in the virtual group setting, including decreased direct observation [84] and not being able to use your hands to correct exercise techniques [85]. Future delivery of *M&C-Y* could mitigate this by providing an individual assessment before the program begins or further individualize the exercises by providing additional opportunities for youth to provide feedback on the exercises throughout the intervention. This aligns with the principles of client and family-centered care, which emphasizes the importance of working with youth with PSaC to align aspects of the intervention to their needs [44].

There are limited educational interventions designed specifically for caregivers of youth with PSaC [34]. Unlike youth in this study who described receiving education about managing their concussion from multiple health care providers, *M&C-C* was the first time that the caregivers received education designed specifically for them. Caregivers were overwhelmingly satisfied with *M&C-C*, and virtually all caregivers agreed that the facilitators were supportive, meeting other caregivers with similar experiences was important, and the discussions were helpful and relevant to their personal experiences. These findings reinforce the importance of developing and evaluating caregiver-centered interventions and support [34]. Caregivers of youth with PSaC report experiencing high levels of stress [28] and being overwhelmed managing multiple health care appointments to support their child [44]. Similarly, caregivers in this study also identified high levels of stress and busy conflicting schedules as barriers to attendance and engagement in *M&C-C*. This was apparent, as the most common modification to the *M&C-C* intervention protocol was omitting the take-home reflection review due to caregivers not completing the reflection between sessions. Strategies like customizing mid-week reminders about reflections were suggested to support caregivers to more fully engage in the intervention.

Limitations

This study has limitations worth noting. First, as is the case with most intervention studies, results from the T_1 satisfaction surveys and interviews only include the individuals that attended the T_1 data collection session and may represent the perspectives of participants who were most engaged with the interventions. To ensure a balanced approach to intervention receipt and enactment, data from individuals who were lost to T_1 follow-up were included in the demographics, attendance, field notes, and engagement ratings. This is important, as individuals with concussion who do not attend follow-up are vastly underrepresented in the literature [86]. As participation in the interviews was optional, the qualitative findings may also be subject to self-selection and positivity bias and may not fully represent the experiences of all intervention participants. There is also potential of nonindependence of observations from members of the same family. In addition, fidelity receipt and enactment were assessed primarily through indirect observer field notes, engagement ratings, and self-report. The participant engagement rating was developed by the research team, as we were unable to identify a validated, observer-rated measure of in-session engagement that reflected the components of the interventions and was feasible for the virtual group context. Although the scale provided useful exploratory insights, its reliability and validity have not been established and therefore may not capture the intended construct of engagement. The scale may also be subject to observer bias, as sessions were not

XSL•FO
RenderX

recorded and observed by a single rater. To mitigate this, our engagement evaluation was multifaceted, and triangulation occurred with surveys and interviews. Additionally, recruitment for this study primarily took place in a hospital-based clinic in a large urban center where individuals may have had increased access to concussion care in general. Although the virtual format of *M&C-Y* and *M&C-C* makes the interventions more accessible to individuals living in rural areas, future efforts should be made to provide access to the interventions and evaluate it in this group. In addition, most participants in this study identified as White and were from high socioeconomic status households. There is a dearth of information about the association between socioeconomic status and concussion; however, recent Canadian studies have identified that individuals from households with lower socioeconomic status are less likely to access care for concussion [41,87,88]. Understanding how individuals from diverse backgrounds engage with the *Move&Connect* program should be a priority for future research. Strategies to engage these underrepresented groups could include providing alternative scheduling, offering translation services, and a focus on community-based recruitment. Last, most participants in this study identified as girls/women. This is consistent with findings from initial feasibility testing of *M&C-Y* [36] and *M&C-C* [37] and may indicate a preference by girls/women toward group-based interventions. Future efforts should be made to understand the experiences of boys/men with the interventions and explore barriers they may experience when enrolling in this type of intervention.

Conclusions

This paper aimed to evaluate the intervention fidelity of *M&C-Y* and *M&C-C* and explore facilitators and barriers to youth and caregiver engagement with the virtual group interventions. The theory-driven fidelity evaluation, including intervention development, training, delivery, receipt, and enactment, demonstrated that the pilot study of *M&C-Y* and *M&C-C* was administered with high delivery adherence. Caregivers reported high levels of satisfaction and engagement, whereas youth satisfaction and engagement had some variability, particularly related to the exercise component. Engagement with the interventions was shaped by individual, intervention, and contextual factors. Important considerations for facilitating virtual group interventions for youth with PSaC and their caregivers are presented. Future research should examine the impact of *M&C-Y* and *M&C-C* on outcomes such as concussion symptoms, goal attainment, self-efficacy, mental health, and family functioning.

Acknowledgments

Thank you to the clients and families that participated in this study and made this research possible. We would like to acknowledge the clinician facilitators on the *Move&Connect* team, specifically Lindsay Brazill, Cynthia Campos, Michelle Tanel, Rashan Edwards, Tess Bardikoff, Sabrina Freud, Emilee Morin, and Kassandra Korcsog. We also acknowledge members of the *Move&Connect* Canadian Institutes of Health Research project grant team, specifically Katie Mah, Nick Reed, William Montelpare, and Jessica Brian for their ongoing support. We would also like to acknowledge the efforts of the members of the NOvEL Lab team (Bloorview Research Institute), specifically Willow Barton, Alexa Irvin, and Christine Muscat.

Funding

This work was supported by the Canadian Institutes of Health Research (#463185) and the Holland Family Professorship in Acquired Brain Injury. Open access publishing costs were generously supported by Dr. Peter Rumney. We are deeply grateful for his support and for his remarkable legacy of advancing care for families affected by pediatric brain injury. HAH received graduate funding support from the Canadian Institutes of Health Research and the Ontario Graduate Scholarship.

Abstract

Background: Geographical and economic barriers limit access to health care services in rural regions of Colombia. In San Vicente del Caguán, the lack of infrastructure and rehabilitation professionals forces patients to travel long distances. Asynchronous telerehabilitation using video broadcasting is a viable strategy to address these challenges.

Objective: This study aims to design and validate a telerehabilitation model using asynchronous audiovisual content broadcasting for rural patients, evaluating functionality, usability, and clinical effectiveness.

Methods: A 4-stage case study developed and validated the model in San Vicente del Caguán: (1) analysis of telemedicine experiences and video-based therapy; (2) solution design including telecommunications infrastructure (radio links and Wi-Fi), mobile app (HSRehabiAPP), and web platform (HSRehabiWEB); (3) fieldwork with 7 patients receiving physical, occupational, or speech therapy, evaluating functionality (11 criteria), usability (8 criteria), and content quality (5 criteria); and (4) results analysis. The infrastructure connected San Rafael Hospital with remote centers in Los Pozos and Tres Esquinas. Participants (aged 7-68 years) from urban and rural areas had conditions including stroke, shoulder injuries, knee pathologies, hypertension, and attention-deficit hyperactivity disorder.

Results: All 7 patients achieved 100% compliance across functional, usability, and audiovisual content criteria. Functional evaluation covered login, navigation, therapy access, session viewing, exercise execution, pain assessment, therapist communication, and satisfaction surveys. Usability assessment evaluated initial access, content location, navigation comfort, instructional guidance, session organization, video playback, instruction clarity, and interface intuitiveness. Content criteria included exercise clarity, step-by-step instructions, visual quality, audio quality, and correct posture demonstration. Patients reported high satisfaction, noting reduced travel costs and time, family convenience, and effective outcomes. Offline functionality proved essential in areas with limited internet connectivity.

Conclusions: The asynchronous audiovisual telerehabilitation model is an effective solution for improving access to rehabilitation services in rural areas. It successfully addressed geographical barriers and infrastructure limitations while maintaining clinical effectiveness across therapies. Implementation requires adequate technological infrastructure, user-friendly platforms with offline capabilities, and quality therapeutic content. Future work demands inclusive health policies, professional training, and research with larger sample sizes to assess long-term sustainability in diverse rural contexts.

(JMIR Rehabil Assist Technol 2026;13:e66343) doi:10.2196/66343

Introduction

Geographical barriers, population dispersion, and economic limitations hinder timely and continuous access to health care, especially in rural areas [1]. In addition, the lack of technological infrastructure and health care professionals forces patients to travel long distances to receive treatment [2]. In this context, telemedicine and telerehabilitation [3], which involve the use of information and communication technologies (ICT) to provide remote rehabilitation services [4], become particularly relevant in rural and hard-to-reach areas where health care resources are scarce [5].

A critical case in Colombia can be observed in San Vicente del Caguán, a municipality in the Department of Caquetá, where social conflict, coupled with difficult access and limited availability of physical, occupational, and speech therapy

XSL•FO
RenderX

rehabilitation services, is exacerbated by the region's geographical and topographical conditions. Although the San Rafael Hospital in the municipality offers rehabilitation services, it does not meet the demand from patients in rural areas. Consequently, the implementation of a telerehabilitation model based on the asynchronous broadcasting of audiovisual content emerges as a viable strategy to improve access to rehabilitation services and support the comprehensive recovery of patients facing geographical barriers. This proposal includes the use of interactive audiovisual content to facilitate patient education and remote monitoring as a solution for physical rehabilitation [6], while also training patients and their families, promoting self-management of health, and reducing dependence on in-person health care services [7]. The proposed infrastructure consists of a radio link and a mobile app containing interactive videos to asynchronously guide telerehabilitation patients.

Methods

Overview

The development of the model consists of 4 stages. The first stage is a case study analysis, aimed at identifying successful experiences to gather references on key aspects that impact the target groups served through telemedicine and telerehabilitation modalities. These aspects include patient satisfaction with the services provided, opportunities to improve access, cases of technological innovation, and technology-centered approaches with coverage analysis. In addition, important considerations regarding the creation and use of videos in therapy are taken into account. This stage also includes a specific case study focused on the regional conditions and services offered by San Rafael Hospital in San Vicente del Caguán and its surrounding areas, addressing telerehabilitation for physical therapy, occupational therapy, and speech therapy. The second stage focuses on designing the proposed solution to support the strategy's model. The third stage involves fieldwork, including functional testing, usability testing, and audiovisual content evaluation, for which evaluation instruments were applied. Finally, the fourth stage involves analyzing the results to establish the final conclusions.

Case Study Analysis

Case Analysis Focused on Service and Patients

Successful cases of telerehabilitation processes and medical consultations carried out through telemedicine platforms are presented in the study by Finak et al [8], highlighting the application of remote communication technologies for physical rehabilitation, occupational therapy, and chronic pain management [9], particularly for rural populations [10,11]. In addition, the following aspects were analyzed:

1. Patient satisfaction: the reviewed studies show high patient satisfaction with telemedicine and telerehabilitation interventions [12]. Similarly, rural patients reported high satisfaction, mainly due to reduced travel costs and time [13].
2. Access to care: telemedicine was found to be not only a viable but also a necessary solution to ensure equitable access to health care [14]. Other studies highlight improvements in the management of chronic diseases in rural areas, such as stroke management in China [15].
3. Technological innovation: the studies emphasize the innovative use of technologies such as mobile apps, eHealth platforms, and remote monitoring devices [16]. These tools enhance treatment adherence and chronic disease management. For example, improvements were reported in participation and self-efficacy among wheelchair users through an eHealth program [17].
4. Consistency measures: consistency across findings suggests that telemedicine and telerehabilitation technologies are effective across a variety of contexts and populations. Although the magnitude of the effects may vary, the general trend indicates improved accessibility, satisfaction, and clinical effectiveness [18].

Case Analysis Focused on Technologies

In this aspect, a review was conducted to understand how the type of technology used and the characteristics of the population influence the effectiveness of telemedicine and telerehabilitation interventions [19]. Effective components in different clinical contexts were analyzed, aiming to optimize technologies to maximize their benefits in medical practice [20].

Regarding access and coverage of telemedicine services in rural and remote areas, significant challenges were identified, which have been addressed through various telecommunication technologies. Key factors in choosing appropriate technology in contexts with limited communication infrastructure, such as rural areas [21], include the scarcity of terrestrial networks and the need for sustainable solutions. The use of technologies such as Very Small Aperture Terminals (VSAT) [22] is justified by their availability and adaptability to local needs, highlighting cost-effectiveness and broad coverage, especially in rural areas. Furthermore, in extremely remote locations such as Maewo Island [23], satellite technology emerges as the most viable solution [24].

For mobile networks in telemedicine, efforts focus on integrating patients and health care professionals through advanced ICT such as 5G, which offers high bandwidth and the capacity to quickly transmit large medical files [25], enabling timely and informed decision-making about patient health [26]. In addition, the future scalability of 5G and its ability to easily upgrade to new technologies are key advantages. The adaptation to available communication infrastructure, along with diverse technological options such as Code Division Multiple Access (CDMA 2000 1X) [27] and Global System for Mobile Communications (GSMC) [28,29], enhances availability and connection stability in both urban and rural environments, complemented by the use of ad hoc mobile networks such as Mobile Ad Hoc Networks (MANET) and Mobile Internet Protocol (Mobile IP) [30].

Worldwide Interoperability for Microwave Access (WiMAX) is another useful technology for covering large distances while providing adequate bandwidth for telemedicine applications, such as the transmission of high-resolution medical images and video [31].

XSL•FO
RenderX

Fiber optic infrastructure and radio networks also enhance access. In the study by Baena and Bríñez [32], a high-speed backbone network is shown to enable the creation of a faster and more robust telemedicine network, compared to other technologies such as satellite connections or radio links. In another case, radiofrequency-based solutions [33] connect a hospital with rural health posts in remote areas using a radio link.

In summary, the technologies used in telemedicine are diverse and vary according to the specific needs of each environment. WiMAX stands out for its high bandwidth and its ability to prioritize critical data. Studies presented in Niyato et al [34], Tchao et al [35], and Aliyu et al [36] further highlight these advantages. The use of portable devices and long-range communication protocols is also important. In the study by Pramanik et al [37], Long Range (LoRa) technology is selected for its broadband wireless access capabilities and security features, facilitating effective transmission of medical data.

Wireless Body Area Networks (WBAN) combined with cloud computing enable remote patient monitoring and real-time health data analysis. An example of remote health monitoring can be found in Suleiman and Adinoyi [38].

A description of how 5G technology, artificial intelligence, machine learning, and the Internet of Medical Things (IoMT) are transforming health care delivery is provided in the study by Latha et al [39]. In addition, WBAN technology [40] and cloud computing are used to create a telemedicine framework, as shown in the study by Park et al [40]. Finally, LTE-Advanced (LTE-A) can also be selected for its higher bandwidth, lower latency, better coverage, increased capacity, and improved quality of service, as highlighted in Kress and Leeuwen [41].

Application Case in San Vicente Del Caguán

To analyze the health care access issues in this region of Colombia, it is essential to consider the years of armed conflict experienced in the Department of Caquetá. This context has hindered progress in various sectors, such as infrastructure, education, and health, limiting access to essential basic services. These deficiencies, recognized as unsatisfied basic needs, not only contradict the Sustainable Development Goals but also widen socioeconomic and territorial inequality gaps in the region.

In the Department of Caquetá, medium-complexity health services are centralized in Florencia, the department's capital. In some municipalities, specialist services (such as gynecology, cardiology, internal medicine, and pediatrics) are only offered through mobile health brigades. Outside the capital, municipalities only provide low-complexity health services, which results in an uneven distribution of specialists across the department. In addition, there is insufficient supply, high demand, long waiting times for appointments managed by health entities, and geographical limitations.

The San Rafael Hospital in San Vicente del Caguán has recently opened a Comprehensive Rehabilitation Center, offering physical therapy, occupational therapy, and speech therapy, making it the only municipality outside Florencia with these 3 rehabilitation services available.

San Vicente del Caguán covers an area of 28,300 km² and has a population of approximately 54,575 inhabitants, where 51.3% of the population lives in rural areas, according to 2024 projections by Departamento Administrativo Nacional de Estadística [42]. The municipality is made up of 287 rural settlements distributed across 14 police inspection zones within the municipal territory. The primary access routes are dirt roads (unpaved), which significantly complicate the journey of rural patients traveling from their villages to San Rafael Hospital for various health care procedures.

In addition, there is no internet access at health service points in the region. However, a significant number of inhabitants own mobile phones, which they use for telephone calls and, when possible, access mobile data services in communal zones where coverage is available.

Considering these regional conditions, the proposed telerehabilitation system, based on broadcasting therapy content (physical therapy, occupational therapy, and speech therapy) through an asynchronous computer-based format, offers a viable solution to expand health care service coverage to rural areas served by San Rafael Hospital. This model would also overcome geographical barriers and internet access limitations, improving health care delivery in the region.

Design and Production of Audiovisual Content for Therapy

A video is an audiovisual content format that combines visual and audio elements to facilitate the understanding of a message and enhance information retention [43-45]. Videos can vary in format, duration, and purpose and are widely used across different industries, including education, entertainment, advertising, and health care, particularly in telerehabilitation where digital platforms have shown effectiveness [46,47].

Based on these criteria, teletherapy is developed as a care modality that uses ICTs, including mobile apps and video-based content, to deliver remote therapeutic rehabilitation services [46].

Considerations for the Use of Videos in Telerehabilitation

When supporting the use of videos in teletherapy, it is necessary to consider the following aspects: the positive impacts that are reflected in the improvement of the understanding of exercises, by providing a visual representation, allow patients to observe precise movements, postures, and appropriate techniques, which reduces the likelihood of errors and increases the accuracy in the execution of exercises [46]. In turn, adherence to rehabilitation treatment is another aspect that is strengthened with the use of videos.

Another significant impact is the reduction of the patients' dependence on the therapist. Video-based interventions and visual feedback allow patients to perform exercises more independently, providing a constant guide that they can review as many times as necessary [48]. In Latin America, several studies have also demonstrated significant positive impacts. Video-based therapeutic interventions for rehabilitation resulted in significant improvements in mobility and pain reduction [49].

XSL•FO
RenderX

Technology-based rehabilitation interventions for poststroke patients helped improve motor coordination and reduce recovery time [50]. Technology-assisted rehabilitation programs have reported improvements in aerobic capacity and reduction of fatigue in patients with chronic conditions [51]. Rehabilitation programs have shown faster recoveries and pain reduction in postsurgical hip replacement patients [52].

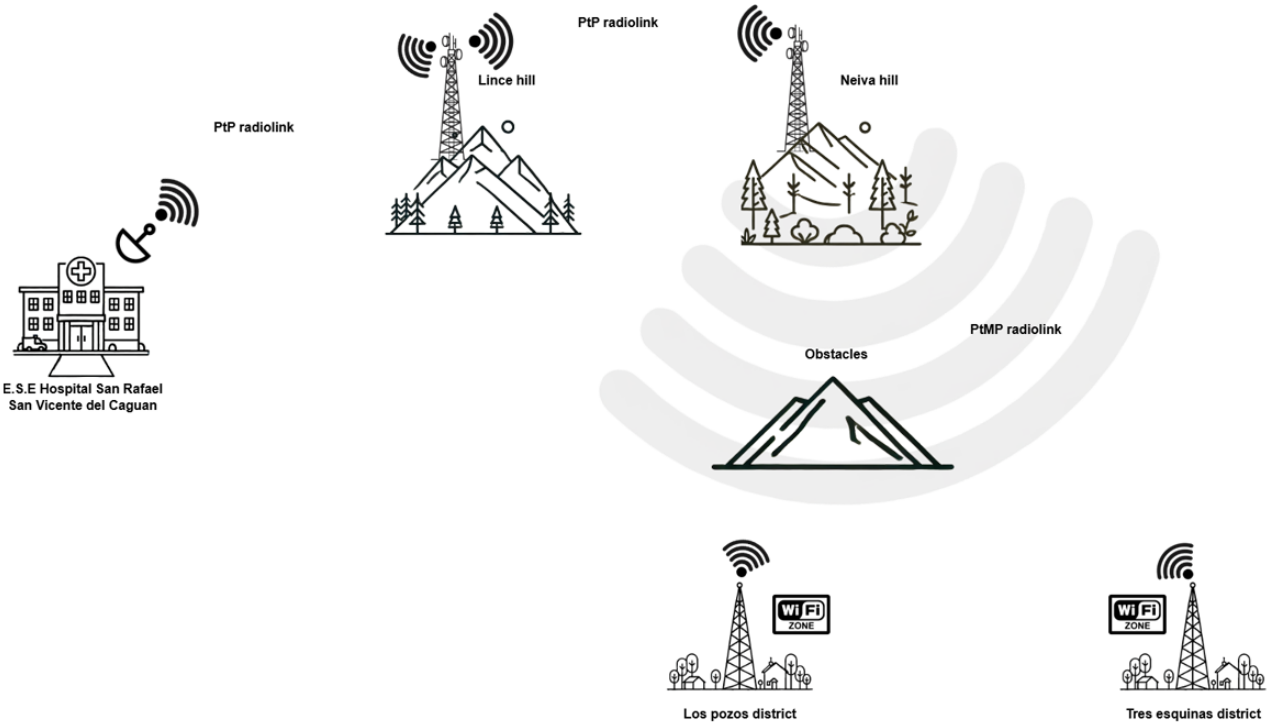
The design of rehabilitation videos requires a methodical approach to ensure that audiovisual content is accurate, understandable, and accessible to all patients. Studies have highlighted [53] the importance of a systematic approach to creating educational videos for rehabilitation.

The need for a structured process for the design of audiovisual content has been emphasized in rehabilitation research [53], highlighting the importance of conducting pilot tests and collecting patient feedback to improve the quality of the videos, an iterative approach that makes it possible to adjust the content to make it more effective and accessible.

Finally, it is important to take into account that the methods or processes that guide the design of videos in telerehabilitation should consider the following recommendations: having the collaboration of multidisciplinary professionals [53], the duration of the video should be short enough to maintain the patient's attention, but long enough to cover all important aspects of the exercise or technique [46], including clear and descriptive visual elements, as effective visual communication is essential in digital health interventions [54], to address the diversity of patients' needs, the videos must be adaptable and customizable [51], the creation of videos must be an iterative process that includes evaluation and continuous feedback from patients and health care professionals, as demonstrated in recent systematic reviews [55], and it is important to consider options for downloading videos in areas with limited internet access [42].

Development of the Telerehabilitation Model for the Implementation of the Content Broadcasting Strategy

Overview



The following are the 3 components of the model, consisting of the telecommunications infrastructure, the mobile app, and the design of audiovisual content with its mode of operation. The teletherapy services implemented support the telerehabilitation services for physiotherapy, occupational therapy, and speech therapy.

The solution has 3 components: a telecommunications component supported by a wireless network based on radiofrequency solutions (long-range and high-bandwidth radio links) and Wi-Fi technologies (802.11a, 802.11b, 800.11n, 802.11ac, and 802ax), which enable the interconnection of a hospital with prioritized and remote health posts far from the municipal or urban center. A software platform (Progressive Web Application [PWA]; Google), user-friendly and interactive, is complemented by the creation of audiovisual content (videos and animations) that are stored in a cloud repository or are synchronously and programmatically loaded with a rehabilitation therapy plan onto the patient's mobile device. This solution can be available for direct access to the cloud or located at remote or rural centers for loading onto the patient's mobile device to be used later at home. The platform allows the administration and configuration of therapies that will be scheduled for patients according to their medical history, needs, and clinical records.

The Implemented Network

Figure 1 shows the general configuration of the telecommunications system.

Figure 1. General configuration of the telecommunications system. (Own elaboration).

XSL•FO
RenderX

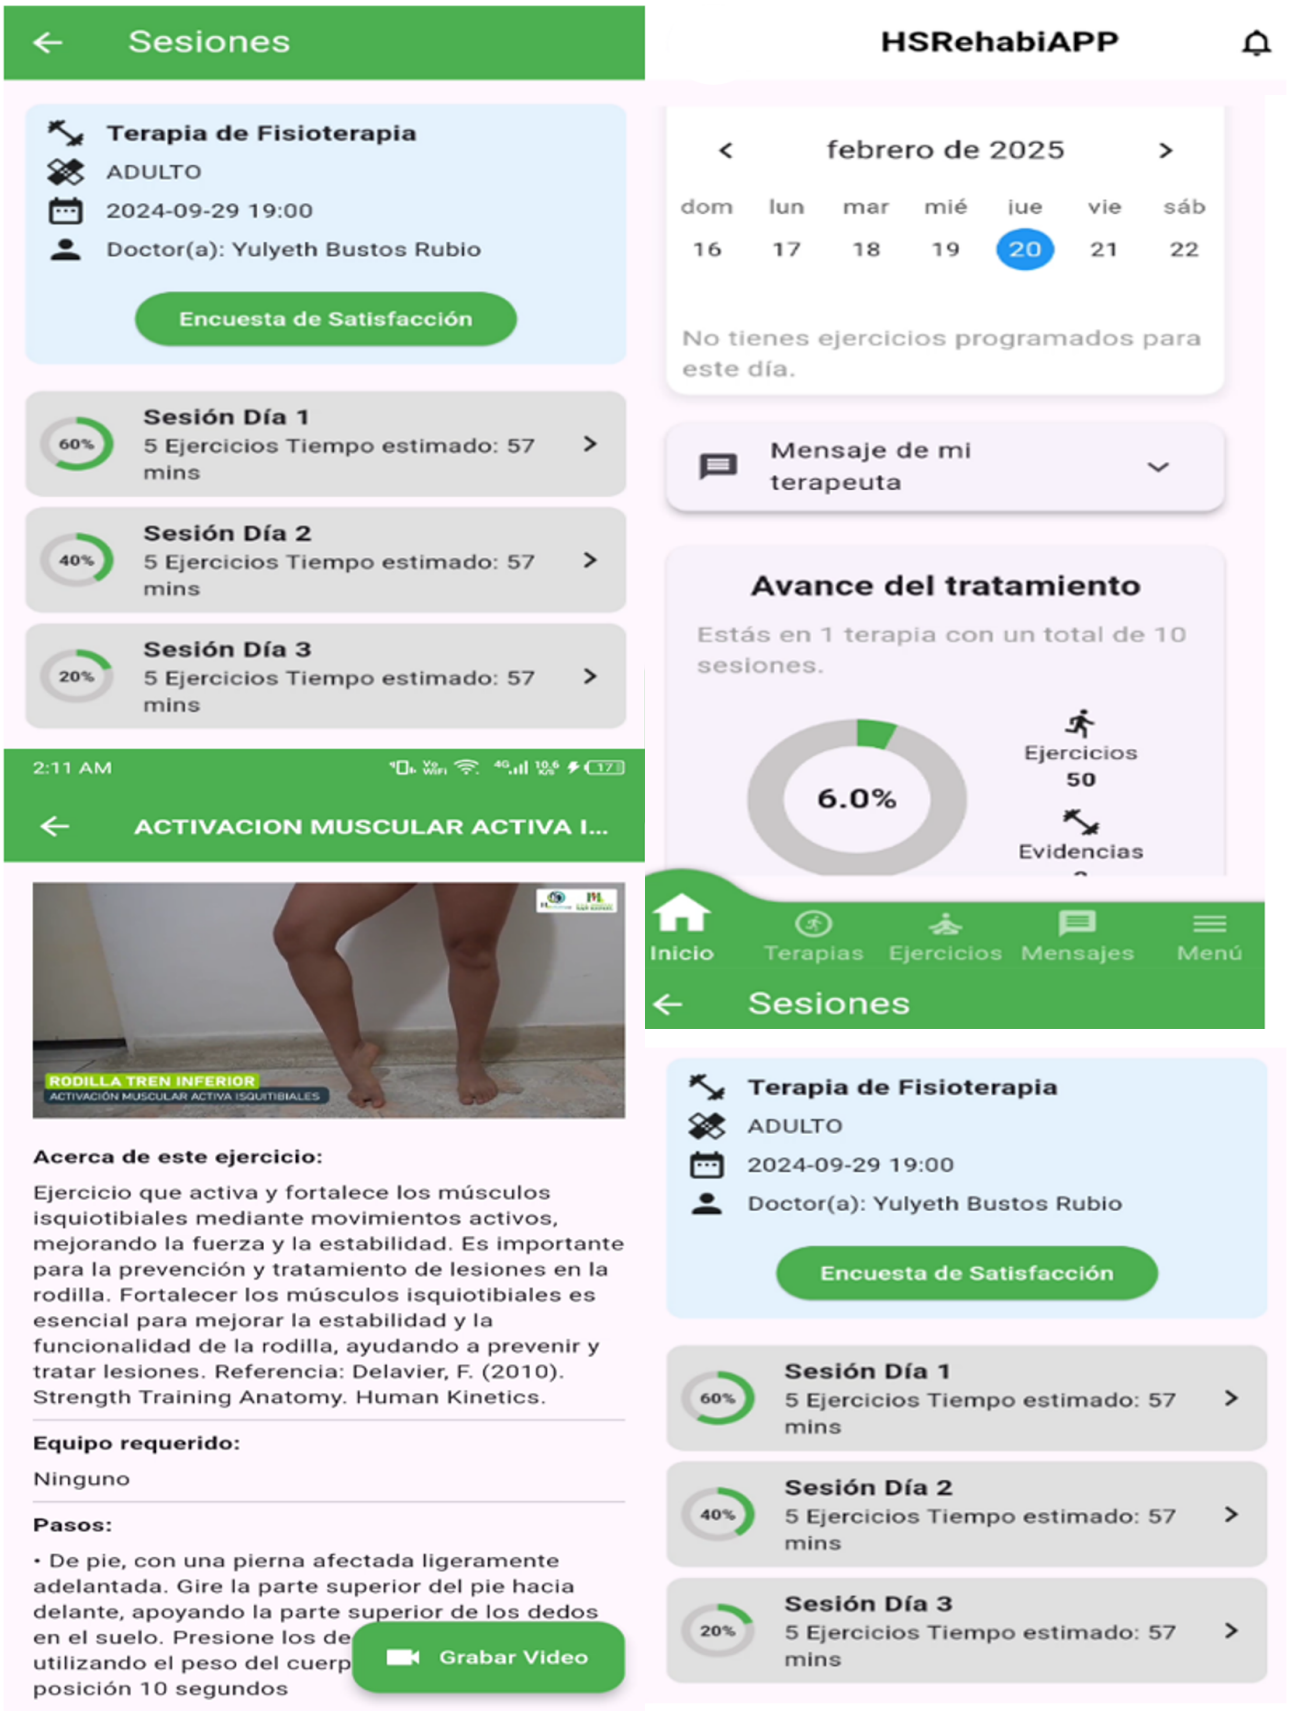
The network is made up of a radio link that guarantees access to rehabilitation services in the telemedicine modality to connect the E.S.E. Hospital San Rafael with remote health centers with difficult access to serve the communities of Los Pozos and Tres Esquinas. The network is composed of several components described below.

E.S.E. Hospital San Rafael in San Vicente del Caguán: from this point, the telerehabilitation service is coordinated, bringing together specialists, training patients referred to teletherapy, and providing follow-up through tele-expertise to patients by connecting doctors and nurses through the radio link. These professionals are responsible for maintaining direct contact with patients once they start follow-up when they come to the center for their check-ups. Finally, monitoring is carried out via telemonitoring and synchronous and asynchronous teleconsultation.

The system has 2 signal relay hops at Lince Hill and Cerro Neiva. This configuration allows communication coverage to reach the remote areas.

Figure 2 shows the installed infrastructure at each of the described points. Figure 2A shows the antenna installed at Hospital San Rafael. Figure 2B presents the configuration at Lince Hill, which maintains a direct line with the hospital. Figure 2C shows the configuration at Cerro Neiva, which maintains a link with Lince Hill. From Cerro Neiva, the highest point in the configuration, communication is established with Tres Esquinas and Los Pozos, as shown in the configuration in Figure 2D for each point.

Figure 2. Installation of the system antennas.



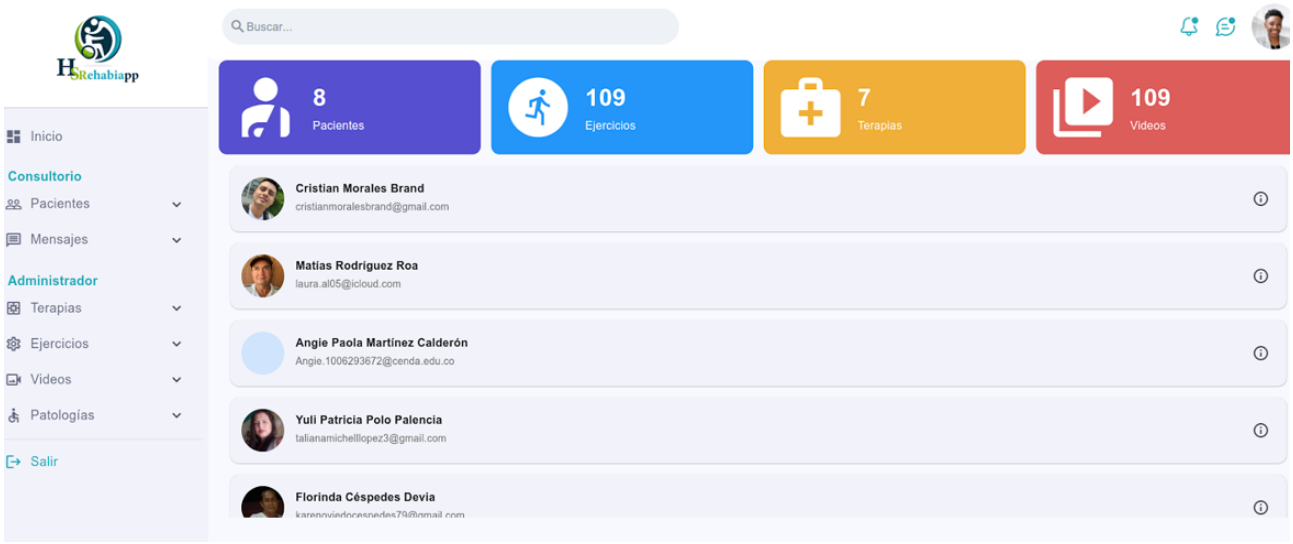
XSL•FO
RenderX

Implemented Software System

The software system of the solution follows a layered architecture that ensures separation of responsibilities. The presentation layer consists of 2 apps. The first one, HSRehabiAPP, shown in Figure 3, is a mobile app designed for online and computer-based use, where users can access their assigned therapies, obtain exercise instructions, prepare evidence, monitor their progress, and securely communicate with the assigned health care professional.

XSL•FO
RenderX

Figure 3. HSReHabiAPP mobile app.



A critical aspect in the design of the mobile app is its offline functionality. This is particularly important considering that most patients are in rural areas with little or no internet connectivity. Data synchronization is fully automated and takes place whenever patients have a connection, using a publish-subscribe model that optimizes data transfer.

The second app, HSRehabiWEB (Figure 4), is a web app where health care professionals manage the catalog of videos and

XSL•FO
RenderX

exercises, configure therapies, register their patients, and monitor their progress. This app serves as the control center of the solution.

Figure 4. Main page of HSRehabiWEB.

The application layer consists of an application programming interface, which provides access points to the application logic (Backend). The application layer is deployed on the AWS platform (Amazon) to ensure adequate quality of service. The data layer, also deployed on AWS, implements a relational model in a PostgreSQL database (Amazon).

Field Work

Overview

A pilot test was carried out between the San Rafael Hospital in San Vicente del Caguán and the centers of Pocos and Tres Esquinas in rural areas, to evaluate the implementation and effectiveness of the telerehabilitation model based on asynchronous transmission of audiovisual content in the municipality of San Vicente del Caguán, Colombia. The test included 7 patients in the telerehabilitation program, which covered physical, occupational, and speech therapies. The criteria observed considered functional tests, usability criteria, and content evaluation.

Description of Participants

Table 1 summarizes the demographic, clinical, and geographic characteristics of the patients in the trial.

Table . Demographic, clinical, and geographic characteristics of the patients in the pilot test of the telerehabilitation model.

ID	Name	Area	Pathology	Life cycle	Age (y)	Zone	Disability	Surgeries
P-1	Cristian Iván Morales Brand	Physical therapy	Left shoulder dislocation	Adult	25	Urban	No	Shoulder surgery
P-2	Matías Rodríguez Roa	Physical therapy	Stroke with left hemiplegia	Adult	55	Rural	Physical	Stroke
P-3	Yuli Patricia Polo Palencia	Physical therapy	Rotator cuff syndrome (right shoulder)	Adult	Not specified	Urban	No	No
P-4	Florinda Céspedes Debia	Speech therapy	Hypertension	Older adult	68	Rural	No	Hypertension
P-5	Emmanuel Lozano Ríos	Occupational therapy	Attention-deficit hyperactivity disorder	Early childhood	7	Rural	No	No
P-6	Jheisson Aguilera Betancourt	Physical therapy	Patella dislocation and right meniscus tear	Adult	31	Rural	No	Right knee surgery
P-7	Cristian Camilo Castro Cuéllar	Physical therapy	Knee sprain	Adult	27	Urban	No	No

Evaluation Instruments

Table 2 presents the criteria evaluated during the tests of the telerehabilitation model and its app, organized by number, specific criterion, and corresponding description. The evaluation covered 3 main areas: functional testing, usability testing, and audiovisual content assessment. Functional testing verified key aspects related to the usability, accessibility, and functionality of the app. Usability testing focused on identifying strengths and opportunities for improvement in the user experience by analyzing different aspects of user interaction with the app. Additionally, the audiovisual content evaluation examined the quality and effectiveness of the multimedia materials used in the telerehabilitation model to ensure that patients could perform the exercises properly and safely.

XSL•FO

Table . Evaluation for CF[a], CU[b], and CA[c] in the telerehabilitation model.

Number	Criterion	Description
CF-1	App login	Were you able to successfully log in using the email and password provided during registration?
CF-2	Navigation through the patient's main page	Were you able to easily access and navigate through the patient's main page, including the calendar, exercises, and messages sections?
CF-3	Access to the therapy module	Were you able to enter the therapy module and view the assigned therapies and their progress?
CF-4	Viewing scheduled therapy sessions	Were you able to access the scheduled sessions for a specific therapy and monitor their progress?
CF-5	Viewing exercises scheduled per session	Were you able to access the exercises defined for each session and track their progress?
CF-6	Execution of scheduled exercises	Were you able to see the instructions, illustrative videos, and other necessary details to correctly perform the exercises?
CF-7	Recording exercise execution	Does the app allow you to properly record and save the execution of an exercise?
CF-8	Pain assessment after the session	Were you able to enter and evaluate your pain level at the end of the session using a 0 to 10 pain scale?
CF-9	Communication with the therapist	Were you able to send messages to your therapist and receive responses through the message module?
CF-10	Therapy satisfaction assessment	Were you able to access and complete the satisfaction survey after completing the therapy sessions?
CF-11	Navigation through the side menu	Were you able to access additional features such as "My therapies," "Messages," and "Settings" through the side menu?
CU-1	Initial access	Was it easy for you to log into the app for the first time?
CU-2	Assigned content	Were you able to quickly find the videos of your assigned exercises?
CU-3	Navigation	Do you feel comfortable navigating through the app menus?
CU-4	Instructional guide	Did you find the step-by-step guide provided by the app at startup helpful?
CU-5	Session organization	Do you find the way your rehabilitation sessions are displayed clear?
CU-6	Video playback	Were you able to play the exercise videos without any issues?
CU-7	Therapist instructions	Was it easy for you to follow the therapist's instructions through the app?
CU-8	Intuitive interface	Do you feel that the app's interface is intuitive and easy to understand?
CA-1	Clarity in the presentation of the exercise	Do the videos clearly present the name and objective of the exercise?
CA-2	Step-by-step instructions	Do the videos adequately explain each step of the exercise in a way that is understandable for the patient?
CA-3	Visual quality	Is the video image quality sufficient to clearly observe the exercise movements?

XSL•FO
RenderX

Number	Criterion	Description
CA-4	Audio quality	Is the audio in the videos clear, and is the verbal explanation of the exercise understandable without interference?
CA-5	Correct postures movements	Does the video highlight the correct postures and proper movements, showing how to perform the exercise safely?

[a]CF: functional criteria.

[b]CU: usability criteria.

[c]CA: audiovisual content criteria.

Ethical Considerations

Ethics Approval

This study was approved by the Research Ethics Committee of Universidad Distrital Francisco José de Caldas. All procedures performed in this study involving human participants were conducted in accordance with the ethical standards of the institutional research committee and with the 1964 Helsinki Declaration and its subsequent amendments. Written informed consent was obtained from all participants included in the study (or from their legal guardians in the case of minors) prior to their participation. Participants were provided with detailed information regarding the nature and objectives of the telerehabilitation model, the procedures involved, the potential risks and benefits, and their right to withdraw from the study at any time without penalty. All participants were given sufficient time to consider their participation and had the opportunity to ask questions before signing the informed consent forms.

Privacy and Confidentiality

Patient data, including demographic information, medical records, therapy videos, and evaluation results, were securely stored in encrypted digital formats with access restricted exclusively to authorized members of the research team. The mobile app (HSRehabiAPP) and the web platform (HSRehabiWEB) were designed with security measures aimed at protecting personal health information, in compliance with Colombian data protection regulations (Law 1581 of 2012 on personal data protection). Video recordings used for therapy sessions were stored on secure servers and were accessible only to the assigned health care professionals and the corresponding patient. Participants were informed about data storage, access, and usage procedures through the informed consent process.

Vulnerable Populations

Additional ethical considerations were adopted to ensure adequate protection of these participants. In the case of the older adult participant, cognitive capacity to provide informed consent was assessed prior to enrollment in the study. For the minor participant, both parental informed consent and child assent were obtained, and therapy sessions were adapted according to the child's age and conducted under parental supervision. Given the rural and potentially socioeconomically vulnerable condition of participants from Los Pozos and Tres Esquinas, measures were taken to ensure that participation was entirely voluntary and that individuals did not feel coerced to participate due to limited access to alternative rehabilitation services.

Data Sharing and Dissemination

Anonymized participant data will not be made publicly available due to the small sample size and the potential risk of reidentification, particularly considering the specific rural and clinical context of the participants. Aggregate results and findings are presented in this publication in a manner that protects the individual confidentiality of participants.

Results

Table 3 presents the results obtained from the evaluation of the telerehabilitation model, including functional tests, usability tests, and audiovisual content assessment conducted with 7 patients (P-1 to P-7). The evaluated criteria are organized in rows, while the patients are presented in columns, indicating whether each criterion was met. Functional test results describe the performance of the telerehabilitation app according to the established functional criteria. Usability test results analyze the interaction of patients with the app, identifying the fulfillment of usability criteria (CU-1 to CU-8). Additionally, the audiovisual content evaluation presents the results associated with 5 assessment criteria (CA-1 to CA-5), focused on the quality and effectiveness of the multimedia materials used to support the correct and safe execution of rehabilitation exercises within the telerehabilitation model.

Discussion

Principal Findings

The considerations made based on the literature analysis to establish the system solution and the telerehabilitation strategy using audiovisual content broadcasting facilitated the validation of the proposal and verification through the case study in San Vicente del Caguán.

Regarding improved access to care, it was observed that telemedicine and telerehabilitation facilitate access to health care services, especially in regions with limited infrastructure.

In terms of patient satisfaction, participants expressed high satisfaction with these services, highlighting the timeliness of care and the convenience for families during recovery processes. In addition, patients noted a reduction in travel costs (both in time and money) and satisfactory levels of treatment effectiveness, achieving acceptable recovery outcomes across the 3 therapy types.

On the other hand, regarding the feasibility in rural health care centers, the technologies implemented proved effective in rural areas, where technology helps address the shortage of specialists to meet service demand. The ease of extending coverage was noted, improving the hospital's service offering, while patients readily accepted and engaged with asynchronous computer-based therapies.

It was necessary to develop training and continuous education tools for all community members involved in the process. In addition, this initiative opened the opportunity to formulate inclusive health policies, recognizing the need to cover diverse conditions and populations, particularly those affected by economic and technological limitations.

XSL•FO
RenderX

Finally, the need for ongoing evaluation and monitoring was established to ensure the impact and effectiveness of technology in supporting patient recovery cases.

Conclusions

The implementation of the telerehabilitation model based on the broadcasting of audiovisual content has proven to be a highly effective strategy for improving access to rehabilitation services in rural areas.

In the case study conducted in San Vicente del Caguán, patients showed high levels of satisfaction with the telerehabilitation interventions. The use of interactive audiovisual content not only facilitated rehabilitation in physical therapy, occupational therapy, and speech therapy, but also empowered patients and their families, promoting greater self-management of their health.

Findings from the literature review highlight the need to integrate telerehabilitation into public health policies, especially in rural contexts. Health authorities should develop appropriate technological infrastructure and promote continuous training for health care professionals to maximize the benefits of these technologies. Furthermore, inclusive policies should be implemented to ensure equitable access to telemedicine and telerehabilitation services for all populations, regardless of economic or technological limitations.

Several areas for future research were identified, including studies with larger sample sizes and long-term follow-up to assess the sustainability of the observed effects. It is also essential to explore the implementation of these technologies in low- and middle-income settings, as well as to investigate new technologies and innovative approaches that could further enhance the effectiveness and accessibility of telerehabilitation.

The positive effects of telemedicine and telerehabilitation interventions remain consistent across studies, regardless of the specific technology used or the target population. This indicates that the observed benefits are not specific to a particular context but are generalizable to various situations and populations.

Despite the variability in the evaluation methods used in the studies, including satisfaction surveys, clinical measures, and cost analyses, the overall findings remained robust. This suggests that telemedicine and telerehabilitation technologies are consistently effective, regardless of how outcomes are measured.

Acknowledgments

Special thanks to all the staff at Hospital San Rafael de San Vicente del Caguán for welcoming and supporting this solution, and to all the personnel at Universidad Distrital Francisco José de Caldas for their work in the execution of the project in San Vicente del Caguán. We also extend our gratitude to the Ministry of Science, Technology and Innovation of Colombia, the Telecommunications Regulation Commission (CRC) of Colombia, and Universidad Distrital Francisco José de Caldas, who founded the research and application project.

Abstract

Background: Leveraging digital technologies in health care is recognized as essential for effective and efficient services. However, significant challenges remain in implementing these technologies in stroke rehabilitation practice, and research on their influence is limited.

Objective: This study aimed to explore the current influence of digital technologies on stroke rehabilitation practices and consider how these technologies could shape the future landscape of rehabilitation for multidisciplinary health care professionals in poststroke rehabilitation.

Methods: A qualitative, exploratory design was used. Data were collected from 12 experienced multidisciplinary health care professionals at 2 Norwegian rehabilitation settings via semistructured interviews, and the data were analyzed using reflexive thematic analysis. Data analysis was guided by social practice theory.

Results: The 12 participants included experienced physiotherapists, occupational therapists, speech therapists, nurses, physicians, and social workers. The following three main themes were generated: (1) Outsourcing information about and to stroke survivors: coordination and continuity within and across services (subthemes on follow-up and interservice collaboration, and user-centered approaches); (2) Navigating the ambivalence of remaining human relations in digital psychosocial support conversations (highlighting multidisciplinary challenges in building relational depth and addressing sensitive topics); and (3) Enhancing digital supplements for assessment and engagement in motor rehabilitation (subthemes on progress monitoring and motor skills exercises). Overall, the use of digital technologies in specialized stroke rehabilitation practices was seen as an adjunct to practices. While digital technologies influenced rehabilitation practices, ambivalence and challenges were noted, particularly in digitalizing multidisciplinary psychological support and exercise programs. Systems for sharing medical records and goal-setting apps, which enhance coordination and involve stroke survivors, were emphasized as future digital technologies that can shape stroke rehabilitation.

Conclusions: Health care professionals used various technologies in their daily specialist practices, as well as for the coordination and follow-up of stroke survivors after referral to community services. This study identified several organizational processes, roles, standards, and rules that can act as barriers or drivers to implementing digital technologies in practice. Viewing familiar digital technology as a supplement to existing practices, rather than as a singular solution for all areas of specialized stroke rehabilitation, offers significant potential for quality improvement. These findings provide valuable insights for technology developers, health care personnel, and user groups in specialized neurological rehabilitation settings.

Introduction

The World Health Organization (WHO) has promoted digital health to enhance the quality and accessibility of health care services [1]. Leveraging digital technologies in health care is recognized as essential for effective and efficient services [2]. Limited resources have led to earlier hospital discharge and outsourced rehabilitation services aided by digital technologies, which are areas where politicians, clinicians, stroke survivors, and researchers have turned their attention to [3]. WHO's initiative of Digital and Assistive Technologies for Aging (DATA) [4] further underscores the importance of using accessible digital technologies in developing and sustaining new stroke care pathways [5]. The term "digital technologies" refers to electronically driven devices or applications [6,7]. Digital technologies encompass various information and communication technologies (ICTs) used in medicine and health care for disease management and wellness enhancement [6]. These technologies include devices, such as computers, smartphones, and tablets, along with their associated applications and internet connectivity [7]. Studies have shown that digital technologies improve activity and function [8-11], social participation [12], and medical adherence among individuals with stroke [13-15]. Technologies, such as gaming, videoconferencing, online health websites, apps, and wearables, have been especially explored for their potential to enhance exercise programs in both clinic and home settings in the stroke population [16]. Despite the rapid adaptation of digital technologies after the COVID-19 pandemic, scaling up remains slow [17].

Effective neurorehabilitation and tailored digital interventions are crucial for future stroke home rehabilitation [18], as they are cost-effective, portable, and motivational solutions to support daily activities [19]. However, challenges persist in home implementation [19], which might explain the lack of superior effects on supervised digital motor rehabilitation at home over conventional training for stroke survivors [18]. Although studies have found overall positive attitudes toward digital technologies in poststroke rehabilitation from the perspective of individuals with stroke, due to increased accessibility and convenience, there is an advocated need for personal contact, shared responsibility, and collaboration with health care professionals (HCPs) [20].

Building on these findings, rehabilitation specialists have introduced many digital solutions for home-based rehabilitation [21], yet significant challenges remain in adapting these technologies in practice, and research on their influence is limited. Despite guidelines and research recommending technology use in stroke rehabilitation, actual implementation and clinical validation are inconsistent [16,22-24]. A systematic review by Borg et al [25] focused on older people and people with disabilities and highlighted the need for research on technology adoption in practice, particularly from a theoretical, multidisciplinary approach. A longitudinal study across inpatient, outpatient, and community rehabilitation settings found that the type and amount of technology use varied between neurological populations, with the most frequent and varying use in stroke rehabilitation [22]. Contrary to this, Langan et al [16] found that physical and occupational therapists do not widely incorporate digital technologies into their practices, often prescribing written, paper-based, and nontechnological home exercises after hospital discharge. The primary barriers often include financial constraints, lack of technological experience, and limited time [26,27]. Despite inconsistencies in technological uptake, researchers assert that organizational readiness for eHealth reveals a dichotomy, with rehabilitation staff feeling ready, but practice preparedness being slower [2].

A broader and multidisciplinary perspective is essential to fully capture the complexity of rehabilitation practices [2,27,28]. This study addresses these opportunities for further inquiry. Existing research argues that the challenge in technology application often lies in social behavior around technology use, rather than the technology itself [29,30]. A second critical challenge lies in understanding organizational readiness for the adaptation of digital technologies in rehabilitation settings [2]. This includes the preparedness of both the organization and its members to adapt and integrate these technologies in their daily practices [2]. A third challenge is that existing studies often overlook the broader social context in which these technologies are used in practice [31]. Therefore, there is a need to consider the interconnectedness of health and social care when evaluating how digital technologies shape practices, where digital solutions should aim to lower barriers and facilitate drivers for access to rehabilitation [32].

We applied social practice theory as a theoretical framework to understand how digitalization affects stroke rehabilitation practices at the individual and social levels. Social practice theory, a behavioral theory, explores how people engage with the social world and how it impacts human behavior [33,34]. This applied practice theory is based on work by Reckwitz and incorporates elements from Bourdieu, Giddens, Foucault, and Schatzki [35]. Instead of focusing only on concepts, such as intersubjectivity, embodiment, language, and power within organizations, it incorporates all these concepts and takes a broader perspective by examining what people do in practice and the interconnected elements of individual actions and institutional structures [33]. Practice entails routine behavior involving linked key concepts, such as agents' skills and meanings needed for practices, the things that shape and enable practices, the rules and social norms guiding practices, and the process structure [35]. This theory, which has gained recognition in various fields, provides a useful lens to address the challenges and solutions related to digital inclusivity [36]. It has been used in environmental research [37], education [33], digital information [38], and public and clinical health [31,34,39,40]. The application of this theory in poststroke settings is novel, and this study adds to the limited qualitative research on the changes in practice through digitalization [40]. This study applies the concept of digitalized stroke rehabilitation as a social practice to explore how digitalization influences rehabilitation within a local context. Therefore, this study aims to examine the current influence of digital technologies on stroke rehabilitation practices and consider how these technologies could shape the future landscape of rehabilitation. This is performed through the following research question: How do digital technologies shape the current and perceived future

XSL•FO
RenderX

everyday practices of multidisciplinary HCPs in poststroke rehabilitation?

Methods

Design

In this descriptive qualitative study, a theoretical framework of social practice theory (henceforth "practice theory") [35] was applied as a lens to explore and interpret the structures shaping the use of digital technologies in 2 Norwegian stroke rehabilitation settings. Inductively generated thematic themes were mapped onto practice theory concepts. This design allowed for an in-depth exploration and assessment of the relationship between various theoretical key components of the challenges and opportunities of digitalization in stroke rehabilitation, providing insights that could shape the future landscape of rehabilitation.

Settings and Participants

Multidisciplinary HCPs from 2 rehabilitation wards in Norway were invited to participate via email and staff meetings. Recruitment at the first hospital (June 2022 to January 2023) and the second hospital (April to May 2024) involved multidisciplinary HCPs, facilitated by team coordinators. Purposeful sampling was used to recruit appropriate and information-rich data for the in-depth qualitative study. Participants were selected for their direct experience with multidisciplinary specialized stroke rehabilitation. There were no a priori guidelines for the amount or the specific data required, such as regular engagement with new technologies. The study started broadly and narrowed naturally as we became interested in what qualifies as specialized stroke rehabilitation and how technologies shape practices, justifying the theoretical delineation of the sample [41]. Both settings specialize in poststroke rehabilitation, regularly engaging with new technologies. Some technologies have been implemented in practice, while others are still being tested or are under consideration.

The first rehabilitation hospital is a large specialist facility with subacute and poststroke wards, allowing for both short- and long-term rehabilitation. Recruitment occurred in the poststroke ward, with an average of 10 days poststroke at admission and an annual average of 279 stroke survivors admitted. The second ward is a community-based clinic within a hospital and focuses mainly on subacute stroke rehabilitation, with an average of 32 days poststroke at admission and an annual range of 150 - 200 stroke survivors admitted. Despite differences in organization, both settings were chosen for their high staffing levels for specialized and intensive multidisciplinary stroke rehabilitation. The first hospital qualifies as performing complex rehabilitation due to the involvement of at least six different professions. Maximum variation purposive sampling [42] was used to recruit 12 experienced HCPs, ensuring diversity in age, sex, and work experience (Table 1). Participants had at least 2 years of experience in poststroke rehabilitation, and both female and male professionals were included. Interviews were conducted on-site at the hospital during appropriate times to minimize interference with daily practices.

Theory

In this study, practice theory offered a lens through which to examine how different HCPs talked about their actions. Grounded in constructionism, the theory posits that learning and knowledge are collectively produced through shared understandings, practices, and language [33]. Practice theory situated digitalization in poststroke rehabilitation within 2 practice settings, and its terminology served as an analytical advancement for understanding how digital technologies influence poststroke practices. Its key concepts are mapped in Table 2 to clarify the description of each concept as it relates to specialized poststroke rehabilitation settings.

XSL•FO
RenderX

Table . Glossary of practice theory concepts related to poststroke rehabilitation practice.

Concept	Practice theory concepts	Example related to poststroke rehabilitation practice
Agent (including skills)	An agent is a carrier of actions with the necessary skills, and this encompasses both bodily and mental routines. It involves ways of understanding the social world and implicit and explicit know-how [35].	Health care professional agents are connected through specialized hospital processes [43] and are norm-following individuals shaped by professional know-how, who adhere to stroke guidelines and hospital policies relative to their hierarchy at the hospital [40]. They use their minds and bodies to perform routine actions during stroke rehabilitation, such as instructing stroke survivors on walking while encouraging progress. In both contexts, they interact with medically stable stroke survivors past the acute phase, when they are cleared for intense rehabilitation. Occupational therapists, physiotherapists, nurses, medical social workers, and speech and language therapists are central to practices when motor rehabilitation is the main focus [43].
Things	To carry out a practice, agents use things in a certain way, such as physical entities or material conditions, where actions take place. However, writing, printing, and electronic media are also a part of things [35].	Things represent all therapeutic devices, equipment, and health solutions that are necessary to carry out the practice of stroke rehabilitation. Physical elements, such as conversation rooms and rooms for exercise or written material, encompass the things that the agents use or interact with [35].
Rules	Structural rules construct a practice around communication chains and signs. Agents endorse cultural norms and meanings to objects, determining actions through routinized nonsubjective understanding [35].	Health care professionals in poststroke rehabilitation follow recommended interventions from recent rehabilitation guidelines and national clinical practice guidelines for stroke rehabilitation [43]. Communication between professionals often occurs via health information systems, electronic medical records, and IT platforms where rehabilitation plans, progress notes, and patient outcomes are documented and coded according to standardized protocols. Communication with patients or their families typically happens through face-to-face consultations, telephone follow-ups, or digital platforms for remote monitoring, ensuring adherence to evidence-based practices [40].
Process structure	Routinized social practices and processes occur in a sequence over time and through repetition, forming the core of the social structure. Changes in practices arise internally, as practitioners challenge or resist established routines, and externally, as intersecting practices influence each other. Practitioners improvise new actions in novel situations, prompting internal shifts, while external interactions among diverse practices foster adaptation and transformation [35].	In poststroke rehabilitation, health care professionals facilitate a process-centered rehabilitation model for stroke survivors. Although structured, it starts flexibly with initial consultations, followed by planning, a discharge meeting, and ultimately self-care. The process includes multidisciplinary subprocesses like therapeutic examinations and collaboration with other institutions [44].

Data Collection

Individual semistructured interviews were conducted over 2 years, from 2022 to 2024, each lasting 40 to 60 minutes. Information power guided the inclusion of 12 interviews, based on data relevance and richness [45] and when sufficient data "told a coherent, convincing, and comprehensive story" [41]. The interview guide, collaboratively developed by the study's authors (Multimedia Appendix 1), explored participants' stroke rehabilitation practices, shared decision-making, and the use of technology and future digital innovations. The inclusion of decision-making as a part of the stroke rehabilitation process was inspired by its person-centered foundation, drawing on literature by scholars, such as Rose et al [46] and Bomhof-Roordink et al [47], in formulating interview guide questions. Interviews were conducted in Norwegian, allowing for probing questions and guided conversations. Audio recordings were securely stored using services for sensitive data. A transcription software assisted with transcription to Norwegian, which was later manually edited for accuracy. Deidentified selected quotations were then translated into English and checked for accuracy by the research team and a secure university-based artificial intelligence (AI) tool

XSL•FO
RenderX

(ChatGPT-4, OpenAI). The research team retained responsibility for final wording and meaning.

Data Analysis

Thematic analysis was chosen to identify, analyze, and interpret patterns across varied meanings [48]. This approach is well-suited as a method for exploring complex phenomena, as it allows for a rich and nuanced understanding of the HCPs' perspectives on how they construct and navigate their practices. The flexibility of thematic analysis enables it to be effectively applied across diverse theoretical frameworks and research questions, making it appropriate for this study's aim of understanding multidisciplinary HCPs' practices. We used reflexive thematic analysis (RTA), specifically developed by Braun and Clarke [48], because it aligns with the interpretative paradigm, emphasizing the active role between researchers and interviewees in generating knowledge and the subjective, situated nature of data interpretation. The in-depth engagement with the data enabled us to explore the social, cultural, and contextual complexities of digitalization in stroke rehabilitation practices, as well as the iterative and reflective process of capturing the underlying meanings and nuances of HCPs' perspectives [48]. The 6 phases of RTA—familiarization, coding, theme generation, review, refinement, and write up—were applied in a back-and-forth manner to accommodate curiosity and interpretation. Familiarization and coding were performed in NVivo (Lumivero), while theme generation, refinement, and write up were conducted in Word (Microsoft Corp). We conducted 2 analyses. The first analysis followed RTA, and the second aligned the findings according to practice theory concepts using Excel (Microsoft Corp). Both descriptive ("semantic," according to Braun and Clarke [48]) and interpretative ("latent") codes were utilized [49] with emphasis on capturing the empirical data during the coding stage. After several rounds of coding, the codes were manually organized into main themes, with practice theory guiding further analysis. The themes from the RTA did not change in meaning, but further descriptions and interpretations related to themes and subthemes were inspired by practice theory as a lens. During theme refinement, an additional analysis mapping qualitative data according to practice theory's 4 concepts was conducted [35] (Multimedia Appendix 2). Practice tasks, forming the final subthemes, were defined. An example of the six phases of RTA, including analyses from both RTA and practice theory, is presented in Multimedia Appendix 3. Key concepts are written in italics in the Results section. Each concept was examined from the points of both the current and future states to understand how digital technologies shape HCPs' practices.

Reflexivity

The researchers' backgrounds acknowledge how the authors' positionality influenced data analysis [48], with several having clinical experience with stroke survivors (AMH-M, CH, AL, and HGH). All authors have academic backgrounds, experience in digital solutions, and multidisciplinary expertise in the fields of rehabilitation within occupational therapy, physiotherapy, nursing, computer science, and medical physics and technology. The first author, a doctoral student and experienced physiotherapy specialist, conducted all interviews, considering subjectivity to be a resource in conducting and analyzing data; maintained a listener's role; and emphasized her role as a researcher rather than an HCP. Still, her clinical background allowed her own experiences to resonate with participants, enabling her to listen and repeat participants' recognizable stories. Reflexivity was considered early in the analysis process by recording initial assumptions after each interview and writing memos and annotations in NVivo during coding to ensure the quality of analytical points and the possibility of reviewing interpretations. A description related to all codes also supported analytical interpretation. To ensure rigor, the authors collaborated in regular meetings and workshops to discuss and enhance understanding, develop comprehensive descriptions, and refine the analysis, strengthening confirmability, coherence, and clear theme boundaries [48,50].

Ethical Considerations

As the study's focus on health service research fell outside the scope of the Health Research Act § 2, ethical approval from The Norwegian National Research Ethics Committee for Medical and Health Research was not required (reference number: 279418). Approval was granted by the Norwegian Agency for Shared Services in Education and Research (reference number: 668899) to ensure privacy protection and adherence to ethical standards. Participants received oral and written information about the study, and written informed consent was obtained prior to the interviews. The first author reiterated consent form details, emphasizing the voluntary nature of participation, confidentiality, and the participants' right to withdraw from the study. Participants did not receive any compensation for their involvement in the study.

Results

Themes and Subthemes

The results are presented in themes and subthemes and exemplified with selected quotes extracted from the analysis based on practice theory.

Theme 1: Outsourcing Information About and to Stroke Survivors: Coordination and Continuity Within and Across Services

Overview

HCPs actively leveraged digital technologies to enable better coordination and continuity of care across services. Digital tools facilitated collaboration not only between HCPs in cross-service collaboration but also with stroke survivors, relatives, and interpreters, forming the first subtheme. Through their practices, they sought to harness digital health to streamline communication and improve rehabilitation outcomes, despite the challenges of sustaining structured coordination. Maintaining continuity after referrals to community services was challenging, requiring constant goal adjustments and balancing person-centered approaches. The rule of involving stroke survivors in their rehabilitation was viewed as a necessary but complex procedure, reflected in the second subtheme "navigating user-centered approaches to rehabilitation for stroke survivors in the digital era."

XSL•FO
RenderX

Subtheme 1.1: Follow-Up and Continuity in Rehabilitation in Collaboration With Stroke Survivors and Between HCPs in Cross-Service Collaboration

In their current practices, HCPs use digital technologies, primarily videoconferencing, for stroke follow-up after discharge, involving additional *agents* such as stroke survivors, community HCPs, interpreters, Norwegian Labor and Welfare Administration (NAV) advisors, and relatives. The importance of HCPs with ICT knowledge as an added skill was highlighted. Coordination and continuity were perceived as crucial owing to the challenges in maintaining structure after referrals to community services, but they often relied on the agency of stroke survivors.

> *Keeping track of who to contact and when is challenging. We've faced logistical issues regarding when the reablement team is supposed to come, and when it conflicts with orthopedic appointments. We lack an overview of these things when the stroke survivors aren't hospitalized and rely on information from stroke survivors or other responsible persons. We do have good contact with some teams, but the organization varies greatly between different districts, making it very inconsistent.* [Informant 2.2]

Increased coordination and continuity aligned with the explicit *rules* of increasing outpatient activity and outsourcing information about stroke survivors. For future practices, an HCP suggested creating a unified individual digital plan between specialist services and communities to address uncertainty about digital progress. This system would provide an overview and ensure that individuals needing long-term, coordinated services receive appropriate care and benefit from effective collaboration to meet their goals. The following comment was made:

> *It would have been quite easy to get started with creating the document and then pass it on to the community. I know that there is no common solution, because it is somewhat up to the community whether they have a digital individual plan, and at least it was a few years back, so I don't know if there is a common solution that all communities can use, but if there is, then there is great potential to look into it.* [Informant 1.8]

Others proposed sharing medical records reporting standardized test results across services and using apps with push-warnings for goal-setting visible to both the HCP and the stroke survivor. Future solutions could involve extended digital therapy skills to include other digital platforms, such as NAV's screening tools, forming a new type of *agent* bridging HCPs and NAV advisors. They also proposed a system between the stroke survivor and health care provider to navigate in-hospital appointments and communicate with staff.

> *Maybe an overview for the patient, in an app, or some kind of guide, showing you this way, you can follow this path to get there. Your physiotherapist is sick today, so your appointment is cancelled. This is somewhat similar to what has already started in other wards. We will also implement it here eventually. It just needs to be adapted to our ward.* [Informant 1.6]

There were societal encouragements for increasing the outpatient activity and outsourcing information to the stroke survivor, enabled by more videoconferencing. Closer follow-up and a more standardized program under the direction of either a general practitioner (GP) or hospitals were mentioned. Enhanced outpatient activity demanded restructuring practices, creating better access to stroke-related information, and introducing a joint communication system between the stroke survivor and the HCP. Digitalizing content on stroke exercise programs, fatigue, rehabilitation experience forums, and cognitive or physical constraints was suggested for improved coordination. However, the complexity arising from multiple medical record systems was highlighted, showing that these systems were used exclusively between HCPs and GPs, leaving out stroke survivors. This suggests the need for integration through a unified platform for visibility and collaboration.

Even though collaboration between HCPs across health services is essential, they expressed a lack of knowledge about available resources for stroke survivors outside their own settings, underscoring the role of stroke survivors in informing their own GPs about rehabilitation opportunities. Paper-based reports were still the main communication tool. Clarifying realistic expectations and outcomes for the stroke survivor's condition helped in establishing routines and maintaining standards and rehabilitation plans. To enable this, HCPs routinely used SMART (specific, measurable, achievable, relevant, and time-bound) goals and educated stroke survivors in SMART goals [51] based on the understanding of being *specific or measurable, achievable or attractive, realistic, and time-bound* (informant 1.5), which gave direction for the future rehabilitation process. However, HCPs expressed that stroke survivors' goals, as revealed in goal-setting conversations and documented in written reports, were often forgotten or changed. The flow of information heavily depended on the stroke survivor's effort to communicate with other HCPs. As a future extension of implementing SMART goal principles in home-based rehabilitation, some HCPs perceived that goals could shift to being more focused on daily routines rather than solely the therapeutic understanding of goals for stroke survivors. For future development, HCPs valued apps with push notifications for goal-setting visible to both HCPs and stroke survivors, and indicated that future practice could consist of increased health-related data and goals. The following comment was made:

> *I wish we could have a bit more follow-up along the way, mostly for the stroke survivor's sake, because it's quite easy to put that binder in a drawer when you get home. Then you have, in a sense, "free time" until they come back. Since we say that goal setting is so important, I wish we could have communication along the way....If they could almost get a push notification through an app.* [Informant 1.2]

Collaboration faced time constraints in cross-service communication, and HCPs highlighted the importance of "setting boundaries for oneself" (informant 1.4) to balance their workload and reduce personal-professional responsibilities.

XSL•FO
RenderX

This perspective was contrasted by another participant, who highlighted differences between specialist health care services and communities in care provision and time allocation, noting the challenges in aligning social expectations.

> *I imagine that in the communities, you might get a couple of assessment visits and then wait a few months for some assistive devices, and you might not get them. You certainly don't get anything weekly and can only address one thing at a time. If we propose ten measures, it might be that you can either spend ten minutes per measure spread over a few weeks, or half of the measures are left out, is the impression I have.* [Informant 1.2]

Conversely, an HCP made the following comment: "We can't really demand that the community follow up on everything we do either" (informant 1.5). Some HCPs desired more follow-up time in their practices due to a known hesitancy in working with stroke survivors in communities, suggesting more knowledge on stroke rehabilitation and restructuring practices for better access to information and logistics. The potential benefits of a joint communication system include a less fragmented goal process and user involvement in rehabilitation goals for stroke survivors and their relatives.

Subtheme 1.2: Navigating User-Centered Approaches to Rehabilitation for Stroke Survivors in the Digital Era

Stroke survivors were routinely involved in their rehabilitation through discussions at several rehabilitation meetings, aiming to foster independence and proactive behavior. Digital preassessment conversations encouraged participation of stroke survivors in decision-making. The *rule* of involving stroke survivors in rehabilitation was to address their existential needs and was echoed by HCPs as fundamental to the nature of rehabilitation. They emphasized constant goal adjustments and the balance of person-centered care as a common but complex procedure. For instance, cognitive (eg, cognitive fatigue) or cultural determinants could undermine their accountability.

> *But of course, there are quite a few cognitive difficulties that cause significant disruption, which also means that if there are psychiatric and other conditions, stroke survivors may resist some of the services offered or do not take the initiative. It is often said that they are not motivated, as many lose due to cognitive impairment or other conditions, the ability to motivate themselves or make decisions and take initiative. And they often fall behind.* [Informant 1.9]

Relatives were involved, and they were invited to meetings either in person or remotely. HCPs supported stroke survivors' relatives by providing written material for support, owing to their role of being both a close relative and a caregiver. The challenge of maintaining this balance was highlighted as follows:

> *It's a challenge for relatives to live with someone who has had a severe stroke and to be both the closest relative, personal trainer, and everything else. They may need to be a home helper, assist with meals, and serve. It's a significant burden. It is beneficial for them to have someone come in who can take on some of the burden.* [Informant 2.1]

HCPs initiated local opportunities to continue rehabilitation, often referring stroke survivors to other services, acknowledging the complexity of stroke rehabilitation where "most need more rehabilitation" (informant 1.7). Many stroke survivors returned to the same rehabilitation hospital owing to gaps in service availability, such as occupational therapy lacking in some communities. Future digital rehabilitation would require stroke survivors to be more involved in discussions about rehabilitation opportunities throughout the process and to take ownership, which are often omitted in current practices. The following comment was made:

> *[In digital communication with stroke survivors it's important to] provide alternatives because there's not just one option; there are often several factors to consider. So, it's also about involving the stroke survivor more actively in the discussions about their future as well.* [Informant 1.6]

Concerns were expressed about current routines that excluded stroke survivors from discussions regarding alternatives in rehabilitation. HCPs viewed passivity after stroke and a lack of insight and comprehension as barriers to increased agency. However, HCPs observed a growing trend of stroke survivors taking an active role in their treatment. Although this was problematic for most owing to a lack of comprehensive medical and rehabilitation knowledge, there was a clear need for enhanced stroke survivor education. The potential for increased use of digitalized materials for relatives was also suggested. However, some HCPs criticized the assumption that most people are digitally proficient, noting that this responsibility often falls on not only stroke survivors but also their relatives. In situations where stroke survivors struggle to learn new skills, the assistance of relatives was seen as essential. The following comment was made:

> *Not all stroke survivors can use digital solutions, and then [the responsibility] might fall to their relatives. However, not all stroke survivors have resourceful relatives either, creating ambivalence about whether this user group can manage it. I believe that a large proportion can, whether it's the stroke survivors or their relatives who take responsibility. As shown in videoconference meetings here, where relatives have participated, most manage if they get a brief introduction to what they need to do, how to do it, and when. Many will be able to be part of such an arrangement in the long term, but it is probably a long way to get there.* [Informant 1.3]

Education was needed for stroke survivors with cognitive difficulties or limited digital skills. High demands were placed on those facilitating digital interactions. There were divided opinions on whether the rehabilitation hospital or the community held the main responsibility for digital home exercises and follow-ups. Some claimed that districts were responsible for digital home rehabilitation and follow-up, while others believed that the hospital's main future task was to spread and utilize their specialist expertise. Nonetheless, the user's capabilities to

XSL•FO
RenderX

become digitally self-sufficient were questioned, and an individualized approach was the top priority. The following comment was made:

> *So, when we say that we aim to provide equitable services to our users and stroke survivors, we must also remember that equitable can mean that some need in-person appointments while others can manage with digital solutions. There are many ahead of us in digital communication, including users and partners, and we are somewhat behind. But many are also far behind us and will never reach where we want to be, so we must remember to cater to the full range of our users. We cannot demand that everyone go digital. If we do, it must be very much based on collaboration. Maybe they can manage an app, but not video. We need to find the right levels.* [Informant 1.2]

Theme 2: Navigating the Ambivalence of Remaining Human Relations in Digital Psychosocial Support Conversations

Multidisciplinary HCPs played a crucial role in providing psychological support through communication, but grappled with the dual promise and limitation of digital technologies in providing support. Psychosocial support remains a multidisciplinary task as a person-centered rehabilitation approach often frames these practices. They engaged in both structured and unstructured conversations to assess existential struggles, self-perception changes following stroke, and quality of life, especially for stroke survivors with multiple cognitive and psychiatric challenges. These conversations often focused on enhancing well-being, and the rehabilitation *process* was about gaining knowledge about the difficulties and the approaches to tackle them.

While digital communication enabled flexibility and accessibility, providing effective support still required building trust and relational depth. HCPs emphasized therapeutic communication skills involving active listening, openness, and sharing, capturing sensitive information in both digital and in-person meetings. Conversations sometimes included topics like depression or suicidality, but often, these were viewed as expressions of an unwanted situation rather than an active plan. The significance of building a relationship with stroke survivors digitally was highlighted through practical strategies to achieve it.

> *Just giving them the time and space to express themselves, joking a lot. I use a lot of humor with the stroke survivors and try to show some understanding of their situation. But I find that if you can mention relevant life experiences, I think it's a good way to build relationships, to dare to open up a bit, so we're not just sitting there as rigid authority figures, making it a one-sided conversation.* [Informant 1.1]

Some HCPs felt that building relations is harder to achieve digitally and raised concerns about digital health potentially diminishing their therapeutic skills, emphasizing the importance of human relationships over relying solely on technology.

> *I think one should be a bit cautious about saying that all therapists are now redundant. Because now they can just train with an app. I don't believe in that. It's about human relationships.* [Informant 2.1]

This ambivalence was further shaped by the need to balance technological efficiency with the irreplaceable value of human connection. As professionals sought to navigate the tension between digital and in-person care, building relationships digitally was seen as a prerequisite for further effective support, particularly for follow-up in the later rehabilitation stages.

> *These conversations, right, which many experience as being more difficult- yes, life can become challenging when you return home. The challenges where perhaps there could also have been more follow-up conversations via video, but also something in a group setting. We currently have groups for those who come here, but the number of participants is somewhat limited Many live far away, and it's difficult for them to travel from home. So, perhaps there should be a type of service specifically directed at stroke survivors and their relatives at a later stage.* [Informant 1.9]

Theme 3: Enhancing Digital Supplements for Assessment and Engagement in Motor Rehabilitation

Overview

HCPs embraced digital tools to enhance assessment, treatment, and patient engagement in motor rehabilitation. These tools provided detailed insights into physical progress, fostering participation and curiosity about their health metrics, as shown in the first subtheme "assessment and monitoring of progress." HCPs emphasized individualized approaches and explored creative solutions, such as using virtual reality (VR) and augmented reality (AR), to simulate real-life scenarios or design exercises based on videos in home environments, as illustrated in the second subtheme "exercises and rehabilitation programs targeting motor skills." However, digital tools also presented challenges, such as balancing safety concerns for patients with poor balance and ensuring engagement across generations. While digital tools offered significant potential for self-managed and supported rehabilitation, they were best suited for less complex cases.

Subtheme 3.1: Assessment and Monitoring of Progress

HCPs used various digital tools to enhance the assessment of stroke survivors' progress and engagement in therapeutic activities. *Things* included pulse monitors, dynamometers with apps to measure and track physical strength and progress, video-based assessments like video fluoroscopy and endoscopic swallowing evaluations, VR tools like "Job Simulator" for cognitive assessments involving kitchen tasks, and step counters that display progress graphs. This fostered curiosity and provided detailed insights into treatment intensity. For instance, pulse monitors, which have been valued as indispensable over the past years, ensured that the pulse rate of stroke survivors remained within a target range.

XSL•FO
RenderX

> *We measure the pulse and check that we are in the zone as much as possible....And after using it for a few years now, I kind of don't understand how I managed without it. It says a lot about the patient's intensity.* [Informant 2.1]

Multidisciplinary assessment was integral to the *processes* of specialized stroke rehabilitation, focusing on holistic understanding and ongoing evaluation, which directly influenced HCPs' replicated behavior and their ability to act on it.

HCPs proposed using digital tools for preadmission consultations to evaluate engagement and proposed involving more community therapists, with local resources aiding preassessment. They suggested video-based visualizations of stroke survivors' home environments and the storage and processing of stroke survivor assessments. Monitoring was perceived as identifying stroke survivors in need of more interventions, but motivation and performance remained challenges. The following comment was made:

> *Monitoring by itself will not be enough, because when you look at the studies that have been done, at least in my experience, stroke survivors, even when they improve in arm function and actually have a higher capacity, don't use their arm as much when they get home. They revert to their usual patterns. Even though capacity increases, performance does not necessarily increase. This is a challenge that the monitor can detect, but the monitor itself will not address the stroke survivor's motivation, incentives, or desire to use the arm, or their understanding that they probably can walk more or use the arm more than they currently do.* [Informant 2.3]

Integrated feedback systems within the monitoring process were seen as potential solutions to motivation challenges. Nonetheless, the question of whether the encouragement of therapists alone is sufficient to enhance arm use or gait remains unresolved, and HCPs are yet to find effective solutions.

Subtheme 3.2: Exercises and Rehabilitation Programs Targeting Motor Skills

Both hospitals implemented gamified rehabilitation. In one hospital, VR was used for intensive balance training or as part of constraint-induced movement therapy for arm training, in addition to being utilized during digital group sessions. The other hospital used biometric equipment with force plates or the Nintendo Wii device in practice and VR for projects. One HCP had experience with asynchronous virtual individual exercises for stroke survivors living at home, when working in the community.

HCPs provided assistance either in person or remotely during the digital programs, but VR sessions required their presence. Language training, in which stroke survivors underwent naming therapy and practiced word recall, was more effective with an HCP present. *Rules* on therapy dose varied, but quantity over quality was mainly emphasized, with the intention of promoting cerebral blood flow and brain reorganization.

Despite efforts to fully utilize each stroke survivor's rehabilitation potential, challenges in maximizing their potential persisted. The following comment was made:

> *You really want that person to have the interventions implemented so they can achieve good functionality. It's very, very sad if there's potential that isn't fulfilled. Then our efforts here feel somewhat wasted. We can figure out and write down what is needed, but if it's not followed up, it feels a bit pointless. I just want people to get as well as they possibly can.* [Informant 1.7]

To enable greater potential for rehabilitation, HCPs proposed future practices involving goal-oriented digital rehabilitation opportunities and motivating exercises. However, they highlighted variations in the types of stroke survivors suitable for undergoing digital motor rehabilitation. As a result, the tasks of future HCPs would include designing motivating exercises while ensuring environmental safety and space. HCPs noted that poor balance and fall risk complicated independent exercise, making approaches to individualized adaptation and treatment effectiveness critical. Simple, self-managed technologies were seen as valuable for catering to different generations. For example, sitting exercises for arm rehabilitation were favored among HCPs owing to safety concerns, especially given that arm rehabilitation tends to receive less focus in stroke rehabilitation across services. Rehabilitation programs could be self-managed or supported by HCPs, depending on the complexity of the stroke survivor's condition. Moreover, they suggested the use of digital apps for low-threshold language training, incorporating features like animations, facial expressions, and tongue position guides. Other HCPs saw potential in creating videos of stroke survivors' homes to design VR or AR rehabilitation programs that simulate real-life challenges and create virtual training apartments, enhancing the transferability of rehabilitation practices to the home setting. Despite some doubts, many saw the potential of digital technologies to improve rehabilitation practices. The following comment was made:

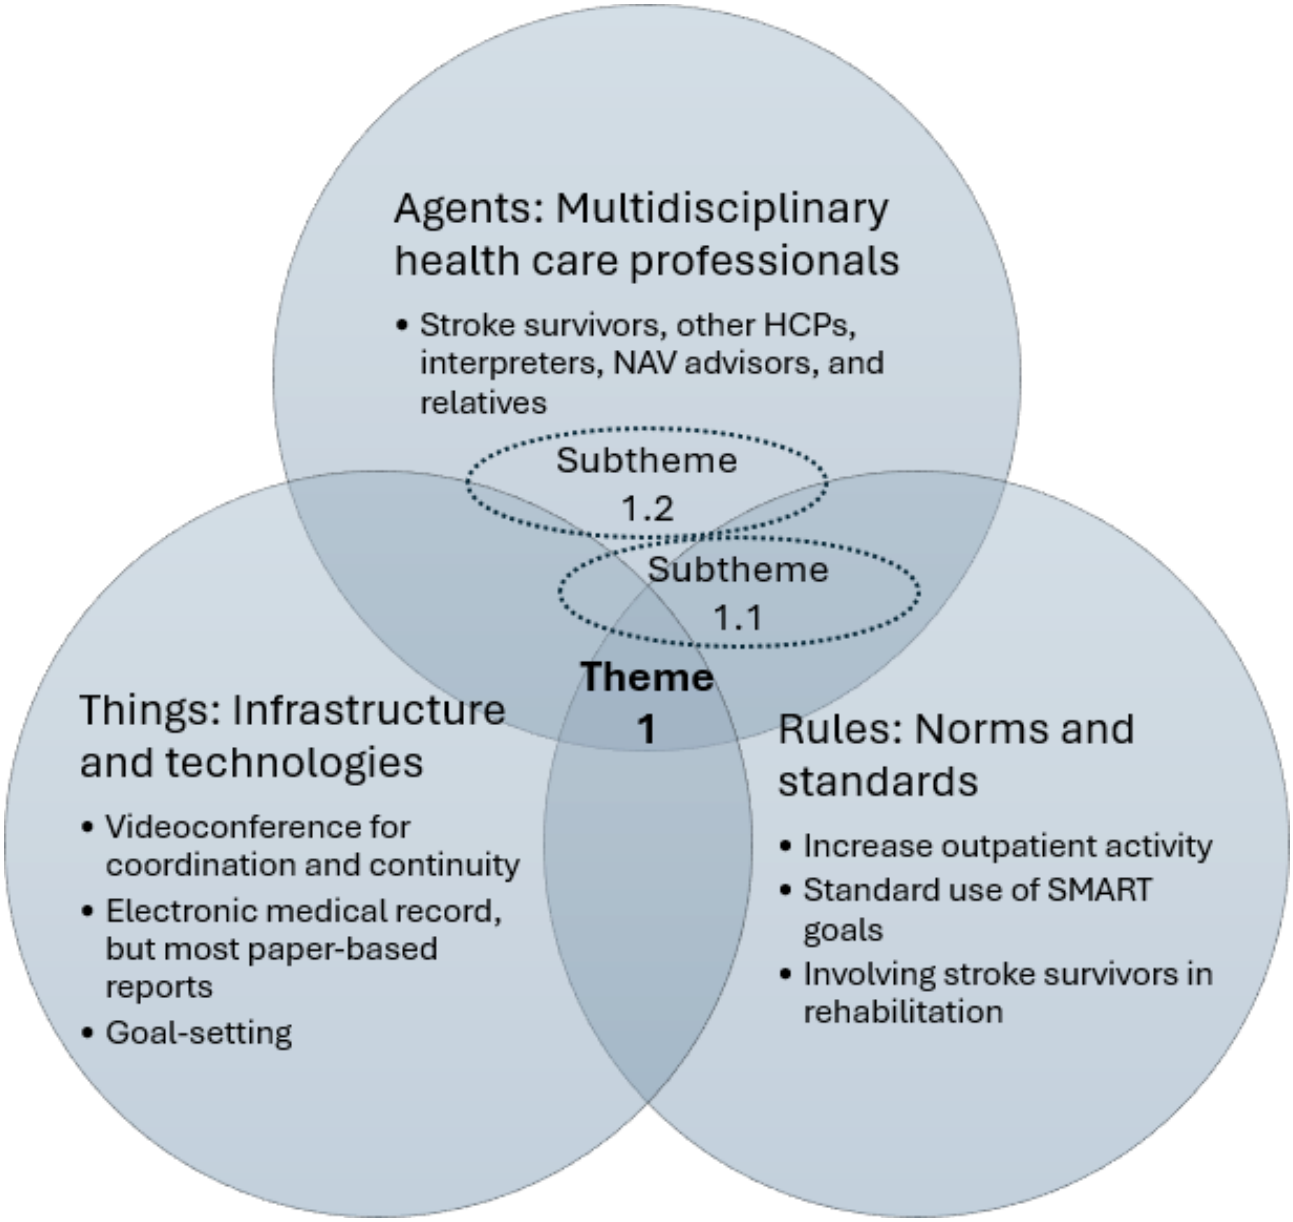
> *Stroke survivors tend to walk very little. Many of them move very little. When they return home, they might train or have follow-up sessions with a physiotherapist maybe two, three days a week, at most. Some might attend a day center, but their overall movement remains limited. In that sense, if there were a low-threshold alternative to encourage them to get up and engage in physical activity would be beneficial.* [Informant 2.2]

Discussion

Principal Findings

This study explored how digital technologies shape the current and future practices of multidisciplinary HCPs in poststroke rehabilitation. According to the results and as linked to practice theory concepts illustrated in Figure 1, the primary agents (HCPs) collaborated with various other agents, including stroke survivors, relatives, interpreters, community HCPs, and NAV advisors, during their practices.

XSL•FO
RenderX



HCPs were influenced by a range of digital technologies, particularly videoconferencing, for rehabilitation coordination and continuity, although paper-based reports remained the primary communication tool across services and with stroke survivors. They used digital instruments for assessment and engagement, including gamified exercises. However, there was ambivalence in using digital technologies for multidisciplinary psychosocial support owing to concerns about their impact on human relationships.

Researchers have highlighted that contextual factors shape technology uptake, including professional discipline, rehabilitation settings, and device features [52]. The use of social practice theory helped us realize and identify how digitalization intersects with particular contextual factors that have not been emphasized in earlier stroke research, which can influence the digitalization of specialized poststroke rehabilitation practices. For example, this theory illuminated the relational dynamics between HCPs and stroke survivors by directing our attention to the required skills and know-how, as outlined in Table 2. Specifically, with regard to theme 2, this perspective highlighted how trust and relational depth are integral to the integration of digital tools. Additionally, this lens revealed how institutional structures, such as differing medical record systems and the digitalization of support conversations, altered established practice routines and were sometimes challenged or resisted by HCPs. Drawing from these core concepts and the results, this study highlights that the primary agents need digital therapy skills, potentially expanding to include knowledge of other digital platforms in cross-service collaboration. Previous research has shown that digital tools, such as apps, can give HCPs a better overview of stroke survivors' rehabilitation processes and can help in follow-up after discharge [53], particularly by using existing digital technologies in transitions between services. However, transitions between specialist health care and community-based services were found to be challenging in this study, requiring familiarization with different practices. Extended use of digital technologies could bridge this gap by enabling therapists to familiarize themselves with different practices during the coordination and continuity of rehabilitation. HCPs highlighted future unified digital systems for sharing medical records and test results across health care services, with goal-setting apps visible to both HCPs and stroke survivors. These could enhance coordination, user involvement in rehabilitation goals, and more active stroke survivor participation and agency in digital follow-up. Despite claims of low technological uptake among therapists [16], other longitudinal studies have found that in a multidisciplinary team, occupational therapists and physiotherapists used digital technologies more frequently across inpatient, outpatient, and community rehabilitation settings. However, studies agree that advancements are needed to match the rehabilitation context, including specific technology training and guidance of implementation [22]. Related responsibilities regarding whether the rehabilitation hospital or the community should lead this practice reorganization were found to be confusing among HCPs in this study. Additionally, they proposed future digital rehabilitation innovations visualizing stroke survivors' home environments and involving more community therapists while addressing safety concerns in stroke rehabilitation exercises. The rehabilitation process usually comprises the following 4 steps: assessment, goal-setting, intervention, and evaluation [54-56]. The results of this study relate to all aspects of rehabilitation and illustrate the complexity of how digitalization is shaping specialized stroke rehabilitation practices.

Consistent with our findings, other qualitative research has indicated that using digital technologies adds value in coordination and continuity, especially where user involvement is lacking. Comprehensive care coordination programs, including home telehealth, can aid stroke survivors and their relatives in managing stroke recovery through weekly real-time video calls and in-home messaging [57], enhancing accountability and self-management [58]. Moreover, tablet-based therapeutic programs can provide alternative access to rehabilitation services and follow-up. Studies have found positive attitudes among other HCPs toward digital apps for sharing stroke rehabilitation information with stroke survivors and their families [53]. However, researchers have highlighted the importance of infrastructure, equipment, space, and support in adapting telerehabilitation [17]. While ICT platforms facilitate communication and effective goal-setting among stakeholders in the rehabilitation process [32], they should also provide feedback to support the interest and progress of individuals with stroke [58,59], which is often limited or not adequately provided in current practices, as observed in this study. However, a range of digital technologies have been found to be integral to self-management for stroke survivors in the rehabilitation process, suggesting that these technologies can prevent therapists from taking over before users are able to do things themselves [20]. Nevertheless, both our findings and the findings of existing research have revealed a distinction between the therapeutic understanding of goal effectiveness and actual digital rehabilitation activities. Resistance to trivial digital technologies offering only engagement has been noted, and there are opportunities to target stroke survivor–specific goals and functional outcomes [53].

Figure 1. Diagram illustrating an example of the first overarching theme (with subthemes) and its relationship with social practice theory concepts. HCP: health care professional; NAV: Norwegian Labor and Welfare Administration; SMART: specific, measurable, achievable, relevant, and time-bound.

The exploration of how digital practices manifest within written documents and in community practices could be valuable, as discharge summaries are important for communication between health care levels and for ensuring continuity of rehabilitation [60]. There is potential for digitalizing written reports, and future research should be performed in this area. Although written reports are widely used, which is consistent with the findings of other studies, they lack the ability to facilitate both adherence and feedback [53]. While this was highlighted by the HCPs, it remains unclear whether therapists' decision-making regarding new technological infrastructure is constrained by institutional requirements of productivity, and if so, to what extent [61]. In this study, paper-based reports contrasted with the incentives of outsourcing digital information. Studies have found that stroke discharge summaries often report on activities of daily living and sensorimotor and general cognitive functions, but they frequently omit stroke survivors' needs and goals [60], and this is likely to increase with further digitalization and user feedback.

Our results contribute to the debate on whether technologies conflict with care and relationship building, emphasizing the need to transfer traditional communication skills, such as empathy, to digital platforms [62]. Claims about jeopardizing interpersonal connections due to being lost in data or a lack of in-person interactions have been made [63-66]. One reason technology may conflict with care is the limited sensory input it provides, highlighting the distinction between the critical social dimensions of humans as social sensors and some technologies as environmental sensors [67]. Despite this limitation, it has been found that using technologies can balance the roles toward a more symmetric relationship compared with the classic asymmetric stroke survivor-caregiver and HCP relationship often found in hospitals [62]. Digital platforms for collaboration, shared decision-making, and data storage can add value to a person-centered rehabilitation process [32], which, despite technology uptake, still drives rehabilitation and remains the rule of practice [52]. Video-based technologies enhance the ability to strengthen confidential and honest communication

XSL•FO
RenderX

[62], but they present ethical [24] and privacy considerations for family members, involve sharing sensitive information, and may invade stroke survivors' homes [68]. However, it is crucial not to lose or diminish face-to-face contact due to increased use of ICT, especially during the initial stage of establishing a relationship with a stroke survivor [12]. In our study, digital technologies interfered with some therapeutic communication skills, especially during communication with individuals having depressive or cognitive impairments, such as aphasia. Nonetheless, being reflexive about the technological environment in which therapists work and its impact on clinical practice has been advocated [69], despite disagreements in rating the importance of factors related to therapists' decision-making in implementing new technologies [61].

This study presented examples of therapists being unable to practice without certain technologies and concerns about losing therapeutic skills or positions owing to technology takeover. Concepts like technological determinism and disruption indicate that technologies shape societal structures and practices [70,71]. Similarly, the idea that new technologies disrupt social practices, norms, and even moral concepts has been revisited in the context of 21st-century technologies, particularly AI [71]. These concepts imply a reduced role for agents in changing practices, which we do not acknowledge, and this rather points back to the distribution of responsibility. In this study, we identified examples of technology that could shift responsibility and change routines. Therefore, new therapeutic communication skills are essential to adapt technology to people [70,72].

Assessments of stroke survivors' functional levels are needed not just in the initial phase but throughout rehabilitation to evaluate necessary adjustments. However, consideration of assessment accuracy must be taken into account [53]. Research supports that assessment is an important feature from the perspective of HCPs when using digital technologies in stroke rehabilitation [57,73]. In this study, digital monitoring enabled closer follow-up on progress and increased stroke survivors' self-management through collaboration with therapists. Shared understanding and priorities can promote technology implementation, including understanding its role relative to conventional therapy, training models, and evidence-based practice [52].

In motor rehabilitation, digital technologies appeared more complicated owing to the principles of intensity and repetition, which often require in-person assistance. While stroke rehabilitation may be too complex for full digitalization, partial implementation is feasible, especially combined with in-person support. Studies have found significant effectiveness of VR for varied outcomes [74], particularly for improving cognitive function compared with conventional care in a hospital setting [75]. Digital technologies for motor rehabilitation might be effective in a hospital setting but might face limitations in home environments [74]. In a previous study, participants continued the same types of exercises at home, transferring skills and preserving performance [75], which HCPs in our study noted as challenging. Additionally, studies have cautioned against the misfit between participants' needs and available technology, emphasizing the importance of coherent content and use to avoid misunderstandings and misuse in practice [32,53]. This approach depends on the stroke trajectory and the practice setting, as individuals may experience different recovery paths and require tailored interventions based on the stroke onset and the environment in which they receive rehabilitation [53]. The diverse perceptions between the 2 practices in this study appear to be related to engaging with people at different stages of stroke onset in the cross-section of hospitalization and home rehabilitation. The consideration of a continuous digital transition that follows stroke trajectories and becomes more self-managed in the chronic phase seems appropriate.

Researching rehabilitation practices raises questions about what is involved in stroke rehabilitation. Motor rehabilitation, as described by Kwakkel et al [43], involves a process that enhances the motor function, activity capacity, and daily performance of stroke survivors, aligning with the International Classification of Functioning, Disability and Health (ICF) framework [76]. Rehabilitation extends beyond restoring function, aiming to maximize independence and facilitate participation in home and community life [77]. Our study highlights varied perceptions of rehabilitation, underlining its multidisciplinary nature and the importance of coordinated and cross-professional contribution [32]. A digitalized rehabilitation service will require changes in the workflows of professionals, fostering cross-disciplinary collaboration to build capacity and ensure greater availability across time and settings. This shift will challenge traditional professional boundaries while breaking down silos between researchers and clinicians [78].

Strengths and Limitations

The data and findings in this study are unique as we applied social practice theory, which allowed us to comprehensively analyze the current and potential future influence of digital technologies for HCPs in poststroke rehabilitation and increased our awareness and reflexive interpretation of the contextual factors influencing these practices. It is acknowledged that the successful implementation of digital technologies depends on not only their inherent qualities but also how they are adopted and integrated into existing practices by HCPs. Maintaining an explorative approach, the findings are broad and consistent with the complexity and comprehensiveness of rehabilitation. A potential limitation of this study is the extended data collection period, which spanned 2 years but was divided into specific recruitment timepoints. While this allowed for a broader capture of experiences and perspectives, shifts in practice or external factors during this period may have influenced the findings. Some digital technologies, such as videoconference systems, VR tools, and webinar tools, were more frequently integrated into HCPs' daily practices at the first site during an earlier recruitment period (2022 - 2023), while step counters were more regularly used at the second site. These differences may reflect evolving practices influenced by project-based initiatives and specific time periods. These temporal variations should be considered when interpreting the results. Representatives of most multidisciplinary HCPs in specialized stroke rehabilitation participated in this study, with the majority recruited from a hospital rather than a community-based clinic. The inclusion of specialist stroke rehabilitation hospital wards provides a more specific context. As the participants emphasized cross-service collaboration and community collaboration, reflections from

XSL•FO
RenderX

community therapists could have added nuances to the findings. No psychologists participated as individual professionals, and only 1 HCP with a background in psychology took part. Future research could investigate the perspectives of psychologists and mental health specialists to expand the theme of psychosocial support and better tailor digital technologies to the psychological and emotional needs of stroke survivors. This study focused on the statements of HCPs regarding how they performed practices, while an ethnographic study would have provided detailed information about the implicit social structures in a specialized stroke rehabilitation practice. The use of RTA allowed for deep engagement with the data, enhancing transparency in the research process. Moreover, the collaboration between experienced researchers and clinicians ensured a robust and informed analysis, strengthening the study's credibility. Although this study covered current and proposed future technologies, it might have missed emerging innovations or future novel digital tools that the participants might not have been aware of, such as generative AI and robotics, which could potentially revolutionize practices. The study acknowledged challenges in stroke survivor follow-up continuity after referral, suggesting that future research is needed to explore detailed solutions and develop strategies for effective digital integration in rehabilitation.

Conclusion

This study found that HCPs used different technologies during their daily specialist care practices, as well as for the coordination and follow-up of stroke survivors after referral to community services. While all practice themes influenced rehabilitation practices, ambivalence and challenges were noted, particularly in digitalizing multidisciplinary psychosocial support and exercise programs. Despite ambivalence, digital technologies can serve as valuable supplements for stroke recovery, enhancing accessibility, competence, information flow, and quality care. This study identified several factors, such as organizational processes, roles, standards, and rules, that can act as barriers or drivers to implementing digital technologies in practices, emphasizing coherence among content (thing), use (agent), and aim (rules). Systems for sharing medical records and goal-setting apps, which are aimed at enhancing coordination and stroke survivor involvement, were emphasized as future digital technologies that can shape stroke rehabilitation. Viewing technology as a supplement to existing practices, rather than a singular solution for all areas of specialized stroke rehabilitation, offers significant potential for quality improvement. By focusing on leveraging already familiar technologies, specialized stroke rehabilitation integrates agent skills, physical tools, and practice guidelines, forming strategies to enhance the use and effectiveness of digital technologies in the field. Our findings may inform technology developers, health care personnel, and user groups in specialized neurological rehabilitation settings.

Acknowledgments

We would like to thank all the health care professionals who participated in the individual interviews in this study.

Abstract

Background: As individuals with HIV live longer, many now face the health consequences of aging and multimorbidity, known as disability. Exercise can mitigate disability; however, engagement in exercise among adults living with HIV varies. Technology-based interventions, such as telerehabilitation, may help mitigate geographical, financial, and time barriers to community-based exercise (CBE). However, little is known about the experiences with technology uptake and usage among adults living with HIV. Understanding these experiences is essential to inform the design of inclusive, accessible, and sustainable online interventions.

Objective: This study aimed to describe experiences with technology uptake and usage among adults aging with HIV participating in a 6-month online CBE intervention and explore how these experiences changed over time, from baseline to postintervention.

Methods: We conducted a longitudinal qualitative descriptive study and secondary analysis using interview data from adults living with HIV who were engaged in a CBE intervention study in Toronto, Canada. Participants engaged in a 6-month online CBE intervention consisting of thrice-weekly exercise supervised biweekly through online personal coaching sessions, weekly group exercise classes, and monthly self-management education sessions (via Zoom). The technology used included Zoom software and a webcam, as well as the Sweat for Good YMCA app and the YMCA Virtuagym website; participants wore a wireless physical activity monitor (Fitbit Inspire 2) throughout. Participants completed interviews at baseline and postintervention. We conducted a group-based content analysis of interview transcripts, focusing on digital access, setup, usage, and perceptions of technology. Questionnaire data describing digital literacy and access to technology provided additional context to the interview data.

Results: Eleven participants completed at least one interview. We analyzed 19 interview transcripts from 11 participants (women: n=6, 55%; men: n=5, 45%; median age 52, IQR 45-60 y). Experiences with technology uptake and usage among adults aging with HIV were characterized by four components: (1) preparations for technology (technology setup), (2) interactions with technology (preferences for different types of technology, preferences for mode of delivery, and ease of usage), (3) facilitators and satisfaction with technology (facilitators to technology uptake and usage and satisfaction with technology), and (4) challenges and frustrations with technology (barriers to technology uptake and usage and frustrations with technology). Experiences with technology across participants were influenced by intrinsic contextual factors (prior exposure to technology) and extrinsic contextual factors (COVID-19 pandemic and technological and social support).

Conclusions: Experiences with technology among adults aging with HIV engaging in an online CBE intervention varied from increasing ease of use to increasingly burdensome over time. Results highlight the need to incorporate personal preferences and ongoing technological support when implementing online CBE with adults aging with HIV.

Introduction

Approximately 65,000 people in Canada are living with HIV as of 2022, with an estimated 40.8 million people globally living with HIV at the end of 2024 [1,2]. Antiretroviral therapy has enabled people with HIV to live longer; however, many may also be living with associated multimorbidity affecting cardiovascular, autoimmune, musculoskeletal, and neurodegenerative systems [3,4]. These health challenges constitute disability that may manifest as episodic over time [5].

The Episodic Disability Framework conceptualizes disability as multidimensional and episodic, characterized by periods of wellness and illness [5,6]. The framework includes 6 dimensions of disability experienced by adults aging with HIV: physical, cognitive, and mental-emotional symptoms and impairments; difficulties with day-to-day activities; challenges to social inclusion; and uncertainty or worry about the future [5,6]. Intrinsic contextual factors (eg, personal attributes and coping strategies) and extrinsic contextual factors (eg, social support and stigma) can exacerbate or alleviate disability over time [5]. This framework provides a foundation to understand the health challenges experienced by adults living with HIV and the strategies to mitigate episodic disability.

Exercise and physical activity are rehabilitation strategies that can mitigate episodic disability among adults aging with HIV. Physical activity is defined as any type of bodily movement that results in energy expenditure, while exercise is a subset of physical activity that is planned, structured, and repetitive, with a goal of improving or maintaining physical fitness [7]. Systematic reviews indicate that adults living with HIV who engage in exercise at least three times weekly can experience improvements in cardiopulmonary fitness, strength, and quality of life [8-11]. The World Health Organization (WHO) recommends that adults, including persons living with chronic conditions, such as HIV, should engage in at least 150 minutes of moderate to vigorous intensity aerobic physical activity per week alongside muscle-strengthening activities on 2 or more days [12]. Despite the benefits, engagement in exercise can vary among adults living with HIV.

Systematic review evidence indicates that only 51% of adults living with HIV met exercise guidelines of 150 minutes of moderate to vigorous aerobic exercise weekly [13,14]. Barriers to exercise engagement were multifactorial, encompassing personal factors (lack of motivation, time constraints, and health concerns), social barriers (competing priorities and HIV-related stigma), and environmental challenges (transportation and financial constraints) [15-18]. Community-based exercise (CBE) programs can facilitate engagement in exercise among adults living with HIV, fostering social interaction and self-management strategies through organized exercise programs under supervision in community-based facilities [19,20]. In-person CBE can improve cardiovascular health, strength, and flexibility outcomes among adults living with HIV [21]. However, the complex and episodic nature of HIV, coupled with stigma, body image concerns, geographical barriers, and scheduling conflicts, can limit the engagement of persons living with HIV with in-person CBE programs [17].

Telerehabilitation, the delivery of rehabilitation services remotely using technologies, offers promising solutions to geographical, financial, and time barriers limiting access to exercise interventions [22-26]. Telecoaching, a component of telerehabilitation, uses technology for remote supervision and guidance to deliver an exercise program to improve physical activity levels and symptom management in chronic diseases [27-29]. Technology is an integral part of telecoaching CBE interventions to facilitate engagement in exercise; however, experiences with the uptake and usage of technology among adults aging with HIV engaged in such an intervention are unknown.

Technology encompasses digital tools designed to streamline care delivery, increase exercise engagement, and improve health outcomes [30]. This includes telecommunication platforms, web applications, and wireless physical activity monitors (WPAMs). Technology uptake refers to the initial adoption of technology by users, whereas usage refers to how individuals apply these tools, considering the frequency, functionality, effectiveness, and adherence of use [31]. Among adults aging with HIV, technology can support health-promoting behaviors and exercise engagement [25,26,32]. Systematic reviews highlight the role of technology in enhancing group exercise participation through social support and can help to alleviate barriers by addressing geographical, financial, and time constraints [33,34]. Technology-based exercise interventions are supported for use in chronic conditions such as Parkinson disease, chronic obstructive pulmonary disease, and stroke [27,29,35]. Despite positive trends in technology-facilitated exercise interventions, it is unclear how technology is taken up and used among adults aging with HIV.

Several factors can influence technology uptake and usage among adults living with chronic conditions, including prior exposure to, and awareness of, types of technologies, digital literacy, accessibility, and required support for use [36-39]. In HIV-specific contexts, there is growing interest in using technology to support engagement in exercise [32,40-42]. The purpose of this study was to describe experiences with technology among adults aging with HIV engaged in an online CBE intervention. The specific objectives were to describe (1) experiences with technology uptake and usage and (2) how experiences with technology may change over time among adults aging with HIV engaging in an online 6-month CBE intervention.

Methods

Study Design

We conducted a longitudinal qualitative descriptive study and secondary analysis using interviews and questionnaire data from

XSL•FO
RenderX

adults aging with HIV who participated in a 6-month online CBE intervention (Tele-Coaching CBE Study) [42]. Our qualitative design was supported by quantitative (questionnaire) data collected at baseline, month 2 (after initial exposure to the intervention), and month 6 (post intervention).

Context: Telecoaching CBE Study

The telecoaching CBE study was a prospective longitudinal mixed-method intervention study designed to evaluate the implementation of a 6-month online telecoaching CBE program for adults aging with HIV, delivered in collaboration with the Toronto YMCA [42]. Participants were community-dwelling adults living with HIV who self-identified as safe to engage in exercise based on the Physical Activity Readiness Questionnaire. Recruitment occurred through the Ontario HIV Treatment Network Cohort Study and community-based organizations in Toronto [42,43].

In phase 1 (intervention phase), participants were expected to engage in 60 minutes of exercise thrice weekly. Sessions were supervised biweekly by a YMCA personal trainer via Zoom, and participants were asked to attend monthly online self-management sessions for 6 months. In phase 2 (independent phase), participants continued with unsupervised exercise thrice weekly for 6 months. Participants were provided with a WPAM (Fitbit Inspire 2; Fitbit Inc) to track steps, distance, calories burned, and active minutes. Throughout both phases, participants received a YMCA online membership that provided access to synchronous group exercise classes via Zoom and recorded workouts (also called Avatar Workouts), YMCA Virtuagym website, and the Sweat for Good YMCA app. An engagement coordinator assisted participants with the setup of the technology and was available to provide support as needed throughout the intervention.

Investigators of the online CBE study conducted qualitative interviews via Zoom with a subset of participants at baseline (time point 1 [T1]) and postintervention (time point 2 [T2]) to explore their experiences and perceived impact of the intervention [44]. Full protocol details for the online CBE study have been published [42]. In our study, we focus on interview data pertaining to participants' experiences with technology during phase 1 of the telecoaching CBE study.

Technology in Online CBE Intervention

Technology was integral to the online CBE study, serving roles in (1) intervention delivery, (2) facilitating engagement in physical activity, and (3) measuring outcomes. For the purpose of this study, we defined technology as the *tools* (hardware, software, networks, and web applications) and *processes* (methods and strategies used for instruction, assessment, and physical activity tracking) used in the telecoaching CBE study. Key technological components included Zoom software (Zoom Communications, Inc) and a webcam for online personal training sessions and self-management education sessions; Sweat for Good YMCA app and YMCA Virtuagym website for live group exercise classes, prerecorded workouts, and recorded personalized workouts created by a personal trainer; WPAM (Fitbit Inspire 2) for motivation and measurement of physical activity; and technology-supported assessments, including online fitness assessments and interviews via Zoom, administration of patient-reported outcome measures via Qualtrics web-based survey software, body composition scale, and Fitbit app for syncing activity data [42]. In this study, we focused on experiences with technology pertaining to components of the intervention delivery.

Participants and Recruitment

Eligible participants for the telecoaching CBE study were required to have access to (1) a cell phone, tablet, laptop, or desktop computer; (2) internet access via Wi-Fi or a wired connection; (3) a webcam; and (4) a personal space for exercise. A subset of the participants in the telecoaching CBE study was invited to participate in the qualitative component of the study. Women living with HIV were purposively recruited to the qualitative study to enhance gender diversity within the sample.

In our study, we included community-dwelling adults aging with HIV (≥18 y) in Toronto, Canada, who considered themselves medically stable and who were safe to participate in the telecoaching CBE study and completed at least one qualitative interview at either baseline (T1) or postintervention (T2).

Patient and Public Involvement

We consulted with 3 community experts who self-identified as living with HIV. These consultations provided contextual insights into exercise and technology experiences within both in-person CBE and online CBE interventions. We met with each community expert via Zoom to discuss their experiences related to exercise engagement, intervention process, technology usability, and feasibility. These consultations provided foundational information for understanding the intervention and technology use and ensured our analysis and interpretation of interview data were informed by persons living with HIV.

Data Sources

Interviews

We used interview transcripts from semistructured interviews conducted at baseline (T1) and postintervention (T2) within the online CBE study to explore participants' experiences with technology uptake and usage and how experiences changed over time. The interviews were completed from October 8, 2021, to July 28, 2022, by members of the research team. We reviewed full transcripts, focusing our analysis on data that pertained to technology experiences. Interview questions at baseline about technology uptake and usage included: "Do you have any concerns or perceived challenges of participating in the upcoming CBE intervention?" and "How do you feel about adopting the technology necessary for the upcoming online CBE telecoaching intervention?" Interview questions at T2 focused on technology experiences, such as: "How would you describe your experience using the technology as part of the CBE telecoaching intervention?" and "Have there been any strengths or challenges associated with the translation of the telecoaching CBE intervention into the HIV community?" Interviewers used open-ended general and probing questions to explore technology uptake, learnability, usability, and change in experiences over time. Relevant interview guide questions

XSL•FO
RenderX

are highlighted in Supplemental File 1 in Multimedia Appendix 1. Participants received a $30 CAD (US $23) electronic gift card for their participation in each interview.

Questionnaires

We used 3 questionnaires to capture participant demographics and describe technology access characteristics, digital literacy, and telehealth experiences. The demographic questionnaire (administered at baseline) was used to describe participants' personal, health, and exercise behavior characteristics. The Information and Communications Technologies Development Index Questionnaire (administered at baseline) included 11 items to describe participants' digital access, connectivity, and literacy [45,46]. The Telehealth Indicator Questionnaire (administered at months 2 and 6) included 22 items with the aim to assess technologies used as part of the online CBE intervention across key telehealth domains, including usability (ease of use and navigation; 7 items), helpfulness (6 items), satisfaction (6 items), and reliability (3 items) [45,47].

Data Analysis

Interview Data

We conducted a collaborative group–based qualitative content analysis using a 6-step approach informed by the DEPICT model [48]. Five team members (JM, RH, MM, CD, and RA) independently read all transcripts, followed by group discussions to identify emerging codes related to technology uptake and usage. A preliminary codebook was developed based on the study objectives and operationalized technology experiences from the online CBE intervention study. We piloted the codebook on 3 transcripts with the most technology-related content. The team met 6 times to refine code definitions, incorporate barriers and facilitators to technology uptake and usage, and eliminate redundancies of codes. After 3 iterative revisions, 2 team members independently coded each transcript [48]. We used NVivo 15 software for data management [49]. For each participant, we wrote brief summaries of their technology experiences and interpretations of change over the intervention with the aim to identify patterns in how participants interpreted technology use and its impact over time. Our analytical process included team discussions for clarification, critical reflection, and consensus building [48]. To identify technology experiences over time, we coded each T1 and T2 transcript concurrently. We summarized individual experiences, documented reflections on changes in experiences, and identified data reflecting temporal changes. We discussed interview findings with questionnaire data to provide contextual interpretations.

Questionnaire Data

We analyzed the questionnaire data using Microsoft Excel [50]. For the Information and Communications Technologies Development Index Questionnaire, Telehealth Indicator Questionnaire, and demographic questionnaire, we calculated frequencies and percentages for categorical variables, and medians with 25th and 75th percentiles for continuous variables. For the Telehealth Indicator Questionnaire, we assessed the direction of change in responses between months 2 and 6 when responses differed between time points. For example, in the "satisfaction" domain, a change from "excellent" to "poor" indicated a negative change in participants' experiences with technology. Supplemental File 2 in Multimedia Appendix 2 provides the Telehealth Indicator Questionnaire. We included all questionnaire data where available at each time point.

We analyzed the interview and questionnaire data concurrently using descriptive approaches. We used the questionnaire data to inform our content analysis of the interview data, specifically by providing additional context to participant personal and health characteristics and their access to and familiarity with technology to enhance our interpretations and deepen our understanding of experiences with uptake and usage of the technology.

Sample Size Justification

We had a fixed sample of 11 participants from the online CBE study who completed at least one interview at T1 or T2. Of these, 8 participants completed both T1 and T2 interviews, 2 participants completed the T1 interview only, and 1 participant completed the T2 interview only. This sample size is comparable to those of prior qualitative studies examining technology experiences in telehealth exercise interventions among individuals with chronic conditions [51,52].

Ethical Considerations

Ethics approval for this study (protocol 47552) and the broader telecoaching CBE study (protocol 40410) was obtained from the University of Toronto Health Sciences Research Ethics Board. All participants in the telecoaching CBE study who completed an interview provided written or verbal informed consent. Data sources including transcripts and questionnaires were deidentified, meaning participant data were identified using a participant number to ensure confidentiality of participants. Participants received a CAD $30 (US $23) electronic gift card for their participation in each interview.

Results

Characteristics of Participants

Of the 11 participants (median age 52, IQR 45-60 y), 6 (55%) identified as women, 5 (45%) identified as heterosexual, and 6 (55%) identified as Black. The majority of participants (n=9, 82%) had an undetectable viral load. Five (45%) participants reported living with ≥3 concurrent health conditions in addition to HIV. Exercise behavior among participants prior to the intervention varied. Three (27%) participants did not engage in exercise in the past week, 5 (45%) engaged in 1 to 2 days, and 3 (27%) engaged in 5 or 7 days of ≥30 minutes of moderate to vigorous intensity exercise in the past week. Table 1 provides participant characteristics.

Access To, Skills in, and Use of Technology at Baseline

At baseline, most participants had access to a cell phone (n=10, 91%), a laptop with a webcam (n=9, 82%), and reliable Wi-Fi access (n=9, 82%). All participants (100%) reported they were comfortable using web browsers, online meeting tools, WPAMs, and fitness apps at baseline. Table 2 provides participant characteristics regarding access to, skills in, and use of technology.

Comfortable using online meeting tools	11 (100)
Comfortable using wireless physical activity monitor	11 (100)
Comfortable using webcam	11 (100)
Comfortable using physical activity apps to track physical activity	11 (100)
Confirmed skills and use of technology	11 (100)

Experiences With Technology Uptake and Usage

Participants' experiences with technology during the online CBE intervention varied. We organized our findings into four interrelated components: (1) preparations for technology, (2) interactions with technology, (3) facilitators and satisfaction with technology, and (4) challenges and frustrations with technology. Participants' experiences with technology were shaped by both intrinsic contextual factors, such as their prior exposure and anticipated comfort with technology, and extrinsic contextual factors, including the COVID-19 pandemic and availability of technological and social support. These factors affected how participants engaged with the technology (uptake and usage) in the study, as well as the benefits and challenges they experienced (Figure 1). Below, we present each component with supportive quotations identified by participant number and interview time point.

XSL•FO
RenderX

Figure 1. Experiences with technology uptake and usage in an online community-based exercise (CBE) intervention among adults aging with HIV.

Preparations for Technology

This component captures how participants prepared their physical spaces and devices to engage with the study. Preparation was not limited to technical setup; it also involved adapting the home environments to accommodate space for exercise and facilitate active participation. These preparatory steps often required creativity and problem-solving. Most participants reported having adequate space for exercise, although some required modifications, as illustrated below:

> *Other than the sense to figure out where my laptop would be so that the instructor could see me and figure out how my apartment would work. It's a small apartment... I wish I didn't have to use my box [exercise equipment] because it would be great to put my laptop on to get the whole view of my workout area. But no. I think I'll figure it out. I've just got to move some things, just change the angle of some things.* [P2, T1]

The following participant described their experiences trying to set up their Zoom to the TV for optimal viewing of their personal trainer during the online session:

> *I'm hoping I can run a Zoom meeting off my iPhone. But I think what I'm going to need is get a cable to connect to the HDMI cable on the TV. So it's just a bit of technical stuff to get all that set up. I've got a little tripod that I can set the phone on. The microphone will work through the phone. It will just be a question of running the display out of the phone with a cable into the HDMI connection.* [P5, T1]

Interactions With Technology

Participants described a variety of experiences interacting with technology, reflecting differences in preferences, confidence, and adaptability. Participants' descriptions of their experiences interacting with technology focused primarily on preferences for different types of technology, preferences for mode of delivery, and ease of technology use.

The preferences for types of technology participants used included Zoom, Fitbit, computer, laptop, webcam, Fitbit app, and Sweat for Good YMCA app. Zoom was the primary platform for online telecoaching sessions with the personal trainer, with most participants accessing Zoom via a laptop or desktop with a webcam, while a smaller number preferred mobile phones or connecting Zoom to their TVs to enhance convenience or visibility, respectively.

The Fitbit device and the Fitbit app were largely used to track step counts by most participants. The following participant explained the use of the Fitbit:

> *I like wearing it [Fitbit] but not for the reason for exercise because I don't understand anything on it. I like it for two reasons; number one, I can see steps and number two I can see time [...]. Besides that, because I don't know technology, I didn't really benefit from the usefulness of having a Fitbit that it*

XSL•FO
RenderX

> *can tell you more stuff. But for these two reasons it was good enough for me.* [P11, T2]

The Sweat for Good YMCA app was used to attend online group exercise classes, prerecorded workouts, and the Avatar workouts, offering participants flexibility with both synchronous and asynchronous options. Preferences for mode of delivery varied between synchronous and asynchronous modes of online exercise delivery. Some found the synchronous Zoom training sessions straightforward, while others found it stressful due to technical challenges and preferred the convenience of the asynchronous classes of the Sweat for Good YMCA app. The following participant struggled with navigating the Sweat for Good YMCA app stating:

> *However, first of all trying to get everything set up for a synchronous event I just found it incredibly stressful again because of trying to navigate the technical challenges. Then when I saw the instructor on the screen they were doing some warmup things at a pace that I could barely keep up with.* [P5, T2]

This same participant (P5) specifically struggled to maintain pace during the synchronous exercise class through the Sweat for Good YMCA app, stating:

> *So the synchronous thing, it just wasn't for me. Really the thing that has most worked for me is just knowing routines that [name of personal trainer] has given me and writing them down and keeping up with that on my own. The less I have to interface with technology in this kind of remote setup, the better.* [P5, T2]

Ease of technology use referred to how easy participants found the technology to be. Many participants anticipated positively adopting the new technology at T1. However, their actual ease of use varied once they began engaging with the technology. This participant describes their experiences with their ease-of-use learning about the technology:

> *With me in trying to figure out technology, it was straightforward. Like once I plugged in to charge it, it told me to download the App and then once I did that, it was a step by step. It's more still figuring out the features. Like, I had no idea that it already recorded my sleep overnight until my roommate and bestie looked it up and was like okay.* [P2, T1]

Another participant was surprised to find the use of the technology to be challenging and required additional support to navigate:

> *Well initially… and this kind of took me by surprise. I didn't realize how difficult the technical part of things would be. It was horrendously difficult, the technical part. In fact, AM, we gave up an entire hour of training because AM got her daughter involved on her daughter's laptop, and we went through setting by setting to try to eliminate the terrible echo. You know I'm a big advocate of clear communication and Zoom has done a terrible job and most software providers do a terrible job of explaining things.* [P5, T2]

Facilitators and Satisfaction With Technology

This component explores what helped participants successfully adopt and use technology and how these factors contributed to their satisfaction. Facilitators ranged from supported features such as activity tracking and sharing their progress in social circles to practical benefits such as convenience and cost savings. These elements often reinforced participants' motivation and sense of accountability.

One participant described using the Fitbit to stay accountable:

> *So my mom has a Fitbit too and I added her as a family member or friend. So now she gets to see how much I am doing for the day. There will be days that she'll talk to me or whatever or like I'll send her my badges that I've won* [P2,T2]

The following participant appreciated not having to commute to a gym facility. They highlighted the convenience and cost-saving benefits of using Zoom rather than having an in-person personal training session:

> *The advantage of just having to get up and not have to drive anywhere. Just get up and you know have your Zoom on. So that was very convenient, very convenient. Yeah. I'm not spending gas. Like gas prices are ridiculous right now.* [P1, T2]

Satisfaction with technology referred to participants' approval with the online platforms they engaged with through the CBE intervention. Some participants indicated that they were satisfied with having access to the tools that supported their goals. Several participants described the Fitbit as helpful for monitoring their progress with physical activity. Many participants found that the weekly summary reports from Fitbit were rewarding and motivated their continued engagement:

> *A part of the study that worked best for me. For me I would say like I have best... okay definitely Fitbit. Fitbit is like... not only having the Fitbit. It helped me to track all my things right; the steps, those all sleeping patterns and even like weekly we have to something that report. Those are all in the Fitbit Apps. So those things that, seeing those all tracked, So those things that, seeing those all tracked, it satisfied me. It motivates me. I want to see like in the number or in the papers and these apps really help give me all those things what I'm looking* [P8, T2]

One participant talked about how features of the Fitbit as well as the online platforms encouraged their participation:

> *It's sort of like an encouragement to do more. These watches are good because I've sort of got used now to whenever I'm out walking to enter the time. The classes, the sessions or lectures that you have are very good.* [P3, T2]

Challenges and Frustrations With Technology

Participants also experienced challenges and frustrations with the study technology. At times, these challenges hindered engagement in components of the intervention.

XSL•FO
RenderX

Zoom was generally perceived as a useful platform; however, some participants reported technical challenges, including audio delays, echoing, and unstable internet connections. At time point 1, one participant shared their concerns about the stability of their internet:

> *In the neighborhood I live in, the internet has gone down I don't know maybe two handfuls of a time within the past six months. So you never really know.* [P2, T1]

Another participant talked about the lack of accessibility of the Fitbit features:

> *The second is if you've got any issues around sight, any, I mean even if you don't have issues around sight, you can't see these things. You go into the... you go outside, it's... so like you do your walk and you're finished and you come back and you go am I at the screen where it's turned off? You can't tell because you can't read it. And of course the writing is so small that people that have impaired vision, even if you can see it, it's difficult to read.* [P10, T2]

Frustrations with technology were tied to the reliability of the technology and to design limitations. This included Zoom audio delays, sound issues, echoing, and connectivity problems. Participants noted that Zoom provided insufficient support, requiring them to troubleshoot issues independently, as per the following participant:

> *It's just technical stuff, those little quarks about my particular setup. There was a time when I was having audio issues, and it was downright stressful to be there [self-management sessions] for the hour and a half-* [P5, T2]

Another participant shared their frustrations related to the Fitbit, including device setup, blank display screen, and concerns about inaccurate tracking:

> *The biggest demotivator for this whole thing is that stupid Fitbit that they gave us, utterly useless, good for nothing, utterly useless. The only thing I use it for is to count whether it's counting the number of steps. That's it. Every month since I got it there's been some issue with it. For some reason it went into some other country time on its own and then at some point it just completely the screen was blank and it dimmed on its own at some point. Every time it does something on its own.* [P7, T2]

Contextual Factors

Participants' experiences with technology were shaped by a range of contextual factors that influenced both uptake and ongoing use of technology in the online CBE intervention. Together, intrinsic and extrinsic contextual factors influenced how participants approached technology, the challenges they anticipated, and the strategies they used to overcome barriers.

Intrinsic contextual factors included prior exposure to technology that influenced a participant's anticipated comfort or challenges with the forthcoming technology in the online CBE intervention. Six (54.5%) of the 11 participants previously or currently owned WPAMs, such as an Apple Watch, Samsung Watch, or a Fitbit. Many participants had previously used Zoom prior to the intervention. Participants with prior exposure to technology often reported increased confidence of use at baseline and anticipated greater comfort with technology use, as this participant stated:

> *That's okay. I have a degree in computer sciences so it's not an issue.* [P7, T1]

When another participant was asked about perceived challenges regarding updating software with technology associated with the CBE intervention, they responded:

> *No. As far as updating the equipment and stuff I'm fairly... that goes fairly easy for me.* [P10, T1]

Extrinsic contextual factors included the COVID-19 pandemic and available technical and social support throughout the intervention. Many participants reported that the COVID-19 pandemic normalized the use of technologies, such as Zoom. For some participants, the COVID-19 pandemic led them to their first exposure to technology as it forced them to engage with technology in new ways. This participant reflected on both the safety and convenience of technology as well as the convenience of exercising from the comfort of their own home:

> *One is the times that we're in with COVID, I mean I think there's a safety component to this. …. for a lot of people too because a person's immunity is a vital part of the constitution. I think the convenience of being able to just be at home and in the comfort of your own home is helpful.* [P10, T1]

Another participant acknowledged the motivational pull that comes from an in-person gym setting yet still preferring online sessions for safety concerns that began during the COVID-19 pandemic:

> *To be honest while in the pandemic I prefer to going online. That way I'm safe, I'm good. But also going into the gym and seeing others working out kind of pushes you like listen that person can do it, why can't I. So, it kind of gives you that push compared to online because online is just me and my trainer. I know they will probably push you but it's not the same as actually seeing somebody else, maybe somebody else bigger or somebody older actually doing it easier than you. So, it kind of gives you that push. But I'm more than happy with online right now.* [P7, T1]

Availability of technical and social support played a key role in how some participants planned to address technical challenges in the study. Some participants mentioned the technology support services having insufficient troubleshooting resources and resulting in alternative methods to troubleshoot. This participant reported:

> *I wouldn't say they [technical issues] become an obstacle. Normally when I can't figure out something I just Google or go on YouTube and figure out what it is, what's going on and how to fix it.* [P6, T1]

Other participants depended on their social support network to assist with device setup or to resolve technical issues. When

XSL•FO
RenderX

asked about navigating technical difficulties at home, 1 participant shared how they relied on their children for assistance:

> *If I can't function something I just call them, 'hey show me how this works.* [P1, T1]

Changes in Experiences With Technology Within the CBE Intervention Over Time

Interview data revealed participants had inconsistent experiences with uptake and usage of technology over the duration of the intervention. Some participants experienced increasing levels of technology fatigue and burden over the course of the intervention. Some participants found technology a challenge at both T1 and T2. For 1 participant, by T2, their concerns evolved into frustrations with the technology expressing technology fatigue and burden, particularly with the requirement to download and sync their physical activity each week for the study:

> *This synching up for the Fitbit and the recording on what's gone on over the week, it gets to be a bit of a pain to be honest.* [P5, T2]

Although participants attempted to problem-solve their challenges, frustrations continued with efforts to use the Fitbit. The requirement to sync their Fitbit data weekly became a burden and at times resulted in disengagement and frustration. In contrast, another participant was optimistic with using the Fitbit at T1:

> *Having the coach itself is a very good benefit right...it will motivate me -- oh I'm wearing a Fitbit, so I have to do, let's just do it' and also do the exercise.* [P8, T1]

By T2, this participant's expectations appeared to have been met, and they expressed their intent to continue using the technology beyond the study*:*

> *even giving this Fitbit, I will use it unless it will not damage. If it damage, then definitely I'm going to buy another one because Fitbit gives all that report.* [P8, T2]

Another participant expressed uncertainty about technology usage in T1 and had an indifferent attitude toward the Fitbit and its role in the intervention, stating:

> *I mean I think they are all the same. They don't have any difference. So I don't know. Like what information do you want from these watches?* [P3, T1]

However, by T2 their perspectives regarding the Fitbit had changed:

> *It's good. Fitbit is… after the first or second time that you enter the information online it becomes very easy. Yeah, it's good.* [P3, T2]

This participant experienced a learning curve but was able to reduce barriers and increase usability of the Fitbit with continued use. Overall, initial attitudes toward the technology did not always predict participants' engagement with participants' engagement or satisfaction during the study. Some participants encountered technology fatigue around repetitive tasks such as Fitbit syncing, while others reported increased comfort and motivation.

Telehealth Indicator Questionnaire Responses

Eight (73%) participants completed the Telehealth Indicator Questionnaire at months 2 and 6 of the intervention. Across the 8 participants, the majority (n=6, 75%) demonstrated no change in most responses to the 22 items at months 2 and 6. Two (25%) participants had a change in a positive direction at month 6 in 10 (46%) and 12 (55%) of the 22 items. Supplemental File 3 in Multimedia Appendix 3 provides each participant's direction of responses to the 22 items of the Telehealth Indicator Questionnaire, related to usability, helpfulness, satisfaction, and reliability of the technology in the CBE intervention captured at months 2 and 6.

Across the 22 items, the majority of participants (50% - 88%) reported similar responses (representing no change) for most items (14/22, 63%) at months 2 and 6 of the intervention. An exception was responses to the usability and helpfulness of self-directed learning modules, whereby 5 participants (62%) demonstrated a positive direction of change in their response from months 2 to 6. Conversely, 4 (50%) participants showed a negative change in direction in responses to the usability of the Fitbit and helpfulness of the YMCA Virtuagym website from months 2 to 6 (Supplemental File 3 in Multimedia Appendix 3).

Discussion

Overview of Findings

Experiences with technology uptake and usage among adults aging with HIV were characterized by 4 components: (1) preparations for technology, (2) interactions with technology, (3) facilitators and satisfaction with technology, and (4) challenges and frustrations with technology. Experiences with technology interacted with intrinsic contextual factors (prior exposure linked to anticipated comfort or challenges with technology) and extrinsic contextual factors (COVID-19 pandemic; and technological and social support). Some participants experienced increasing technology burden and fatigue over time, others maintained neutral perspectives throughout, while others developed intentions for continued use postintervention.

Experiences With Technology Uptake and Usage

Technology in the online CBE intervention included a combination of digital tools and platforms, including WPAMs (Fitbit Inspire 2), a videoconferencing platform (Zoom), webcams, the Sweat for Good YMCA app, and YMCA Virtuagym website. Participants demonstrated variation in experiences with technology uptake and usage across different technologies, with preferences emerging for specific types of technology and modes of delivery. Synchronous coaching sessions via Zoom achieved relatively high amounts of uptake following initial setup, likely facilitated by prior exposure gained during the COVID-19 pandemic [53]. The widespread adoption of Zoom during the COVID-19 pandemic likely created a foundational level of comfort that translated well to the synchronous coaching sessions, with participants expressing

XSL•FO
RenderX

appreciation for the flexibility and immediate feedback available through this platform [26,53]. In contrast, participants in this study had variable experiences with the Sweat for Good YMCA app and WPAMs. While WPAMs were primarily used for real-time monitoring of physical activity metrics such as step counts and sleep patterns, the Sweat for Good YMCA app was used to administer asynchronous exercise content. Participants had varied preferences for synchronous or asynchronous tools that had implications for engagement with technology within the intervention. This has direct implications for considerations of technology uptake and usage in digital intervention design, suggesting the need to align online CBE interventions with user preferences for both the type of technology and the mode of delivery. Hence, it is important to recognize that adults aging with HIV may respond differently to synchronous tools that offer real-time human connection versus asynchronous tools that require greater independence [17,18,26].

All participants recruited for the telecoaching CBE study were required to have access to and comfort with the usage of technology. Despite all participants reporting comfort with different forms of technology at baseline, participants expressed challenges with uptake and usage of technology in the intervention. Of the 11 participants, 6 (66%) had prior exposure to a WPAM; however, this was insufficient for sustained uptake and usage of the Fitbit Inspire 2. Additionally, participants voiced inconsistent usage of more complex platforms, such as the Sweat for Good YMCA app. The disconnect between high baseline comfort and subsequent struggles with technology may reflect the requirement for participants to simultaneously navigate multiple technology platforms in the intervention that exceeded individual comfort with each component of the technology [18,26]. These findings suggest that technological complexity, rather than basic digital technology skills, posed a greater barrier to sustained use among adults living with HIV [39]. Future interventions should move beyond one-time onboarding to include tailored, continuous support that addresses and simplifies multiplatform navigation and adapts to participants' evolving needs among adults aging with HIV [17,39,54]. Additionally, future CBE interventions may consider offering a broader range of WPAMs, such as commercially available smartwatches and fitness trackers. Tailoring digital health wearables based on individual preferences, digital health literacy, and accessibility may provide customizable feedback and enhance usability and sustained use over time.

Participants highlighted several facilitators and points of satisfaction with the technology used in the online CBE intervention, including flexible access to workouts, real-time interaction with personal trainers, and digital tools for self-monitoring physical activity. Zoom was consistently highlighted for its convenience and flexibility, supporting real-time interaction with personal trainers, accountability, and routine building, factors shown to improve exercise adherence among adults aging with HIV [17,54,55]. The WPAM served as a motivator for some, enabling self-monitoring of physical activity, steps, and sleep, which some participants found satisfying and empowering. Similar to prior studies, gamification features of WPAMs and real-time feedback supported users' sense of progress and enhanced intrinsic motivation among adults aging with HIV [30,32,40]. The Sweat for Good YMCA app provided asynchronous, on-demand workouts that aligned with participants' preferences for flexibility and autonomy, reinforcing the importance of choice between synchronous and asynchronous formats among adults aging with HIV [55]. These findings suggest that digital tools and processes can support engagement in exercise among adults aging with HIV when designed to be adaptable, user-friendly, and reinforced through personalized feedback and social accountability [18,41,55]. Future interventions should leverage these features by integrating reliable self-monitoring technologies and offering multiple modes of delivery to enhance engagement in online CBE interventions among adults aging with HIV.

Challenges and frustrations with technology use in this study included device syncing failures and navigation difficulties with the Sweat for Good YMCA app and connectivity problems with Zoom videoconferencing. WPAMs were valued for their feedback features but also generated frustration when step counts were perceived as inaccurate or syncing required repeated effort. This aligns with systematic measurement errors in consumer WPAM devices and the importance of balancing the motivational benefits of self-monitoring technology against potential user frustration from technical limitations for adults aging with HIV [40,56]. Participants described difficulty finding exercises to match their activity levels due to navigation difficulties on the Sweat for Good YMCA app. While Zoom was generally reliable, several participants reported audio lag and video freezing, issues commonly experienced in online digital health interventions with synchronous videoconferencing among adults aging with HIV [26,39,55]. Difficulties with device accuracy, navigation of fitness apps, and technical troubleshooting are widely reported in studies involving adults living with HIV using WPAMs or engaging in online exercise interventions [17,44,55]. While these technical experiences are not unique to this sample population, they occur within a context shaped by the challenges of aging with HIV, including health unpredictability, stigma, and the risk of loneliness [57-60]. Embedding lived experiences into intervention design and ongoing technical support are essential strategies to overcome digital barriers and promote uptake and usage with online CBE interventions among adults aging with HIV.

Changes in Technology Experiences Over Time

Changes in experiences with technology over time demonstrated initial attitudes toward technology that did not always predict sustained use with the technology. Some participants experienced increasing technology burden and fatigue, others maintained neutral perspectives throughout, while others developed optimistic intentions for continued use postintervention. Participants used Zoom consistently throughout, as evidenced by consistent usability responses on the Telehealth Indicator Questionnaire, likely due to its relative simplicity, prior exposure, and use as a communication platform with their personal trainer. While the use of WPAMs and the Sweat for Good YMCA app may have declined, this may be attributed to persistent technical issues and limited adaptability. This mirrored patterns of engagement with digital health technology seen in adults aging with HIV [32,55,61]. Some participants reported feeling overwhelmed by syncing

XSL•FO
RenderX

requirements, app navigation, and inconsistent device feedback in the online CBE intervention, factors that diminished motivation and created friction in maintaining regular technology use. This aligns with research that prolonged exposure to poorly optimized tools can lead to emotional and cognitive fatigue, especially among users managing multimorbidity [19,41]. Positive changes in technology use were most apparent in self-directed components, suggesting that asynchronous, exploratory technology use may become more rewarding over time as users gain confidence. For adults aging with HIV, these findings reinforce the need for sustained technical support and simplified interface design, as digital interventions must be responsive, flexible, and grounded in lived experience to facilitate long-term engagement in online CBE interventions [17,18,55].

Strengths, Limitations, and Implications for Future Research

A strength of this study was the longitudinal observational design involving both interview and questionnaire data, allowing for an in-depth understanding of participants' experiences with technology over time. Interview and questionnaire data were analyzed separately, with the questionnaires used descriptively to provide context to the interview findings. We conducted a collaborative content analysis among the team, allowing for diverse perspectives to be integrated throughout coding and interpretation. This iterative, team-based process supported reflexivity and rigor in the analysis. Additionally, input from community experts living with HIV helped ground the analysis in the lived experiences of the HIV community.

Our study sample size was fixed based on the existing data in the telecoaching CBE study. Reaching thematic saturation was not a goal of our study. However, in the results, we indicate the participants via participant number and time point alongside interview quotes to indicate the contribution of participant perspectives across the breadth of categories. Other strategies to enhance rigor included our inclusion of all available interview and questionnaire data for participants across the study. Collectively, we believe we were able to capture an ample description of participants' perspectives related to experiences with uptake and usage, enabling us to achieve our study objectives.

Regarding study limitations, the interviews were not solely focused on technology; hence, the amount of data and depth of insights specific to technology use was limited. Not all participants completed interviews at T1 and T2 or the Telehealth Indicator Questionnaire at T2, which limited the ability to explore participants' changes in technology experiences over time. Our sample was drawn from community-dwelling adults living with HIV in Toronto, a large urban center with strong digital infrastructure, limiting transferability to rural or remote settings with greater barriers to connectivity and access to the internet. Additionally, future work should examine sex and gender differences in technology experiences and engagement within online CBE interventions among adults aging with HIV to promote equitable access, engagement, and effectiveness [62].

Conclusions

Experiences with technology uptake and usage among adults aging with HIV were characterized by 4 components, including preparations for technology use, interactions with the technology, facilitators and satisfaction with technology, and challenges and frustrations with technology. Experiences with technology interacted with intrinsic contextual factors (prior exposure linked to anticipated comfort or challenges with technology) and extrinsic contextual factors (COVID-19 pandemic and technological and social support). Among adults aging with HIV, changes in technology experiences over time highlighted the unpredictability of initial impressions, with some participants expressing technology fatigue and burden, whereas others maintained consistent attitudes of usage over time with intentions to continue using digital tools and processes beyond the intervention. Findings with experiences of technology uptake and usage in this study underscore the importance of incorporating personalized and tailored onboarding and sustained technological support with an online CBE intervention to promote engagement in physical activity among adults aging with HIV.

Acknowledgments

This research was completed in partial fulfillment of the requirements for an MScPT degree in the Department of Physical Therapy, Temerty Faculty of Medicine at the University of Toronto. We thank Maple Leaf Medical Clinic for their support with recruitment via the Ontario HIV Treatment Network Cohort Study for this study. We acknowledge members of the original and ongoing telecoaching community-based exercise study team who were instrumental to the acquisition of funding and implementation of the study: Francisco Ibáñez-Carrasco, Ahmed M. Bayoumi, Ada Tang, Kiera McDuff, Tizneem Jiancaro, George Da Silva, Brittany Torres, Mona R. Loutfy, Shaz Islam, Joanne Lindsay, Colleen Price, Mehdi Zobeiry, Zoran Pandovski, Ivan Illic, Puja Ahluwalia, Darren A. Brown, Lisa Avery, and Patricia Solomon. We specifically thank Kiera McDuff and Julia Nathanson for their support with the telecoaching community-based exercise study. We acknowledge the individuals who volunteered their time to participate in the research as well as the staff, volunteers, and community-based settings who supported the implementation of the study. Specifically, we thank community experts, John, George, and Richard, who generously shared their time, perspectives, and lived experiences throughout the course of this study.

Abstract

Background: Community-based exercise (CBE) can prevent and mitigate disability and improve health outcomes in people aging with HIV; however, engagement in exercise can vary.

Objective: This study aims to describe the fidelity of implementation (FOI) of an online telecoaching CBE intervention with adults living with HIV.

Methods: We conducted an observational longitudinal study involving a 6-month online CBE intervention involving thrice-weekly 60-minute exercise sessions; online biweekly supervised one-on-one exercise sessions with a personal trainer (13 sessions); and online monthly group educational sessions. We assessed fidelity using (1) online structured interviews with participants living with HIV at months 2 and 6, comprising 20 fidelity items on trainer performance, participant engagement, and exercise experiences; and (2) coaching logs completed by personal trainers after biweekly training sessions (frequency, intensity, time, and type of physical activity during supervised sessions and self-reported physical activity in the prior week). We considered FOI criteria to be met if ≥80% of the participants living with HIV: (1) attended ≥80% of training sessions (11 of 13 sessions); (2) engaged in thrice-weekly exercise the week of the personal training session ≥80% of the time over the 6-month intervention, as reported on the coaching logs; (3) reported "complete criteria met" for ≥80% of the fidelity items (≥16 of 20 items) at month 2 and month 6, as reported from the interviews; and (4) engaged in a combination of aerobic, strength, balance, and flexibility exercise ≥80% of the time over the 6-month intervention, as reported in the coaching logs.

XSL•FO
RenderX

Results: A total of 29 of 32 participants completed at least 1 fidelity interview; 69% (22/32) were male. FOI was met for 1 of our 4 criteria among the 18 participants who completed the intervention and FOI assessment at month 6, specifically criterion 1, whereby 83% (15/18; 95% CI 66%-100%) of participants attended ≥80% of the 13 coaching sessions. For criterion 2, 50% (9/18; 95% CI 27%-73%) of participants engaged in thrice-weekly exercise in the week of the personal training session ≥80% of the time over the 6-month intervention; criterion 3: ≥80% of participants reported criteria as "completely met" for 70% (14/20 items; 95% CI 50%-89%) of items at month 2 (n=27 participants) and 30% (6/20 items; 95% CI 10%-50%) of items at month 6 (n=18 participants); and criterion 4: 22% (4/18; 95% CI 3%-41%) of participants engaged in a combination of all 4 exercise types ≥80% of the time. Barriers to engagement included scheduling issues, lack of interest, technology problems, and episodic disability.

Conclusions: FOI was achieved for supervised components of the CBE intervention and less so with independent exercise. Health and rehabilitation providers should tailor exercise interventions to personal preferences and abilities to improve engagement among adults living with HIV.

Introduction

Overview

In Canada, over 65,000 people were estimated to be living with HIV at the end of 2022 [1]. More individuals are living longer and aging with HIV; globally, persons living with HIV aged 50 years or older increased from 5.4 million in 2015 to 8.1 million in 2020 [2]. As people living with HIV age, they can experience health-related consequences of HIV, including an increased risk of cardiovascular disease, diabetes, bone and joint disorders, neurocognitive disorders, and certain cancers [3-5]. Rehabilitation, such as physical therapy and occupational therapy, can mitigate disability associated with HIV and multimorbidity, such as fatigue, pain, cognitive impairments, body composition changes, and employment challenges [6-9]. Exercise is a rehabilitation intervention and self-management strategy that can address disability and improve or sustain the health of individuals with HIV. Systematic review evidence indicates that exercise is safe and can lead to benefits in cardiopulmonary fitness, strength, weight and body composition, and psychological outcomes for people with HIV [10,11]. However, this evidence primarily involved supervised interventions by physical therapists and exercise physiologists that can be costly and unsustainable [10,11]. With up to an estimated 73% of people living with HIV classified as sedentary or physically inactive, it is essential to consider exercise interventions that are accessible and practical for people with HIV to sustain over the long term [12].

Community-Based Exercise

Community-based exercise (CBE) is a promising approach that may help people living with HIV increase their engagement in exercise and physical activity [13-16]. Exercise is purposeful, planned, and repetitive bodily movement that has the objective of improving or maintaining physical fitness, while physical activity is any bodily movement that results in energy expenditure [17]. Persons living with HIV perceive benefits from exercise and physical activity as a component of health promotion, with the potential to improve physical function and mental health and reduce isolation [18]. CBE can be provided under the guidance of a health or fitness instructor, with the aim of encouraging consistent exercise and physical activity within the community [13,14,16]. CBE enhances the benefits of traditional exercise as it can improve social interaction, provide support and motivation, and promote emotional, cognitive, and behavioral self-management strategies to help individuals manage health challenges [14,19,20]. CBE has been associated with engagement in physical activity and improvements in health outcomes for adults living with HIV [19,21]; however, the factors influencing the implementation and uptake of CBE are less clear.

Implementation of CBE

Using the Consolidated Framework for Implementation Research (CFIR), Cooper et al [22] conducted a qualitative systematic review of CBE interventions to explore barriers and facilitators of implementing CBE interventions in the general population [22]. Barriers included lack of participant motivation, insufficient resources allocated for implementation, the complexity of the CBE intervention, and lack of participant knowledge about the intervention [22]. Facilitators included the flexibility to adapt the intervention to the context, intervention compatibility with participants, and participants having a positive perception of those implementing the intervention [22]. The authors concluded that making minor changes to tailor an intervention while maintaining core components, such as clear implementation strategies and coordination of delivery, can facilitate the implementation of a CBE intervention.

Members of this authorship team assessed the impact of an in-person CBE intervention with adults living with HIV at the YMCA in Toronto, Ontario, Canada [21]. While the team reported improvements in cardiovascular health, strength, flexibility, and self-reported physical activity, barriers to taking part in CBE were documented among women, persons who are gender diverse, and persons who did not live geographically close to the YMCA [21]. Persons with HIV may experience obstacles to exercising in traditional gym environments, including interpersonal, financial, and geographical barriers, self-image issues and stigma, and difficulty initiating exercise following periods of inactivity [23,24].

Telerehabilitation in the Context of HIV

Telerehabilitation, and more specifically telecoaching, is a potential strategy for implementing CBE with persons living with HIV. Telerehabilitation is the delivery of rehabilitation programs or services via technology, such as phone and video calls, web-based platforms, or mobile apps, used initially to increase efficiency, quality of care, and access to health care for populations with geographical [25,26], financial, or time-limiting barriers for persons living with HIV [27]. Telecoaching is a component of telerehabilitation that uses technology for remote supervision, guidance, and communication of an exercise program to improve physical activity levels and manage symptoms for people living with chronic diseases [28-33].

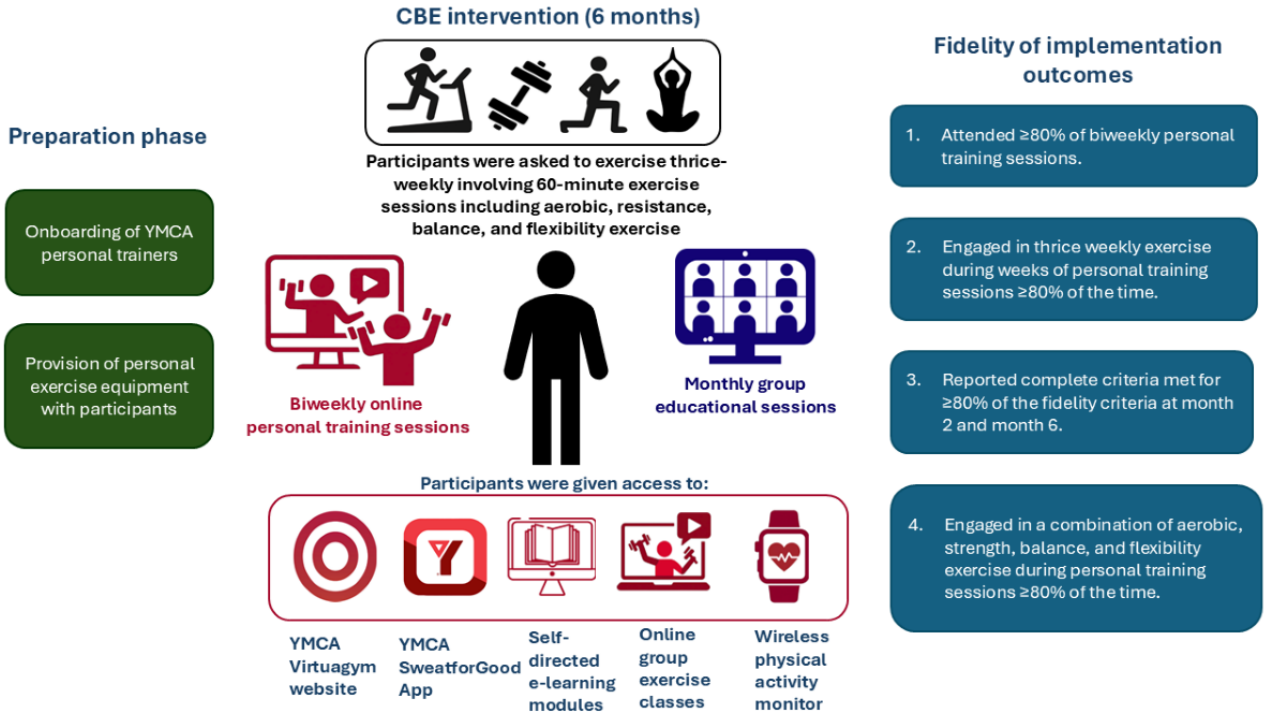
Telecoaching CBE Study

We established an online telecoaching CBE intervention with the aim of enhancing engagement in physical activity among adults living with HIV in Toronto, Canada [34]. The intervention was developed based on foundational considerations for developing and implementing online CBE with adults living with HIV that included: (1) person-specific considerations (episodic nature of HIV, stigma, and HIV disclosure), (2) accessibility of the program, (3) program delivery and technology, (4) attributes of program personnel, (5) program content and design, and (6) building community and peer support [35].

Fidelity of implementation (FOI) is important to consider in online CBE interventions to develop practical interventions that lead to sustained physical activity. FOI, or integrity, is the degree to which programs are implemented as intended by the program developers [36-38]. The National Institutes of Health Behavior Change Consortium (BCC) treatment fidelity framework specifically refers to treatment fidelity and the link between training the providers, delivery, receipt, and enactment of the intervention for research involving health behavior interventions [39]. The fidelity with which an intervention is implemented can influence its level of success and uptake, and the impact on the outcome, with high fidelity promoting improved outcomes. However, it is important to consider planned adaptations to the intervention to optimize treatment fidelity while acknowledging the need to accommodate practical needs, study demands, and provider and participant burden, requiring pragmatic approaches in real-world settings [39]. Lack of fidelity can lead to failure in intervention implementation in a real-life context [40]. Hence, reporting fidelity is essential to determine the credibility, validity, and replicability of intervention study findings [41]. Despite the importance of understanding intervention fidelity, lack of knowledge or understanding about assessing fidelity may be barriers to assessment and reporting [42]. While quantitative and qualitative methods are recommended to comprehensively assess fidelity, this guidance is not consistently followed [39,42-44]. To our knowledge, there is limited evidence assessing the FOI of exercise interventions for persons living with HIV. Assessing the FOI of exercise interventions in the context of HIV is important because (1) sustained exercise can mitigate HIV-related disability, and (2) people living with HIV can face unique barriers and facilitators to exercise, such as episodic disability, which can influence the FOI of exercise interventions [45].

Our aim was to describe the FOI of a 6-month online telecoaching CBE intervention with adults living with HIV from the perspectives of participants (adults living with HIV) and personal trainers.

Findings from this study may help inform policy and programming for broader scale-up and optimal CBE implementation that can be adopted by fitness centers and community-based organizations to proactively prevent multimorbidity and improve health outcomes among persons living with HIV.



Methods

Study Design

We conducted an observational longitudinal study involving (1) online structured interviews with adults living with HIV who participated in a 6-month online CBE intervention and (2) coaching logs of training sessions completed by personal trainers. Details of the study protocol have been previously published [34]. Figure 1 provides an overview of the CBE intervention and fidelity outcomes.

XSL•FO
RenderX

Figure 1. Overview of online community-based exercise (CBE) intervention and fidelity of implementation outcomes. YMCA: Young Men's Christian Association.

Participants

We included adults living with HIV who participated in the telecoaching study and personal trainers from the YMCA who were involved in supervising personalized online exercise sessions with the study participants [34]. Eligibility criteria for the telecoaching study were adults (aged 18 years or older) who considered themselves safe to engage in exercise as determined by the self-administered Physical Activity Readiness Questionnaire (PAR-Q) and had access to an electronic device with an internet connection and a webcam, as well as space at home for exercise [34]. We recruited potential participants living with HIV through community-based organizations, an HIV clinic in Toronto via the Ontario HIV Treatment Network Cohort Study (OCS), and participants from a prior CBE study who agreed to be contacted about future research [21,46].

Telecoaching Online CBE Intervention

Prior to the CBE implementation, fitness instructors (certified personal trainers and staff at the YMCA) took part in workshops on HIV, rehabilitation and exercise for adults living with HIV, goal setting, and research procedures [47]. We piloted the setup of the technology, including (but not limited to) Zoom software [48], a webcam, YMCA membership, web-based questionnaire software, and the Fitbit app [49] with the participants living with HIV and fitness instructors.

The telecoaching online CBE intervention included a 6-month structured intervention phase followed by an independent 6-month exercise phase [34]. During the 6-month intervention phase, participants were asked to engage in the following three components of the intervention: (1) an exercise regimen of aerobic, resistance, balance, and flexibility exercise occurring thrice weekly at moderate to vigorous intensity for ≥60 minutes per session; (2) attend online biweekly individually tailored one-on-one exercise sessions with a certified personal trainer from the YMCA, involving supervision and progression of aerobic, resistance, balance, and flexibility exercise; and (3) engage in online monthly group educational sessions on sleep, nutrition, goal setting, cognitive health, chronic pain, and other topics related to self-management, health, and physical activity while living with HIV, delivered by members of the research team. Each participant met with their personal trainer prior to the intervention to tailor the intervention to their goals, abilities, and interests [50]. Participants received a YMCA membership allowing them to access online YMCA classes through the YMCA SweatforGood app. Personal trainers uploaded the individualized exercise plans to the SweatforGood app, allowing participants to access, review, and track their exercises [34].

After the 6-month intervention, participants entered a 6-month follow-up independent exercise phase, during which they were asked to continue with thrice-weekly exercise. They continued to have access to the YMCA online membership, providing access to group online classes, and the SweatforGood app, but the study no longer provided one-on-one personal training sessions or monthly educational sessions.

Participants were given home exercise equipment (Therabands and a wooden step) and a wireless physical activity monitor (Fitbit Inspire 2) to monitor and encourage exercise during both the 6-month CBE intervention and the 6-month follow-up period. Participants documented their physical activity through a weekly online exercise log. Participants were given the Fitbit Inspire 2 and exercise equipment to keep at the end of the study as a token of appreciation for their participation. For more details, see the published protocol [34].

We aimed to recruit 40 adults living with HIV and 30 to complete the intervention, enabling us to achieve our primary

XSL•FO
RenderX

study aim of assessing the impact of the CBE intervention [23,51].

Data Collection

Overview

We used a combination of structured interviews with participants living with HIV and information collected in coaching logs completed by personal trainers to assess FOI.

Structured Fidelity Interviews: Perspectives of Persons Living With HIV

We conducted structured interviews with participants living with HIV to obtain perspectives on experiences with the CBE intervention and assess the extent to which the prescribed exercises were delivered according to the established program (FOI). Two members of the team conducted the interviews on Zoom. Interviews were approximately 10 minutes in duration and occurred partway through (month 2) and at the completion of the intervention (month 6). Participants were asked to share their experiences based on their most recent online personal training session and provided insights on any deviations from the prescribed regimen in an open-ended comment section. Responses were recorded electronically on an FOI form developed in Microsoft Word (Multimedia Appendix 1). Each question was scored by research staff as 0 (no criteria for fidelity were met), 1 (partial criteria met), or 2 (complete criteria met). For example, for the item regarding whether the "fitness provider provided direct and clear instructions during...[the] exercise session," the item would be rated 0 if the participant stated that the instructions provided by the fitness provider were never clear or direct; 1 if the participant stated that the instructions provided by the fitness provider were sometimes clear and direct; or 2 if the participant stated that the fitness provider's instructions were always clear and direct. TJ also documented open-ended responses from the participants to further describe barriers and facilitators to fidelity and provide additional context to the numeric ratings.

We evaluated FOI based on 20 items (defined a priori) captured in the interviews. The items were divided into four sections: (1) the completion of their exercise session within the allotted time (1 item), (2) their personal trainer's performance during the session (7 items), (3) participant engagement and experience within the session (6 items), and (4) the broader online CBE study (6 items; Multimedia Appendix 1). FOI for a participant was defined as met if a participant met ≥80% (16/20) of the indicators at months 2 and 6 (from the perspective of the participant living with HIV). Overall, we considered FOI as met if ≥80% of the participants in the study met (achieved) ≥80% of FOI indicators (16/20 items; criterion 3).

Coaching Logs of Personal Training Sessions: Perspectives of Personal Trainers

After each supervised online training session with participants living with HIV, the personal trainers completed an online web-based questionnaire, referred to as the "coaching log." Personal trainers were asked to document (1) whether the participants attended their biweekly personal training session; (2) whether they engaged in aerobic, strength, balance, and flexibility exercise during their biweekly personal training session; and (3) the number of days each participant exercised in the week prior to their session (Multimedia Appendix 2).

FOI for a participant was defined as met, from the perspectives of the personal trainers, if a participant attended ≥ 80% (11 out of 13) of their biweekly coaching sessions (criterion 1), if they exercised 3 times over the past week for ≥1 hour per session (criterion 2), and if they completed a combination of all 4 exercise components (aerobic, strength, balance, and flexibility) ≥80% of the time across their personal training sessions (criterion 4). Collectively, we considered FOI as met if ≥80% of the participants in the study achieved these 4 criteria (Table 1).

Table 1. FOI[a] interpretation criteria.

FOI criteria for each participant[b]	Target population	Data source
Criterion 1: attended ≥80% of biweekly training sessions (at least 11 of 13) over the 6-month intervention	Personal trainers	Coaching logs
Criterion 2: engaged in thrice-weekly exercise the week of the personal training session ≥80% of the time over the 6-month intervention	Personal trainers	Coaching logs
Criterion 3: reported "complete criteria met" for ≥80% of the fidelity items (at least 16 of 20 items) at months 2 and 6 of the intervention	Participants living with HIV	Structured interview at months 2 and 6
Criterion 4: engaged in a combination of aerobic, strength, balance, and flexibility exercise during supervised personal training sessions ≥80% of the time over the 6-month intervention	Personal trainers	Coaching logs

[a]FOI: fidelity of implementation.

[b]Overall FOI was considered "met" for the community-based exercise intervention if the 4 criteria were achieved by ≥80% of participants.

Participant Demographic Questionnaire

We administered a web-based demographic questionnaire to participants living with HIV to collect baseline characteristics such as age, gender, time since HIV diagnosis, and race and ethnicity.

Analysis

Overview

We entered numeric responses from the FOI form collected during the interviews, coaching logs, and demographic questionnaires into Microsoft Excel and analyzed the data using

XSL•FO
RenderX

descriptive statistics [52]. We calculated frequencies and percentages for categorical variables and the median and IQR for continuous variables.

Structured Fidelity Interview

We reported the number and percentage of participants living with HIV who reported "no criteria met" (0), "partial criteria met" (1), and "complete criteria met" (2) for each of the 20 items assessed at months 2 and 6, based on the participants' most recent training session (criterion 3). Open-ended responses from the structured interviews were analyzed using content analysis [53].

Coaching Logs

We calculated the median number of personal training sessions attended over the 6-month intervention (out of 13 sessions total). We calculated the number and proportion of participants who engaged in a combination of all 4 exercise types (aerobic, strength, balance, and flexibility) during the supervised coaching session. We calculated the number and proportion of participants who reported engaging in thrice-weekly exercise in the week of the personal training session, as recorded by the personal trainers in the coaching logs. We summed the number and proportion of participants who attended ≥80% (11/13) of biweekly coaching sessions (criterion 1), summed the number and proportion of participants who engaged in thrice-weekly exercise ≥80% of the time over the 6-month intervention (criterion 2), and the number and proportion of participants who completed the combination of all 4 exercise types in ≥80% of the sessions they attended (criterion 4) [54-56].

To account for attrition across the 6-month intervention, we reported baseline characteristics of participants at baseline and at months 2 and 6. We reported fidelity outcomes among participants who remained in the study at month 2 and who completed the intervention at month 6, as well as the original sample of participants who initiated the intervention.

Fidelity Interpretation

We defined overall FOI of the CBE intervention as achieved if the following 4 criteria were met by ≥80% of the participants in the study: criterion 1, attended ≥80% (11/13) of their 13 training sessions; criterion 2, engaged in (at least) thrice-weekly exercise in the week of the personal training session ≥80% of the time over the 6-month intervention, as recorded by the personal trainers on the coaching logs; criterion 3, reported "complete criteria met" for ≥80% of the fidelity elements (at least 16 of 20 items) at months 2 and 6, as reported in the interviews with participants living with HIV; and criterion 4, engaged in a combination of aerobic, strength, balance, and flexibility exercises during the supervised coaching sessions ≥80% of the time over the 6-month intervention, as reported by the personal trainers in the coaching logs. Our criteria are based on the literature, whereby 80% to 100% is considered high fidelity, and ≤50% defines low FOI [54-56].

Ethical Considerations

This study was approved by the University of Toronto Health Sciences Research Ethics Board (#40410). Participants provided informed verbal consent to participate in the study, which was documented on the consent form. Participant data were anonymized and stored on a secure server at the University of Toronto. Participants did not receive compensation for their participation in the exercise intervention. They were able to retain their exercise equipment and wireless physical activity monitor at study completion.

Results

Overview

Adults living with HIV who initiated the intervention and had at least 1 completed coaching log were included in the study. Of the 32 participants, 18 (56%) completed the 6-month intervention and had an FOI interview assessment. A total of 29/32 (91%) participants who completed at least 1 fidelity interview were included in the FOI analysis. Further, 16 (50%) participants completed the FOI assessment (interviews) at both months 2 and 6; 11 (34%) completed the assessment at month 2 only, and 2 (6%) completed the assessment at month 6 only. Of a potential 64 fidelity interviews, 45 (70%) were completed. At month 2, a total of 84% (27/32) of assessments were completed, and at month 6, a total of 56% (18/32) of assessments were completed.

Of the 32 participants at baseline, the majority were male and living with 2 or more concurrent health conditions in addition to HIV. Table 2 provides characteristics of participants enrolled in the study at baseline, month 2, and month 6.

XSL•FO
RenderX

Table 2. Characteristics of participants living with HIV at baseline and among those who completed an FOI[a] interview at months 2 and 6.

Characteristic	Baseline (n=32)	Month 2 (n=27)	Month 6 (n=18)
Age (years), median (IQR)	53 (44-60)	50 (42-59)	57 (47-59)

Living with 2 or more concurrent health conditions in addition to HIV, n (%)	23 (72)	18 (67)	11 (61)

[a]FOI: fidelity of implementation.

[b]Participants could select more than 1 response.

[c]CAD $1=US $0.71 as of August 1, 2026.

Of the 32 participants, a total of 8 (25%) who initiated the intervention completed all 13 coaching sessions, 7 (24%) of whom were among the 29 participants who completed an FOI assessment interview. We received responses to 72% (298/416) of the coaching logs out of the total possible for 32 participants living with HIV to determine FOI from the perspectives of personal trainers.

Fidelity Results

Overall Fidelity

FOI was met for attendance criterion 1 among participants who completed the intervention, whereby 83% (15/18; 95% CI 66%-100%) of participants attended ≥80% of their personal training sessions (Table 3). We describe results as they pertain to each criterion below.

XSL•FO
RenderX

Table 3. Summary of FOI[a] criterion achievement.

FOI criterion	Data source	Participants who met the criteria among those who initiated the intervention (n=32), n (%); 95% CI	Participants who met the criteria among those who completed the intervention and month 6 FOI assessment (n=18), n (%) 95% CI	Fidelity met: achieved by ≥80% of participants (yes or no)
Criterion 1: attended ≥80% of biweekly personal training sessions (at least 11 of 13 sessions)	Coaching log attendance documented by personal trainers	18 (56); 39-73	15 (83); 66-100	Yes[b]
Criterion 2: engaged in thrice-weekly exercise the week of the personal training session ≥80% of the time over the 6-month intervention[c]	Coaching logs documented by personal trainers	11 (34); 18-50	9 (50); 27-73	No
Criterion 3: reported "complete criteria met" for ≥80% of the fidelity criteria (≥16 of the 20 items) at months 2 and 6[d]	Structured interview at months 2 and 6 with participants living with HIV	Month 2 (n=27): 21 (78) 62-93 and month 6 (n=18): 8 (44); 27-67	Month 2 (n=16): 12 (75); 54-96 and month 6 (n=18): 8 (44); 21-67	No
Criterion 4: engaged in a combination of aerobic, strength, balance, and flexibility exercises during supervised personal training sessions ≥80% of the time over the 6-month intervention	Coaching logs documented by personal trainers	8 (25) 10-40	4 (22) 3-41	No

[a]FOI: fidelity of implementation.

[b]Indicates that criterion 1 was met among participants who completed the intervention (≥80%).

[c]For criterion 2, the week of the first personal training session was excluded; baseline was defined as the start of the intervention.

[d]For criterion 3, the proportion of participants who selected "complete criteria met" for ≥80% of the fidelity criteria also were calculated based on the total number of participants who initiated the intervention (n=32). Participants who did not complete the fidelity assessments were assumed not to have met the criteria: At month 2, n=20/32 (63%; 95% CI 46%-79%); at month 6, n=8/32 (25%; 95% CI 10%-40%).

Criterion 1: Attended ≥80% of Personal Training Sessions by ≥80% of Participants

This FOI criterion was met for the participants who completed the intervention and an FOI assessment at month 6; 83% (15/18; 95% CI 66%-100%) of the participants attended ≥80% of the 13 coaching sessions (Table 3). Of all 32 participants, 18 (56%; 95% CI 39%-73%) attended ≥80% of the 13 coaching sessions (Table 3). Of all 32 (100%) participants who attended at least 1 personal training session, the median number of training sessions attended was 11 of 13 (IQR 6-12). Reasons for not attending or having to reschedule the online coaching sessions included scheduling issues, health reasons, or unknown reasons.

Criterion 2: Engaged in Thrice-Weekly Exercise the Week of the Personal Training Session ≥80% of the Time Over the 6-Month Intervention by ≥80% of Participants

This FOI criterion was not met. A total of 34% (11/32; 95% CI 18%-50%) of all participants and 50% (9/18; 95% CI 27%-73%) of those who completed the month 6 FOI assessment engaged in thrice-weekly exercise in the week of the personal training session ≥80% of the time over the 6-month intervention (Table 3). The median number of days of exercise per week for all participants (n=32) and for those who completed the intervention and month 6 FOI assessment (n=18) was 3 (IQR 3-5) and 4 days (IQR 3-5), respectively.

Criterion 3: Participants Living With HIV Reported ≥80% of Criteria as "Completely Met" by ≥80% of Participants

This FOI criterion, defined as ≥80% of participants reporting ≥80% of FOI elements (items) as "completely met," was not achieved at months 2 or 6 (Table 3). Among the participants who completed an FOI assessment, 78% (21/27; 95% CI 62%-93%) and 44% (8/18; 95% CI 27%-67%) of the participants completely met the FOI elements for ≥80% of the 20 items at months 2 and 6, respectively. When considering the entire sample of 32 participants, fewer items met the criteria, whereby ≥80% of participants reported the FOI element as "completely met" for 4 of 20 items at month 2 and none of the 20 items at month 6 (details are provided in Multimedia Appendix 3).

Table 4 provides a detailed breakdown of the FOI assessment across the 20 interview items. At least 80% of participants reported the FOI element as "completely met" for 70% (14/20; 95% CI 50%-89%) of items at month 2 (n=27) and 30% (6/20; 95% CI 10%-50%) of items at month 6 (n=18). At month 2, the following 6 elements did not achieve fidelity at the threshold of ≥80% of participants: (1) participant completed their session in the allotted time (1 hour with coach online; 21/27, 78%; 95% CI 62%-94% of participants completely met this item), (2) participant responded to and completed the most recent weekly exercise email or SMS text message (20/27, 74%; 95% CI 58%-91%), (3) participant completed their additional individual independent exercise sessions (60 minutes twice per week, for a total of 60 minutes thrice per week) in the past week (13/27,

XSL•FO
RenderX

48%; 95% CI 29%-67%), (4) participant managed the required technology (eg, Zoom and SweatforGood app; 15/27, 55%; 95% CI 36%-74%), (5) participant engaged in monthly self-management sessions online (12/27, 45%; 95% CI 26%-63%), and (6) participant attended weekly group-based classes online at the YMCA (8/27, 30%; 95% CI 13%-47%; Table 4). At month 6, the following eight additional elements were not met: (1) fitness trainer instructed participant to complete resistive exercises according to their set exercise program (13/18, 72%; 95% CI 52%-93% of participants completely met this criterion), (2) fitness trainer instructed participant to complete flexibility exercises according to their set exercise program (13/18, 72%; 95% CI 52%-93%), (3) participant engaged in the prescribed strength exercises during the most recent session (12/18, 67%; 95% CI 45%-89%), (4) fitness trainer instructed participant to complete neuromotor/balance exercises according to their set exercise program (12/18, 67%; 95% CI 45%-89%), (5) participant engaged in the prescribed flexibility exercises (12/18, 67%; 95% CI 45%-89%), (6) fitness trainer instructed participant to complete aerobic exercises according to their set exercise program (11/18, 61%; 95% CI 39%-84%), (7) participant engaged in the prescribed neuromotor/balance exercises (11/18, 61%; 95% CI 39%-84%), and (8) participant engaged in the prescribed aerobic exercises during the most recent session (9/18, 50%; 95% CI 27%-73%; Table 4).

Content analysis of the open-ended responses identified barriers to meeting some of the criteria and coaching practices that were helpful for participants. The most common barriers to attending YMCA group-based classes were scheduling issues, lack of interest, and technology issues. Fitbit Inspire 2 wristband discomfort was cited as a barrier to wearing the physical activity monitor regularly. Illness, injury, pain, discomfort, and lack of interest were common barriers to completing the aerobic, resistance, balance, and flexibility exercises. Statements of appreciation for the personal training sessions included “[coach] demonstrates exercises to ensure participant understands proper form” (P16; month 2) and “[coach] demonstrates all exercises/modifications then participant performs, and trainer provides feedback” (P2; month 2). Overall, exercise demonstration, adaptation to participant circumstances, and providing feedback were positive coaching practices identified by participants.

[a]FOI: fidelity of implementation.

[b]Participants were asked about their experiences at their most recent personal training session.

[c]Indicates ≥80% of participants 'completely met' the criteria.

Discussion

Principal Findings

Among participants who completed the intervention and FOI assessment at month 6 (n=18), FOI was achieved for 1 of the 4 criteria, whereby 83% (95% CI 66%-100%) of participants who completed the study engaged in ≥80% of biweekly online personal training sessions. However, fidelity criteria were not met for independent exercise thrice weekly (50%; 95% CI 27%-73%), participant-reported fidelity criteria at month 6 ("complete criteria met" for at least 16/20, 44% of items; 95% CI 21%-67%), or engagement in all 4 exercise types in ≥80% of sessions (4/18, 22%; 95% CI 3%-41%).

Within the training session, the majority of participants engaged in strength and flexibility exercises, followed by aerobic and then balance exercise. This may be attributed to strength training requiring a higher level of supervision as opposed to aerobic activity that was done independently outside the formal personal training session. In the absence of equipment for aerobic activity, such as a treadmill or stationary bike, participants may have engaged in this type of activity independently outdoors.

Fidelity was achieved for some components of the intervention. At least 80% of participants completely met 14 out of 20 FOI elements at month 2 and 6 out of 20 FOI elements at month 6, as reported in the structured interviews. The FOI items least commonly met were independent engagement in exercise (for a total of thrice weekly or more of 60 minutes or longer), attendance at weekly group-based online classes at the YMCA (8/27, 29% of participants met this criterion), and attendance at monthly online group-based educational sessions (12/27, 45% of participants met this criterion).

Supervised vs Independent Forms of Exercise Intervention

Low engagement in the online group-based YMCA classes and independent exercise outside of supervised one-on-one personal training sessions may be influenced by the unsupervised components of the intervention, as participants had higher engagement rates when supervised (ie, personal training sessions). This is consistent with the literature, which shows increased engagement in supervised exercise programs, with adults aged 65 years or older favoring supervised exercise programs [57]. As found within the open-ended FOI responses in this study, receiving feedback, education, and modified exercise tailored to participant preferences and abilities may be important factors driving adherence to supervised exercise [57-60]. The identification of the least-implemented intervention components can help inform future intervention design and may also inform the supports necessary for participants to sustain regular exercise routines postintervention. This may help to identify components of an intervention that require supervision and suggests the importance for future interventions to tailor

XSL•FO
RenderX

CBE based on personalized preferences to promote engagement. Further, there is a need to explore population-specific factors that impact adherence to unsupervised exercise to better develop strategies that improve long-term behavioral change for adults living with HIV.

Group-Based vs Individual Exercise Intervention

FOI criteria were not met for the group-based elements of the intervention. At month 2, a total of 45% (12/27; 95% CI 26%-63%) of participants reported attending the monthly online self-management sessions (≥80% of the time), and 22% (4/18; 95% CI 3%-41%) at month 6 (item 18 in the FOI assessment). At month 2, a total of 29% (8/27; 95% CI 12%-47%) of participants reported attending weekly online group-based exercise classes at the YMCA, and 33% (6/18; 95% CI 12%-55%) at month 6 (item 17 in the FOI assessment; Table 4). With HIV stigma being a barrier to seeking treatment, care, and health- and wellness-related programs, the lower engagement in group-based interventions may have been attributed to fear of HIV disclosure and discrimination [61-64].

The Influence of Environmental and Personal Factors

Personal and environmental factors may further explain the FOI findings in this study. HIV is characterized by episodic disability, where there are unpredictable periods of wellness and illness [65]. Barriers to engaging in the intervention, as reported by participants, included illness, pain, or injury. The fluctuating nature of chronic conditions like HIV may make it challenging for participants to follow highly rigid schedules and training plans if their health and ability to engage in exercise vary day-to-day [23,51]. Perhaps our FOI criteria were too rigid and did not align with or consider the episodic and fluctuating nature of HIV. We recommend providers adapt the frequency and type of exercise to the nature of the illness to maintain the well-being of an individual living with HIV. Our findings indicate the need for flexibility with CBE interventions, enabling persons to cancel or reschedule sessions due to illness more frequently and engage in exercise at home [23,51]. We recommend that exercise interventions in this population be adaptable and considerate of the dynamic nature of the illness experience to ensure that intervention studies are pragmatic and translational to the real world [23,51,60].

While participants were provided with a YMCA online membership at no cost and access to a personal trainer biweekly, their financial situation still may have influenced engagement in the intervention. Income is positively correlated with exercise adherence [66,67]. Qualitative insights from this telecoaching CBE study reported that participants in this study highlighted cost as a limiting factor to engagement in physical activity [60]. A lower socioeconomic status may be correlated with poor exercise adherence due to a lack of leisure time. Individuals of higher socioeconomic status, on average, allocate more leisure time to exercise than those of lower socioeconomic status [66,67]. An association exists between low socioeconomic status and exercise in persons living with HIV, with barriers to exercise including caregiver responsibilities, time dedicated to childcare, unsafe neighborhoods, strict work schedules, and living in temporary dwellings [68,69]. Traditional exercise interventions may not be suitable for those living with HIV who are socioeconomically disadvantaged because of barriers related to employment, financial constraints, stigmatization, and inaccessible or lack of transportation, requiring interventions to be tailored to the needs of this population [68,69]. Collectively, it is important for health and fitness trainers to consider the environmental and personal factors that can influence exercise engagement and intervention adherence to tailor interventions accordingly. This may include tailoring modes of exercise delivery (eg, online and in-person; individual training or group-based classes) based on individual preferences.

Strengths: Assessing Fidelity From 2 Different Perspectives

Strengths of our approach included our multimethod data collection at multiple time points of the CBE intervention and engaging perspectives of both participants living with HIV and personal trainers involved in implementation of the intervention. FOI in our study was assessed more positively from the perspectives of the participants living with HIV (through structured interviews), as opposed to the personal trainers' logs of the coached sessions. Our fidelity assessment from the perspectives of participants living with HIV pertained to their most recent personal training session, whereas fidelity assessment from the perspective of the personal trainers captured engagement in all coached training sessions and the independent exercise done in the preceding week. Using multiple methods to assess intervention fidelity provided a greater understanding of fidelity [70,71] and allowed for different populations to have different perspectives on a shared phenomenon [37,44,70]. Toomey et al [71] recognized that disagreements between results of different fidelity assessment approaches from providers and persons with lived experiences may occur. Some of the differences in FOI findings in our study may be due to participants' overestimation of their performance when completing self-reported measures (2 time points), as compared to the personal training coaching logs completed by providers more frequently across the biweekly supervised sessions (13 time points). Nevertheless, our assessment captured perspectives from both persons living with HIV and the trainers at different stages of the intervention.

Limitations

Our study protocol included methods for capturing the implementation of the intervention components but did not explicitly state the definition of implementation fidelity. Prior to the analysis, we defined the FOI threshold most commonly reported in the literature as achievement of ≥80% of criteria [54-56]. We considered all 4 criteria for FOI to be weighted equally; however, in reality, specific aspects of the CBE intervention may be more important (eg, attendance at biweekly training sessions) to achieve FOI than others (ie, engaging in all 4 types of exercise in the training session). Given that we did not collect fidelity data in the same manner for both target populations (persons living with HIV and personal trainers), we were unable to directly compare the influence of perspectives on fidelity assessment. Furthermore, participants were asked about fidelity based on their most recent coaching session, meaning that a number of sessions were not captured in this analysis, nor do we have the reasons for noncompletion of the

XSL•FO
RenderX

FOI interviews or coaching logs. We did not report physical activity as measured by the wireless physical activity monitor, as this was beyond the scope of this study. However, as the Fitbit was a component of the intervention, our FOI assessment included Fitbit usage (item 19 on the FOI assessment), whereby 89% to 100% of participants at months 2 and 6 wore the wireless physical activity monitor regularly. The uptake and usage of the Fitbit aligns with experiences of technology uptake and usage in the telecoaching CBE study [72].

Our study is limited to participants who remained in the study and completed the FOI assessment interview at month 6. Of 32 participants, only 18 (56%) completed the intervention and an FOI assessment at month 6, resulting in an overestimation of FOI. In our sensitivity analyses, assuming participants who withdrew or were lost to follow-up did not meet the criteria, only 18 (56%; 95% CI 39%-73%) achieved the criteria of engaging in ≥80% of biweekly online personal training sessions (Table 3 and Multimedia Appendix 3), resulting in none of the 4 FOI criteria being met for the study.

Another limitation was that the majority of participants living with HIV in this study identified as males and men; hence, findings may not be transferable to individuals who identify as females or women living with HIV. Also, we did not assess the association of contextual factors such as level of income, stigma, and discrimination. Future research should consider the intersecting components of sex, gender, culture, socioeconomic status, and stigma and their influence on engagement in exercise [73].

Recommendations

There is a need for balancing FOI with personalized and tailored implementation of interventions for adults living with HIV [74-76]. While fidelity is important, solely prioritizing the implementation of the intervention as intended at the cost of tailoring the intervention to the population may not be the most beneficial for the population of adults living with HIV. To ensure the integrity and quality of intervention fidelity assessments while adapting the intervention to the population and its needs, it is important to define, a priori, the intervention components that may be modified to meet participant needs and circumstances. These include optimal frequency of supervised sessions (weekly vs biweekly), mode of exercise, and exercise setting to support independent exercise.

Conclusions

FOI was achieved for the supervised personal training components of the CBE intervention but was not achieved for independent exercise among adults living with HIV who engaged in this 6-month online CBE intervention. Future research should consider tailoring online CBE interventions to personal preferences to foster uptake and sustained independent engagement in exercise over the long term.

Acknowledgments

This study is a substudy of the Ontario HIV Treatment Network Cohort Study (OCS). We thank the OCS (Abigail Kroch and Tsegaye Bekele) for their collaboration in the study. We thank Maple Leaf Medical Clinic, and specifically Raj Maharaj, for their role in facilitating recruitment of participants from the OCS with the Maple Leaf Medical Clinic. We acknowledge and thank Brittany Torres for her coordination role in the study and for conducting a portion of the fidelity interviews with the participants. We thank the YMCA staff, Annamaria Furlan, Helen Trent, Emilia Przybyl, and Dwayne Campbell, for their roles in the fitness assessments and personal training sessions for the intervention. We acknowledge and thank Mehdi Zobeiry at the YMCA of Toronto for their support with this study.

We did not use AI in the development of this manuscript.

Funding

This research was supported by the Ontario HIV Treatment Network HIV Endgame Funding Program—Breaking New Ground (grant number EFP-1121-BNG). KKO was supported by a Canada Research Chair (Tier 2) in Episodic Disability and Rehabilitation (CRC-2022-00510); AMB was supported by the Foundation Alma and Baxter Ricard Chair in Inner City Health at St Michael's Hospital and the University of Toronto.

Data Availability

Results of the study are supported by the data provided in the manuscript and its supplementary files. The complete dataset is available upon reasonable request from the corresponding author.
