centralized systems. Although their focus is on data security in academic platforms, their findings on decentralization and security are highly relevant to the design of mobile apps that manage digital ID in essential public services. Using a SWOT (strengths, weaknesses, opportunities, and threats) analysis and a waterfall development approach, the study implements blockchain to ensure a network resilient to external interference. However, scalability in larger environments remains a challenge. Our research advances this by proposing technical solutions that improve the efficiency and accessibility of essential services, overcoming these limitations by integrating blockchain for secure and decentralized digital ID.

Similarly, Asmawi et al [34] developed BlockScholar, a blockchain-based mobile educational app to facilitate the understanding of blockchain. Their research addresses the gap in interactive and accessible educational resources, highlighting the need for platforms that offer immersive and accessible learning on blockchain. They used the rapid application development model to create interactive and gamified content, as illustrated in Figure 9. Although the study made progress in accessibility and comprehension, it still faces challenges in adaptability to diverse educational contexts. Therefore, our research proposes solutions that enhance learning personalization and expand the coverage of blockchain-related topics.

Figure 9. Rapid application development model phases.

Security, Identity, and Digital Inclusion with Blockchain

Gumilar et al [35] explore the integration of financial technology in digital inclusion, with an emphasis on digital financial literacy as a catalyst for reducing economic and social disparities [35]. Through a systematic literature review, they used Scopus databases (2020-2024) to examine how the adoption of digital financial services optimizes inclusion. The results highlighted the importance of improving digital financial literacy but noted limitations in consumer use and protection. In line with these findings, our research extends the analysis by proposing innovative technological solutions and a more accessible design to improve adoption in underserved populations.

On the other hand, Musa et al [36] propose a blockchain-based approach to improve the security of data storage in Android mobile apps. They address the problem of vulnerability and unauthorized access to sensitive data by using blockchain to provide decentralized and secure storage. Their methodology includes the implementation of a 6-layer framework called BSADS (blockchain-based secure android data storage), which optimizes efficiency and security, as detailed in their proposed framework. Despite advances, scalability and costs remain limitations. This research contributes to overcoming these challenges by proposing lightweight node solutions and cost optimization techniques.

Identity and User Experience Management on Blockchain

Alanzi and Alkhatib's [37] study presents blockchain-based identity management solutions aimed at improving privacy and security in traditional centralized systems. Using blockchain technologies such as Ethereum and smart contracts, they address issues of third-party control, single point of failure, and vulnerability to data manipulation. However, limitations in scalability and weak authentication of some proposed systems are identified. In this context, our research extends these approaches, proposing improved decentralized infrastructure and optimizing the design of smart contracts to increase security and efficiency in digital identity management systems.

On the other hand, Jang and Han [38] developed a user experience framework for blockchain-based services, specifically focused on improving user interaction in contexts

XSL•FO
RenderX

such as finance and health care [38]. Through an analysis of active services, they identified both general and blockchain-specific functions, highlighting improved efficiency and security. However, their study faces limitations in general applicability due to a lack of standardization. Consequently, our research extends this framework, addressing the implementation of blockchain in digital identity and essential services, improving accessibility and user experience through advanced technological solutions [38]. Table 5 summarizes the key approaches and inputs underlying the development of a blockchain-based mobile app for digital ID and access to essential services.

Conclusions

This study designed a functional architectural proposal for a blockchain-based mobile app that facilitates digital ID and access to essential services, with a focus on the inclusion and data security of older adults. The solution addresses usability, privacy, and decentralization issues, overcoming the limitations of traditional centralized and vulnerable systems. In addition to its technical and usability benefits, the proposed system entails ethical challenges related to data governance. If local authorities or institutions act as blockchain nodes, they could potentially exert undue control over users' identity data. To prevent this, future implementations should ensure transparent node management, community oversight, and independent auditing. These measures are key to promoting genuine digital inclusion while safeguarding autonomy and trust in rural contexts. Nevertheless, usability tests applied using the SUS revealed high acceptance and perceived ease of use by older adults, demonstrating that the proposal represents a solid basis for the comprehensive development of the app, which has been implemented in a functional prototype currently undergoing real-world testing with older adult participants in rural areas.

Acknowledgments

The authors would like to thank the Dirección de Investigación de la Universidad Peruana de Ciencias Aplicadas (UPC) for the support provided for the publication of this article.

Funding

This work received financial support from the Dirección de Investigación de la Universidad Peruana de Ciencias Aplicadas (UPC) exclusively for the article processing fee (APF). No additional funding was provided for the research activities.

Data Availability

The data collected in this study consist of usability evaluation responses (eg, survey data such as System Usability Scale scores and qualitative feedback) obtained from voluntary participants during prototype testing. No clinical, laboratory, or medical record data were collected. The dataset is not publicly available due to privacy and ethical considerations, but can be provided by the corresponding author upon reasonable request.

Authors' Contributions

WA-R and AFP-L contributed equally to this work. They led the study execution, including participant recruitment, data collection, usability evaluation, analysis of results, and drafting of the manuscript. JCM-A provided research supervision and leadership, contributed to the study planning and methodological guidance, ensured alignment with journal requirements, coordinated the submission and revision process, and performed critical review and editing of the manuscript.
All authors reviewed and approved the final version of the manuscript.

Conflicts of Interest

None declared.

Abstract

Background: The advent of telerehabilitation has created new opportunities for the care of patients with metabolic syndrome. In distant rehabilitation, technology acceptance is particularly important because home-based projects are based on digital devices, and many patients are less familiar with their use.

Objective: Our aim was to explore technology acceptance among patients undergoing a 3-month complex, telemedicine-supported metabolic rehabilitation. We were curious to see how different factors influence the intention to use rehabilitation technologies and how this changes through the telerehabilitation process.

Methods: Participants were selected from patients in the metabolic telerehabilitation program at the university. Our model was based on the unified theory of acceptance and use of technology 2, which we supplemented with various other constructs. A paper-pencil questionnaire survey was administered on the last day of the preparatory week of the rehabilitation program (T1, n=145) and at the follow-up visit after the closing (T2, n=139). We used structural equation modeling with the least squares method to explore the relationships between model variables. Respondent segments were also identified by performing a hierarchical cluster analysis using Ward's method.

Results: Facilitating conditions (FC) have the greatest impact (0.366) on the behavioral intention (BI) to use technology. Effort expectancy has no direct effect on BI; it operates only through performance expectancy (PE), which may be because, in telerehabilitation settings, patients are more goal-driven than experience-driven. The analyses of the T2 data show that the direct impact of social influence on BI has disappeared by the end of the rehabilitation process. This can be explained by the fact that during device use, it becomes clear that the devices are secure and the data are safe, making this factor implicit in the patient's behavior. Only 2 constructs appeared in both the T1 and T2 models: PE and FC. By comparing the 2 datasets, we have provided empirical support for an old hypothesis: the experience of using the tool for a time has led to a significant reduction in the impact of FC and a corresponding increase in the dominance of PE, which has "absorbed" the impact of some other constructs. Based on respondents' attitudes, we found 3 clusters. The telerehabilitation program itself has a significant impact on patients' BI, as the relative share of "enthusiastic users" (73/145, 50.3%) increased by about 20%, while the share of "distrustful reluctants" (25/145, 17.2%) decreased to a quarter by the end of the program.

Conclusions: This behavior-based functional approach enables treatments to be tailored to actual technology-use demands rather than to presumptive societal features. This means that before beginning rehabilitation, attempts should be undertaken to identify patients' clusters in clinical practice, and rehabilitation should be planned according to the individual's attitude toward technology.

Introduction

Background

Obesity and metabolic syndrome, as a consequence, are serious public health challenges worldwide, significantly raising the risk of cardiovascular disease, type 2 diabetes, and other chronic conditions [1,2]. The prevalence of obesity has increased steadily in recent decades, not only in affluent countries but also globally, including in middle- and low-income regions [3]. Structured rehabilitation programs play a key role in the care of patients with metabolic syndrome, but access to these programs is limited. Traditional, location-based rehabilitation programs often face capacity constraints, long waiting lists, and geographical or mobility limitations of patients [4-7]. Telerehabilitation offers an alternative to these problems, enabling the therapeutic process to be carried out in the home environment using mobile technology and digital platforms [5].

The 2 most common uses of telerehabilitation are cardiac and poststroke rehabilitation. Mobile technology has been well accepted in rehabilitation programs for patients with ischemic heart disease and congestive heart failure, and digital self-confidence was a significant predictor of acceptance [8]. A comparison of a technology-based, home-based, remotely monitored program and a traditional cardiac rehabilitation program showed that the home program is feasible and acceptable to patients, but that home rehabilitation presents challenges, including maintaining motivation over the long term, which makes its widespread implementation difficult [9]. A focus group study of 188 patients examining telemedicine rehabilitation care for people with chronic diseases [10] found that the possibility of exercising at home, working on one's own recovery, and receiving better-quality exercise instruction thanks to exercise videos on the portal were among the factors that facilitated the acceptance of mobile health (mHealth) rehabilitation. The majority of participants also viewed the benefits of the telerehabilitation program for survivors of stroke as positive [11]. Widespread mobile phone use has helped to make rehabilitation strategies involving the families of survivors of stroke and remote monitoring via telemedicine feasible and cost-effective even in low- and middle-income countries. Participants in another stroke telerehabilitation program also rated regular contact positively, particularly the provision of care-related information and exercise reminders, which helped them to maintain their commitment to the exercise program [12].

Telemedicine has become a key tool in digital health care over the past decade, with the COVID-19 pandemic accelerating the adoption of digital solutions [13]. However, the success of telemedicine-supported programs varies a lot around the world. The main barriers are technology-specific [14], as the success of a program depends on its user-friendly interface and ease of use, especially for older or less technologically experienced users [15]. On the other hand, the effectiveness of programs strongly depends on patients' general attitudes toward technology use, digital competence, socialization background, and perceived privacy in their personal sphere [16,17].

Prior Work

The basis for predicting technology acceptance behaviors can be traced back to the theory of reasoned action of Fishbein and Ajzen [18], which posits that the adoption of a given behavior depends on an individual's attitude and subjective norms. Davis [19] further developed this framework specifically for the study of technology acceptance, creating the technology acceptance model (TAM), in which perceived usefulness and perceived ease of use determine the intention to use. As a next development of the model, Venkatesh and Davis [20] identified factors influencing perceived usefulness in the TAM 2 model, followed by Venkatesh and Bala [21] identifying factors influencing perceived ease of use in the TAM 3 model. The consecutive step was the unified theory of acceptance and use of technology (UTAUT), developed by Venkatesh et al [22]. A further development of this, the unified theory of acceptance and use of technology 2 (UTAUT2) model [23], specifically examines technology adoption among everyday consumers. The research frameworks for exploring technology acceptance listed here share the commonality that they examine use intention and actual use as target variables. Intent to use reflects the extent to which consumers are open to adopting a new technology based on their existing attitudes, while actual use reveals how much time they spend using the device once they have the opportunity.

In their comprehensive methodological study, Holden and Karsh [24] pointed out more than a decade ago that an important future direction for technology acceptance is to adapt the model explicitly to the health context. Notwithstanding, a decade later, Niknejad et al [25] still identified in telerehabilitation far fewer studies than expected that had shown a quantitative association between promoting factors or inhibitors of telerehabilitation adoption and intention to use. Patient-side adoption of telemedicine is influenced by a number of factors that are not part of classical models explaining technology acceptance but are more specific, contextual determinants [10]. Liu et al [26] showed that expected performance was the strongest predictor of intention to use technology for rehabilitation, whereas effort expectancy (EE) and social impact were not significant. In contrast, facilitating conditions (FC) significantly influenced not only intention but also the actual use. Koo et al [27], analyzing the adoption of personalized health management mobile apps by older patients, highlighted the role of performance expectancy (PE), EE, FC, social influence (SI), habit, hedonic motivation (HM), and trust. Huang et al [28] also confirmed the influence of TAM variables for electronic health recording and sharing apps, while Fezzi et al [29] identified perceived usefulness, perceived ease of use, skill level, task

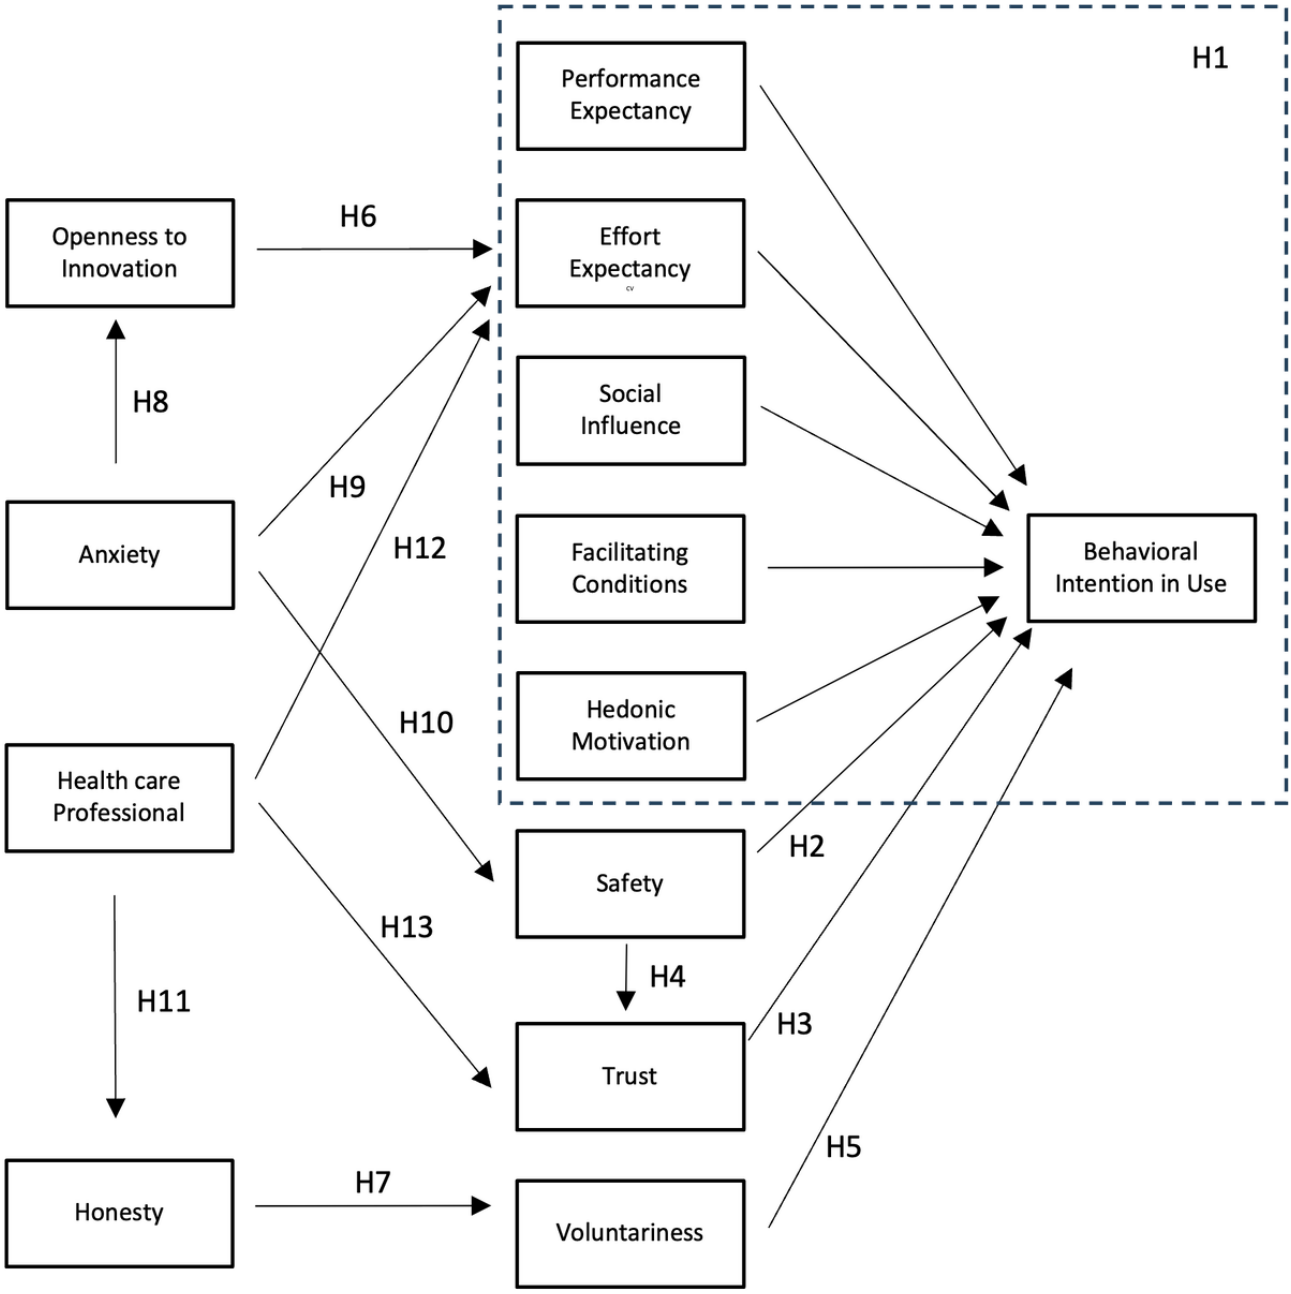
XSL•FO
RenderX

complexity, and the nature of the technology as influencing factors for functional insulin therapy. Cooks et al [30] associated the acceptance of virtual health care professionals (HPs) with a sense of belonging, local identity, self-concept, similarity, and attractiveness, while Kauttonen et al [31] found that the acceptance of artificial intelligence–based health care apps is determined by trust, data security, and the role of the vendor. Schomakers et al [32] and Siebert et al [33] noted that, for therapeutic mobile apps, trust is an independent explanatory factor alongside the UTAUT construct. Rajak and Shaw [16] attempted to generalize the TAM model to mHealth users and demonstrated its high predictive power. Zhu et al [34] used the UTAUT2 model for a similar purpose and demonstrated that the model's original constructs have a meaningful impact on the intention to use. Schretzlmaier et al [35] also extended the UTAUT2 model with their own constructs and found that the factors trust and received threat of illness are also relevant for the acceptance of mHealth technologies. Yang et al [17], building on the UTAUT theory, have recently demonstrated the impact of the convenience, accuracy, and privacy protection factors on technology intention to use. Examining the adoption of mHealth technologies in a national sample, it was found that, in addition to the classic variables of the UTAUT2 model, privacy, lifestyle, self-efficacy, and trust in Bangladesh [36], while resistance to use, data privacy issues, and HM in the Philippines [37], also influence behavioral intention (BI) to use.

In conclusion, in addition to the application of classical TAMs such as TAM and UTAUT, there is a growing emphasis in practice on the inclusion of psychological and technology-specific constructs that make the explanation of technology acceptance in health care more complex and viable. It is also evident from decades of practice in the widespread use of models that constructs influencing target variables can be freely modified by dropping some constructs or adding new ones to suit specific research contexts or objectives [38]. In line with this, AlQudah et al [39] also emphasize the scope to integrate new constructs to enhance the robustness of models of user acceptance of new technologies in health care. This is also confirmed by Ramachandran et al [40], who argue that although the usefulness of home-based telemedicine-supported rehabilitation programs is clear to patients, adoption is also influenced by a number of external factors.

Study Objectives and Proposed Hypotheses

Overview



The aim of this study is to investigate the factors influencing technology acceptance in a telemedicine-assisted rehabilitation program for patients with metabolic syndrome. Our aim was to investigate how constructs influence the intention to use technology and, in turn, to develop an acceptance model for the telerehabilitation process for patients with metabolic syndrome. On the other hand, we sought to answer how the experience of the telerehabilitation process influences patients' technology acceptance parameters, that is, how participation in the process shapes their intention to use.

Our modeling was based on the UTAUT2 model [23]. Since the technologies provided to users were free, we omitted the price construct from our model. We did the same with habit, as the participants in the rehabilitation program did not have a routine in using the devices. For the remaining constructs in the UTAUT2 model, we assumed the specified impacts [23] on the intention to use rehabilitation technologies (hypothesis 1).

To further describe the factors influencing technology adoption in metabolic rehabilitation, we also conducted an exploratory qualitative study. The aim of this was to identify additional relevant constructs that may influence the intention to use the technologies, based on the experiences of professionals directly involved in the program, in line with the suggestion of Kapser and Abdelrahman [38], and to incorporate them into our baseline model. Data collection consisted of 1-hour semistructured interviews with a total of 3 physicians, 2 nurses, 2 dietitians, and 2 physiotherapists from different specialized groups within the clinic. The participants all had direct contact with patients undergoing metabolic rehabilitation and were thus able to provide meaningful insights into the manifestation of attitudes, barriers, and supportive factors related to technology use. The information gathered was subjected to a content analysis, which revealed several factors that are less or differently emphasized in models in the literature. Therefore, we have included these constructs (safety, trust, voluntariness, openness to innovation [OP], honesty, anxiety, and HPs) in our conceptual model (Figure 1), and we explain their use in detail below.

XSL•FO
RenderX

Figure 1. The extended UTAUT2 model as research hypotheses. H: hypothesis; UTAUT2: unified theory of acceptance and use of technology 2.

Safety

A sense of safety plays a key role in the acceptance of health technologies, especially for patients who use digital or invasive devices regularly. In this context, the safety factor refers to the extent to which the user perceives the technology as physically harmless, psychologically reassuring, technologically reliable, and privacy-safe [41]. Kitsiou et al [42] also showed that perceptions of safety have a significant positive impact on intention to use, especially in sensitive application areas such as continuous glucose monitoring or remote monitoring systems. Examining the use of home telehealth services among older people, Cimperman et al [43] also found that perceived safety positively influences the intention to use. Lack of safety (eg, fear of device malfunction or data leakage), which is effectively equivalent to the perceived threat variable [34,44], can significantly reduce trust in technology, which plays a key mediating role in acceptance models. On this basis, we hypothesized that the safety construct would positively affect the BI to use rehabilitation technologies (hypothesis 2).

Trust

Trust plays a key role in technology adoption, as patients are in a vulnerable position in health care. Trust, in this context, reflects the user's belief that the technology is reliable, predictable, and safe to use during the treatment process [45]. In the case of telemedicine applications, this belief extends to the system's technical stability, data security, and the belief that HPs will use the device appropriately and ethically [46]. Higher levels of trust can significantly increase the intention to use the technology [34-36,47]. Accordingly, in our modeling, we hypothesized that trust would have a positive effect on intention to use for rehabilitation technologies (hypothesis 3). However, we also hypothesized that safety would have a positive effect

XSL•FO
RenderX

on trust, also because safety enhances overall trust (hypothesis 4).

Voluntariness

Voluntariness is a key factor in technology adoption models, especially in environments where users are sensitive to issues affecting their autonomy, such as health care. This latent variable measures the extent to which a user feels that the use of technology is based on free choice rather than on external constraints or expectations [22]. A sense of voluntariness contributes significantly to the development of positive attitudes, increases willingness to accept, and reduces resistance, especially when new technologies (eg, telehealth systems or wearable sensors) are introduced to populations vulnerable to a loss of control [48]. In a clinical setting, it is particularly important that patients perceive technology as a choice rather than an instruction from the treating physician or institution, as this indirectly influences the likelihood of engagement and long-term use. Voluntariness, as a latent variable, appears as a moderating variable in the UTAUT1 model but is no longer included in the UTAUT2 model [23], as it is implicit in the consumer context that consumption is voluntary. Since in health care, a patient may always feel "pressure" from health care staff, so voluntariness is not implicit, we reintegrated this variable into the model and assumed that voluntariness positively influences intention to use rehabilitation technologies (hypothesis 5).

Openness to Innovation

OP reflects an individual's willingness and ability to try new technologies, solutions, or services, even if they initially have little information about how they work. This personality dimension often serves as a moderator or indirect variable in models of technology adoption, as it significantly impacts attitudes toward technological innovations and, in turn, the intention to use them [49]. Individuals with high OP tend to be more willing to use digital health solutions, such as telemedicine applications, and are less likely to be apprehensive about novelty, making it easier for them to turn initial experimentation into regular use [50]. In the context of metabolic rehabilitation, this is particularly relevant, as patients need to regularly monitor their own condition and provide data, which requires the use of digital tools, the acceptance of which can be greatly facilitated by a positive attitude toward technological novelty. As openness is primarily associated with technology-use efforts, we hypothesized that OP would have a positive effect on EE within the rehabilitation technology adoption model (hypothesis 6).

Honesty

Based on the experience of qualitative in-depth interviews with health care staff, we included social effects such as honesty. This is the willingness of users to share sensitive personal information when using the tools provided to them [51]. This depends on the provider's transparent data management and open communication with the user [52]. These suggest that user honesty, as a specific form of social interaction, can be incorporated into the TAM in digital tool–assisted rehabilitation, where accurate, fair, and voluntary data disclosure is key to effectiveness (hypothesis 7).

Anxiety

Anxiety describes the negative anticipatory reactions and emotional responses associated with technology use, arising from fear of use, fear of making mistakes, or experiencing the complexity and unpredictability of technology. This psychological factor is particularly important in digital health settings, where users often perceive improper use as a health risk [53]. Technology anxiety often negatively impacts perceived ease of use and perceived usefulness, thereby weakening the intention to use [54]. This is particularly relevant for patients undergoing metabolic rehabilitation, as most have limited digital experience and may be more sensitive to the risk of digital system failure due to their health conditions. Anxiety may therefore also be a barrier to OP (hypothesis 8), EE (hypothesis 9), and sense of safety (hypothesis 10).

Health Care Professionals

From the construct called SI in previous models, we have separated the influence of HPs to more accurately describe the effects, as their role is multifaceted and more actively helping than the encouraging role of family or friends. In particular, doctors, nurses, physiotherapists, and dieticians have a significant impact on patients' willingness to use technology in rehabilitation when they introduce new digital solutions such as telemedicine systems or mHealth apps. For patients, health care staff are a key source of information and a point of trust, so their positive attitudes may facilitate technology acceptance, while their skepticism or passivity may prevent it [55]. Accordingly, we hypothesized that HP would positively impact the honesty (hypothesis 11), EE (hypothesis 12), and trust (hypothesis 13) factors.

Methods

Sample Size Estimation

Given the finite population of eligible program participants (N=170), we calculated the minimum required sample size using a conservative proportion-based approach (P=.50), a 95% confidence level, and a 5% margin of error with a finite population correction, resulting in a minimum of 118 participants. Our achieved sample size exceeded this threshold (T1: n=145; T2: n=139). We also included a power-based verification aligned with the primary partial least squares-structural equation modeling model, confirming that the baseline sample provides adequate power (α=.05; 80% power) to predict BI from the number of model predictors.

Recruitment

Participants in the study were selected from patients in the metabolic telerehabilitation program at the Cardiometabolic Rehabilitation Unit of the Internal Medicine Clinic, University of Szeged, using convenience sampling. The study included individuals between the ages of 25 and 70 years who had low levels of physical activity (less than 30 minutes of self-reported exercise per week) and lived with metabolic syndrome. To define metabolic syndrome, we used the Adult Treatment Panel-III criteria [56], according to which, participants must have at least 3 of the 5 risk factors listed therein, as determined from a review of their medical records.

XSL•FO
RenderX

Individuals with any of the following conditions were excluded from selection: planned invasive cardiological intervention, uncontrolled hypertension, type 1 diabetes mellitus, type 2 diabetes treated with more than 1 daily dose of insulin, heart failure, renal failure, cancer, severe cognitive impairment, lack of cooperation, known conditions preventing physical training, and mental conditions severely limiting judgment or capacity to act.

Questionnaire Development

To measure the variables in the model shown in Figure 1, a self-completion questionnaire was developed through a multistep procedure to ensure adequate content and face validity. The selection of constructs was grounded in the theoretical framework and the qualitative semistructured interviews described earlier. Content validity was ensured by aligning questionnaire items with both established literature-based measurement scales and the expert-derived thematic findings. The preliminary questionnaire was reviewed by members of the research team with expertise in health economics, preventive medicine, and digital health research to evaluate item relevance, clarity, and domain coverage. Face validity was assessed through a pilot evaluation involving representatives of the target population participating in the rehabilitation preparation phase, focusing on the comprehensibility, clarity of wording, and interpretability of the items. Based on feedback received, minor linguistic and formatting adjustments were implemented before administering the final questionnaire. All items were measured using a 5-point Likert scale, reflecting the level of agreement with each statement. The constructs and corresponding measurement items are presented in Table 1.

The translation of the questions was carried out using the following method: 2 independent experts translated them, and their translations were then reconciled. The reconciled version was back-translated and approved by the corresponding author (NB).

Data Collection

In this study, a paper-pencil questionnaire was administered to patients with metabolic syndrome who had participated in a 3-month complex rehabilitation program on 2 occasions: on the last day of the preparatory week prior to the rehabilitation program (T1) and at the follow-up visit after the program closed (T2). Patients completed the questionnaires in a separate, quiet room. All questionnaires were recorded in an electronic database by one of the researchers (ZT).

Statistical Analysis

The first step in analyzing the collected data was to use descriptive statistics to describe the sample population's sociodemographic characteristics. To answer our research question, we used structural equation modeling with the least squares method to explore the relationships among model variables using SmartPLS software (version 4; SmartPLS GmbH). The path analysis allowed us to investigate the extent to which each variable directly influences the intention to use the devices dispensed to patients during metabolic telerehabilitation and to identify interactions between these variables, thereby identifying which variables have an indirect effect on intention to use. Finally, to provide a deeper interpretation of the results, respondent segments were identified through a hierarchical cluster analysis using Ward's method. The procedure uses the participants' responses to the indicators as criteria and, based on these, classifies those with similar responses into similar inwardly homogeneous clusters, while the system ensures that the different clusters are heterogeneous along their criteria, that is, well distinguishable. The output of the cluster analysis is to identify clusters by saving the clusters as variables and comparing averages along the indicator variables to identify the respondent groups.

Ethical Considerations

The study was conducted in accordance with the guidelines of the Declaration of Helsinki and was approved by the Medical Research Council of Hungary (approval BM/25016-1/2024). The research was based on prior written informed consent from the participants. The questionnaire was completed in a separate room, with participants seated at a distance from one another to ensure privacy. After completing the questionnaire, participants could not be identified, thus ensuring confidentiality. Participants did not receive any compensation for their participation in the research.

Results

Demographic Characteristics

The demographic profile of respondents (n=145) is shown in Table 2. During the study period, 58.5% (83/145) of the participants in the telemedicine-supported metabolic rehabilitation program were female, and 41.5% (59/145) were male. Patients aged 25 to 82 years (mean age 52.6, SD 12.65 years) completed the questionnaire. In terms of age distribution, 19.6% (28/145) were younger than 40 years, almost half were between 51 and 70 years, and only 9.8% (14/145) were older than 70 years. In total, 28.7% (41/145) of respondents came from a large city, 37.8% (54/145) from a small town, and 1 in 3 from a village. In terms of education, nearly two-thirds of respondents had a secondary education, one-third had a higher education degree, and 2.1% (3/145) had only a primary education. In terms of marital status, 63.9% of respondents are in a couple, 43.7% have children, and 29.9% declared themselves completely single. Regarding their financial means, 45.5% (66/145) of respondents said that everyday expenses are not a problem, that they can afford some extra expenses in their monthly budget, but that they cannot save. A total of 36.6%

XSL•FO
RenderX

(53/145) of respondents can afford extra spending beyond living expenses and can save at the end of the month. Only 2.8% (4/145) of respondents have serious financial difficulties.

Table 2. Participants' characteristics.

Demographic factors	Values, n (%)
Sex	
Male	59 (41.5)
Female	83 (58.5)
Age (years)	
≤40	28 (19.6)
41-50	31 (21.7)

College or university	47 (32.4)
Other	4 (2.8)
Financial situation	
My monthly income is not enough to buy basic necessities	4 (2.8)
I can buy basic necessities, but I have no money for anything else; it just about lasts until the end of the month	21 (14.5)
I can buy basic necessities and occasionally allow myself 1 or 2 extra expenses, but I cannot save any money	66 (45.5)
I can buy what I need and even put some money aside, and I can afford occasional extra expenses	53 (36.6)
I can buy what I need and even put some money aside, and I can afford regular extra expenses	1 (0.7)

Partial Least Squares-Structural Equation Modeling Model

The results confirming the reliability and validity of the constructs are also summarized in Table 1. Construct reliability was assessed using the Cronbach α coefficient and the composite reliability (CR) coefficient [57]. The CR is more accurate because it accounts for the model structure and covariances. Both coefficients above 0.70 are considered satisfactory. The results showed that Cronbach α and CR were all above 0.7, with the lowest values being 0.744 and 0.797, respectively. However, none of the values exceeded the redundancy threshold of 0.95, indicating that the constructs are reliable. The convergent validity of the constructs was determined using average variance extracted. The results showed that all average variance extracted values were above 0.5, indicating adequate convergent validity for all constructs, reflecting their 1D nature.

XSL•FO
RenderX

Table 3 presents the hypothesis testing results for the path analysis based on the questionnaires collected in T1, and Figure 2 shows their graphical representation. Table S1 in Multimedia Appendix 1 contains the more detailed statistical parameters. It can be seen that the intention to use (BI) is directly and positively influenced by the PE, SI, and FC factors, all of which are included in the UTAUT2 model. No direct effect of EE was detected, and HM only has an indirect effect on intention to use through PE. Thus, we have only partially confirmed hypothesis 1.

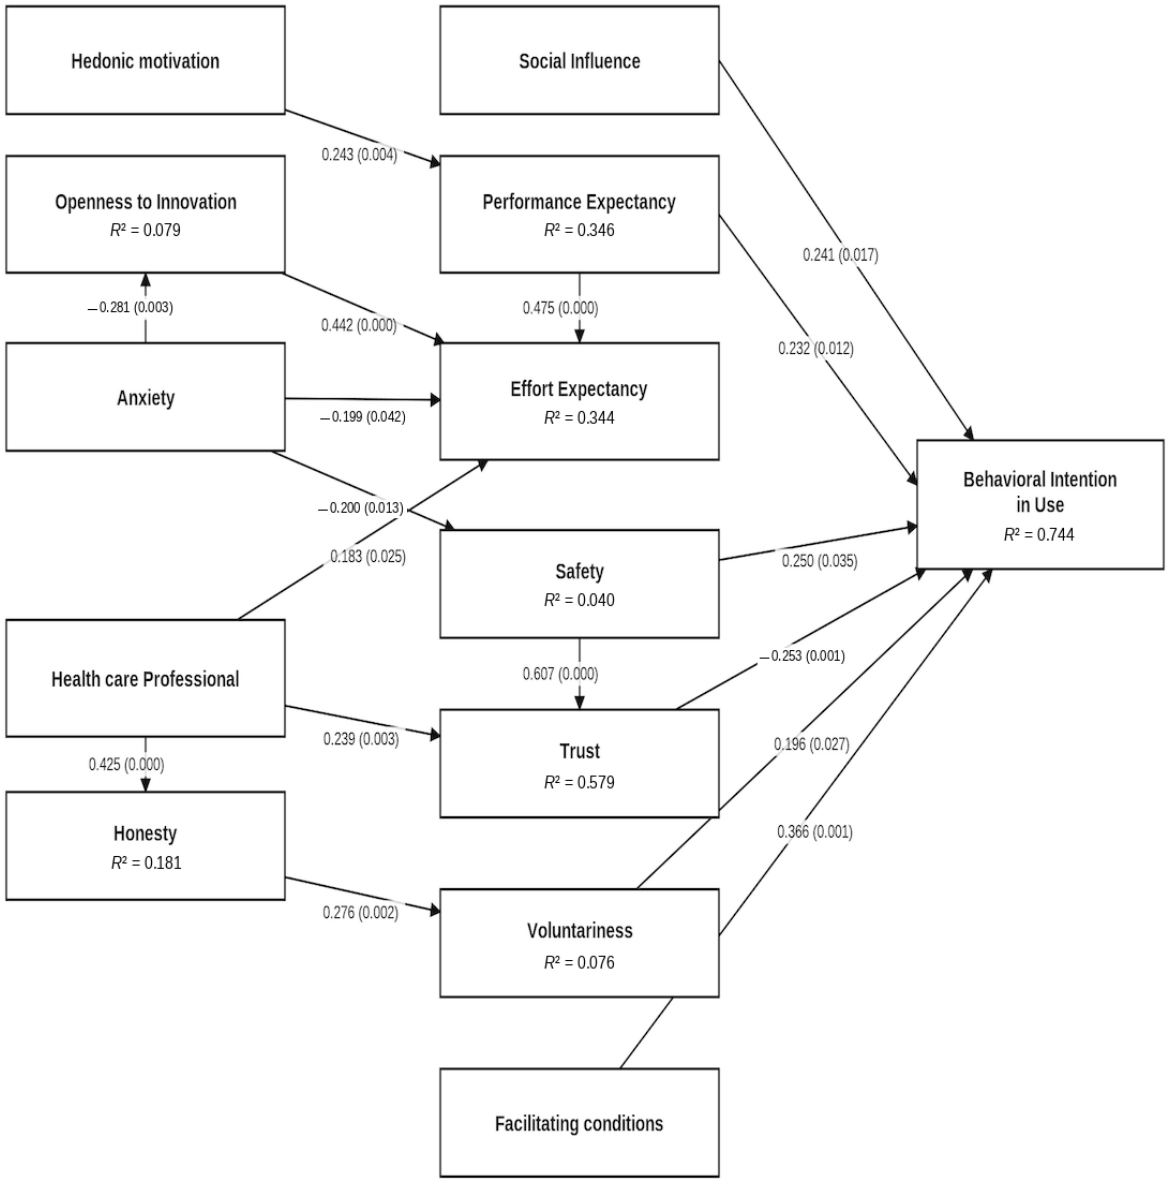

Table 3. Hypothesis testing summary for T1 and T2 surveys.

Figure 2. Extended UTAUT2 model with latent variables and path coefficients in T1. UTAUT2: unified theory of acceptance and use of technology 2.

In addition to the above, BI is also directly positively affected by safety and voluntariness. Therefore, hypotheses 2 and 5 are accepted. Trust also has a direct negative effect on BI, so hypothesis 3 is not confirmed. Safety, on the other hand, has a very strong effect (0.607) on trust, confirming hypothesis 4. Although EE does not have a direct effect on BI, it has a strong effect on PE (0.475), indicating that the tools used in the telerehabilitation program are easy and user-friendly without prior training.

In terms of the strength of constructs directly affecting intention to use, the largest influence (0.366) is FC, which includes 4 items: the conditions in the rehabilitation participant's home, the problem-solving ability required to use rehabilitation tools, the compatibility of the tools used with those the user is currently using, and the expected assistance with problems that would arise during use. Nearly equally influential on BI is PE (0.232), that is, the perception of how useful the rehabilitation program and the tools used in it will be in achieving the goals set. Just like SI is 0.241, which indicates the influence of close people to the patient; and safety is 0.250, which indicates that the perception of security in the use of the devices and the inaccessibility of the data generated by the use of the devices to unauthorized persons. Voluntariness, that is, the intention to use the system despite the fact that its use is not compulsory, is less significant (0.196) than the former ones.

Examining which other constructs moderate the direct influence on intention to use, we see that FC and SI are not related to other factors. Trust is significantly influenced by HP (0.239), that is, the expectation of active assistance from health staff is a clear contributor to the perceived safety. HP also has a significant effect on honesty (0.425), implying that the attitude of doctors, nurses, dieticians, and physiotherapists toward

XSL•FO
RenderX

patients contributes to the honesty of the data. HM, which has a direct effect on BI in the UTAUT2 model, has a direct effect on PE here, indicating that performance expectations are also proportional to the enjoyment of technology. Anxiety, as originally hypothesized, also affects 3 other factors: OP, EE, and safety. The effect is negative in all 3 cases: lower innovation anxiety is beneficial for openness to new technologies, expectations of the effort required to operate, and perceptions of safety. Figure 2 also shows that all hypotheses (hypotheses 6-13) related to constructs with a moderating effect were confirmed.

To investigate how participation in the rehabilitation program influences intention to use technology, we also conducted a survey in T2 among patients (n=139) returning to the final medical control at the end of the program. The results of this path analysis are also shown in Table 3. Additional statistical parameters are provided in Table S2 in Multimedia Appendix 1. The model appears to have been simplified. The effect of SI on intention to use was eliminated, so the variable was eliminated from the model. In addition, the effects of voluntariness on BI and of honesty on voluntariness have been discontinued, so voluntariness has disappeared from the model. The direct effects of trust and safety on BI have also ceased, so that only FC and PE have an effect on the intention to use after the rehabilitation program. The effect relationships of anxiety and their sign have not changed, but their effects have increased significantly. The effects of HP also remained unchanged, but while its influence on honesty was weakened, its influence on EE was significantly strengthened.

Cluster Analysis

Overview

TAMs provide a useful framework for understanding how patients perceive digital health solutions in the context of telerehabilitation. However, these models assume linear relationships and cannot capture heterogeneity within patient populations or the diverse patterns of technology use. Based on this consideration, we also apply cluster analysis to our research to identify distinct groups of patients with metabolic syndrome characterized by different attitudes and behavior patterns.

By performing hierarchical cluster analysis on the questionnaire data recorded at T1 (using a dendrogram created with a combination of Ward's minimum variance clustering algorithm and squared Euclidean distance), 3 distinct clusters were identified. The groups are heterogeneous among themselves and homogeneous within the cluster. The clusters are not segregated by demographic characteristics; no category of age, education, residence, or income is predominant in any cluster. Consequently, clusters were further analyzed by comparing the means of responses to questions across variables, that is, functional behavioral patterns, attitudes, emotional reactions, and social support related to digital technology use.

Based on the attitudes of the respondents, the 3 distinct groups and their characteristics are described.

Enthusiastic Users

About half of the participants (73/145, 50.3%) belong to this group. They are open and active in their attitudes toward the use of technology. They enjoy using rehabilitation tools and are eager to try new technologies. Their characteristics are as follows: they most enjoy using rehabilitation tools, they are most likely to try new technologies, and they find those who influence their opinions most encouraging in their use of devices.

This group is the engine of rehabilitation programs: their commitment and positive attitude can serve as a model for others.

Liberated Adopters

Members of the second-largest group (32.4%) are open to using tools but are less active and, in some respects, more moderately engaged than enthusiastic users. The following attributes define this group: technology anxiety is the lowest, they rely most on family and friends for help, they have above-average device use, and they learn and use tools more easily than the average person.

This group is a stable base for the program: if given support and encouragement, they can easily become enthusiastic users.

Distrustful Reluctants

This is the smallest, but no less important, group of people (25/145, 17.2%) who are reticent and critical of rehabilitation technologies. This distrust is often due to anxiety, insecurity, or poor social support. They are the ones who enjoy using the devices less, are less attracted to trying new technologies, have above-average anxiety about using devices, are less likely to rely on family support, have more difficulty than average in learning to use new devices, and have the least belief in the role of device use in rehabilitation.

They are the group most in need of attention: personalized support, confidence-building, and mentoring can help them develop a more positive relationship with rehabilitation tools.

The cluster analysis was also performed on the questionnaire data collected in T2. We found that cluster blocks with practically identical characteristics can be distinguished, but their relative numbers of elements have changed. Among those who completed the program, the proportion of enthusiastic users increased from 50.3% to 61%, and the proportion of liberated adopters was almost the same (32.4% and 34.6%, respectively), while the proportion of distrustful reluctants decreased from 17.3% to 4.4%.

Due to the different cluster sizes and the varied distribution of participants, we cannot statistically say that different age groups behave differently. At the same time, the distribution of participants across clusters is not uniform: the group aged 60 years and older is concentrated in the "liberated adopters" cluster, whereas there are no participants aged 50 years and older in the "distrustful reluctants" cluster (although this cluster has the fewest members). Even after adjusting for unequal cluster sizes and the sample's underlying age distribution, age

XSL•FO
RenderX

remained associated with cluster membership, suggesting that age was a significant structuring variable of the clusters.

The association between sex and cluster membership was examined using a chi-square test of independence. The analysis indicated that sex distribution did not differ significantly among clusters (chi-square test, $P>.05$), suggesting that cluster membership was independent of sex.

Discussion

Principal Findings

As the results show, EE in the T1 study has no direct effect on intention to use, only through PE. This seems surprising at first sight, because EE usually has a direct positive effect on BI in UTAUT2 models. Although Venkatesh et al [23] suggested that if BI is highly dependent on PE, it may "absorb" the effect of EE, this has not been quantified. Several studies have found a significant relationship between EE and PE [43,58,59], but in no case did this prevent both constructs from also impacting BI. However, Kim et al [60] observed no direct effect of EE on BI when they used a UTAUT model to examine the adoption of mHealth tools and found that EE only affected BI as a moderating variable of trust. The lack of a direct effect of EE may be due to the fact that the experience of ease of use (EE) is not important per se, but because it increases the perception of usefulness (PE). In telerehabilitation settings, patients are not experience-driven but rather goal-driven, that is, they place more emphasis on whether the technology actually helps their recovery than on how easy it is to use.

In addition, as a result of the study in T1, although HM is included among the influencing constructs in UTAUT2, we did not measure its direct effect on intention to use (BI). Instead, HM moderates only through PE, that is, an enjoyable experience increases willingness to use only if it also positively influences perceived usefulness. Similar results are reported in the mHealth adoption study by Schretzlmaier et al [35], where the influence of PE and fear of illness on BI is clear, while the effect of HM is only conditional. The moderating effect of HM has also been demonstrated by Sitar-Tăut [61], who, in an m-learning setting, found that HM strongly influences PE within the HM-PE-BI sequence.

In addition, the analysis of the T1 study yielded the surprising result that trust has a negative effect on BI. This means that the more users trust the system, the less likely they are to want to use it. This seems to be a logical contradiction, as one would expect trust to have a positive effect on willingness to use, which is confirmed by several previous studies [34,35]. However, this phenomenon is consistent with a kind of safe bubble effect described in the literature [62], whereby users, due to excessive technological trust, feel less motivated to actively use technologies that require more interaction. Excessive technological confidence reduces user participation, and when confidence in the system exceeds perceived need, the active use of technology may even be abandoned [63]. In our case, this may have been reinforced by the technology's actual trial, as data collection for the prerehabilitation analysis was conducted at the end of the preparation week, by which time, patients had learned to use the required tools in practice. In contrast, in T2, we found that the direct effect of trust on BI had disappeared, remaining relevant in the model only as a moderator. The experience gained during use and active participation in the operation is already reflected in the PE, resulting in a PE dominance in T2.

The analysis of the data recorded in T2 shows that the direct influence of SI, voluntariness, and safety on BI has also disappeared by the end of the telerehabilitation process. SI plays an important role in initiating device use, but later, this driving force is replaced by utility and effectiveness, embodied in PE. By examining the development of long-term device use habits, Peng et al [64] also found that SI before use is important, but that later regular use is no longer fueled by SI. The disappearance of voluntariness has no antecedent in the literature, as it is not included in the UTAUT2 model; it was reintroduced only under possible medical and eminence-based pressures, and its validity was confirmed by the T1 analysis. Sharif Abbasi et al [65], using the UTAUT model, found a result similar to ours when examining internet adoption over a longer period: while in T1, the effect of voluntariness on BI was measurable, in T2, it no longer remained significant, as experience with use increased. The disappearance of the effect of safety on BI can be explained by the fact that during device use, it becomes clear that the devices are secure and the data are safe, making this factor implicit in the patient's behavior.

Of the constructs that directly influence technology use intention, only 2 remain: PE and FC, which appear in both the T1 and T2 models. While in the previous measurement, FC is by far the strongest (0.366) and PE is almost the weakest (0.232) direct effect on BI, in the latter measurement, FC's influence is significantly weaker (0.258). One of the most important extensions of UTAUT2 was the introduction of user experience as a moderator on the constructs, including FC [23]. It was argued that, over time, as the routine of using the technology increases, FC becomes less crucial, sometimes even acting as a pullback force. By comparing the 2 datasets, we have now been able to provide empirical support for this hypothesis: the experience of using the tool for 3 months has led to a significant reduction in the impact of FC and a corresponding increase in the dominance of PE, which has "absorbed" the impact of SI, trust, and safety as well.

While clustering approaches commonly used in telemedicine are typically based on static categories such as socioeconomic status [66] or health literacy [67], we investigated how patients behave in a technological environment, what barriers they experience during use, and what motivational dynamics characterize them. The 3 groups explored represent different levels of technological engagement. This concept is more complex than technology acceptance because it includes emotional involvement (enjoyment or anxiety), motivation and volunteering, openness to novelty, willingness to learn, and self-efficacy, as well as the role of social support in technology use.

The cluster analysis of questionnaires collected before and after the telerehabilitation program shows that the program has a significant impact on patients' intention to use. The relative

XSL•FO
RenderX

share of enthusiastic users increased by about 20%, while the share of distrustful reluctants decreased to a quarter. Our results show that 2 factors are crucial for willingness to use: on the one hand, a meaningful trial of the technology (not just a demonstration, but an actual data collection simulating real-life situations at home) is the best way to dispel fears and anxieties about it, that is, a project where participants in a rehabilitation program can try out the technologies for a longer time during the preparation period can significantly contribute to their acceptance and willingness to use. On the other hand, the supportive and motivating role of the immediate environment is crucial; that is, where the family is indifferent or unsupportive, it is worthwhile to motivate family members with targeted communication during the preparation period of the telerehabilitation program.

Conclusions

Our study has shown that the enabling environment is a key determinant of technology adoption in a telerehabilitation program. Consequently, when developing such a program, the focus should be on creating user-friendly interfaces, clearly communicating the benefits of technology and its relationship with other devices, and developing patients' technological competencies. For patients more experienced with the technologies, PE will be the determining factor; if patients can experience the benefits of the technology in action during the preparation for the telerehabilitation program (training in the technologies and data delivery), their engagement will be stronger. If the impact of technological competency is to remain strong throughout the duration of a telerehabilitation program, it makes sense to adopt an adaptive strategy, that is, to measure increases in competency and reduce support intensity accordingly. This is both a way to signal user autonomy and to avoid a sense of excessive control. The cluster analysis also confirms that the key factor in the success of such a program is the tailored support and communication to the specific characteristics of each group, thereby strengthening their long-term commitment to participation. Indeed, the groups identified are not merely descriptive categories but operational profiles directly linked to the practical challenges of telerehabilitation. This functional approach, based on behavioral patterns, allows interventions to be personalized not according to assumed social characteristics but to real technology use needs. In clinical practice, using this, efforts should be made to identify clusters before initiating telerehabilitation. The next task is to develop personalized coaching techniques for each identified cluster and then examine whether attitudes toward technology use and the effectiveness of the entire telerehabilitation process can be improved through personalized interventions. We have already initiated developments in this direction, incorporating artificial intelligence support.

Limitations

A limiting factor could be that, assuming a lack of technological experience, we omitted this from the model, even though there were certainly patients who possess such experience. We also did not assess whether the patients had participated in a similar rehabilitation program before or how this influenced their current attitudes. As the study was designed to compare intentions to use, actual use may have been influenced by factors we were unable to fully account for. With a larger sample size, it would also be possible to explain the behavioral differences observed across clusters using structural equation modeling analysis, which could be an exciting direction for future research.

Acknowledgments

The authors would like to thank the staff of the Cardiometabolic Rehabilitation Unit at the Internal Medicine Clinic, University of Szeged, for their assistance with the questionnaire survey.

Funding

The research was financially supported by the Healthcare Development Cluster of the Centre of Excellence for Interdisciplinary Research, Development and Innovation of the University of Szeged.

Data Availability

The datasets generated during this study are available in the Mendeley Data repository [68].

Abstract

Background: Stroke is a leading cause of disability and death, resulting in a clinical, social, and economic burden upon families and the health system worldwide.

Objective: This study aimed to introduce nurse-led rehabilitation services for patients after stroke to improve functional independence for self-care management.

Methods: A pilot, open-label, 2-arm (1:1), randomized controlled trial was conducted at the National Institute of Neuroscience & Hospital in Bangladesh between March and August 2025. A total of 64 patients with stroke were enrolled using simple randomization. In the intervention group (IG), patients received rehabilitation education and assistive devices to improve activities of daily living. The control group (CG) received usual hospital care for stroke. Data were collected through a structured questionnaire. After discharge from the hospital, study nurses enrolled patients after stroke after a face-to-face assessment and provided rehabilitation education at the hospital and monthly rehabilitative education at home for 3 months. The study outcomes were improvement of functional independence, self-efficacy, social participation and reduction of caregivers' burden.

Results: Among 64 participants, 47 (73%) completed the study. Results depict an increase in self-care capacity, self-efficacy, social involvement and a decrease in care burden in both groups from baseline to end line; nevertheless, there was no statistically significant difference between IG and CG ($F_{2, 44}$=0.113; P=.74). Functional Independence Measure mean scores (IG: mean 78.4, SD 37.6; CG: mean 74.3, SD 35.4; P=.70; 95% CI –25.16 to 18.14), self-efficacy (IG: mean 27.0, SD 6.9; CG: mean 26.6, SD 7.1; P=.83; 95% CI –3.6 to 4.6), social participation (IG: mean 30.4, SD 21.4; CG: mean 28.2, SD 17.2; P=.61; 95% CI –9.33 to 13.61), and care burden (IG: mean 24.9, SD 13.6; CG: mean 25.2, SD 12.6; P=.83; 95% CI –8 to 7). In qualitative analysis, we noticed enhanced self-care capacities of patients with poststroke disabilities after rehabilitative intervention, as indicated by participants' perceptions.

Conclusions: In this study, patients' self-care capability was improved after the intervention from baseline, and improvements were noted by using assistive devices based on patients' perceptions and responses. The study findings demonstrated the importance of early self-care management for patients with poststroke disabilities. Future research should focus on long-term, community-integrated strategies that involve primary care, enhanced technological support, and caregiver-focused disability adjustment programs to achieve better outcomes.

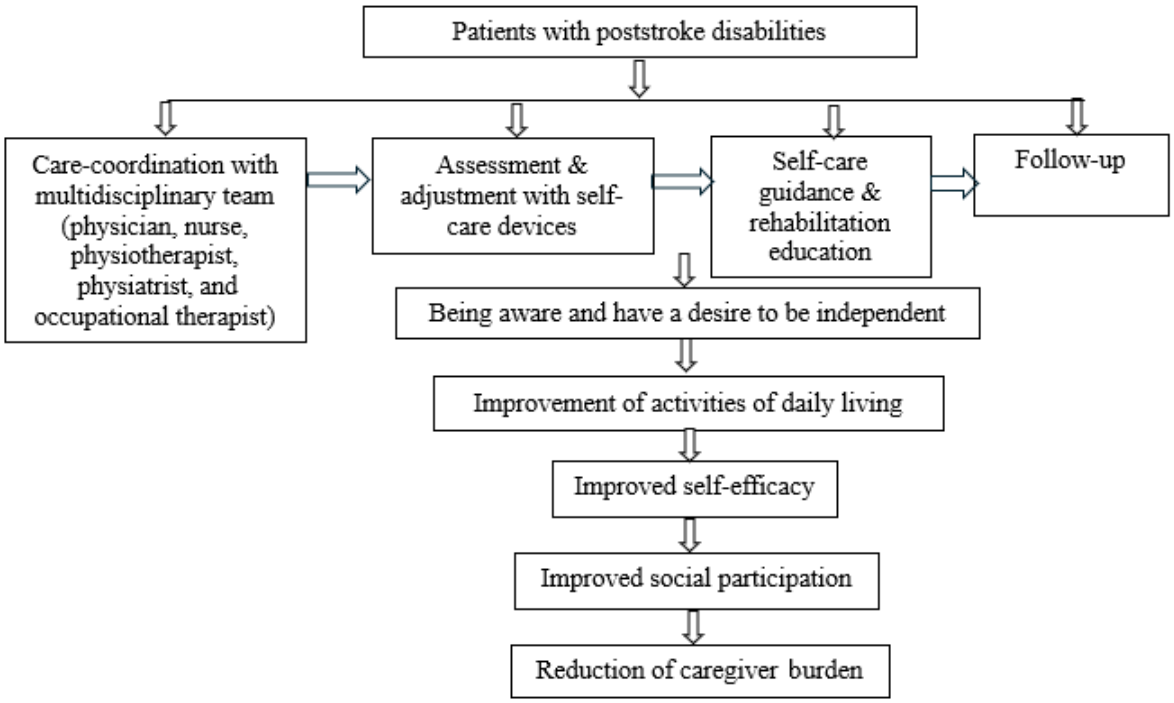
caregiver burden; post discharge; rehabilitation; self-care management; stroke

Introduction

Stroke is a leading cause of disability and death, particularly in low- and middle-income countries (LMIC) [1]. Notably, about 86% of stroke-related deaths and 89% of stroke-associated disabilities have occurred in LMIC. The causes are mainly a lack of prevention, acute management, and rehabilitation facilities and services [2]. The prevalence of stroke globally was 1.2%; in developed countries, 3%; and in developing countries, in 2021 [3]. In Bangladesh, stroke prevalence was 1.1% in 2018 [4], and the trend is rising due to an increase in hypertension, diabetes, smoking, and other modifiable risk factors. High mortality and disability are driven by poor access to acute interventions and limited rehabilitation [5]. Unfortunately, developing countries lack a national database system; therefore, the occurrence of stroke is often underreported [6].

Stroke rehabilitation is a multidimensional process provided by multidisciplinary teams, including physicians, physical and occupational therapists, nurses, psychologists, and social workers [6-8]. It encompasses physical rehabilitation [6], occupational therapy [7], and speech and language therapy [9]. Rehabilitation also includes cognitive therapy for improvement of memory and executive deficits [10], psychological care for poststroke depression and anxiety [11], and social/vocational programs for reintegration of patients into society [6].

The *International Classification of Functioning, Disability, and Health* (*ICF*) is the World Health Organization (WHO) framework for measuring functioning disabilities in the environment where patients with disabilities act and are involved in social participation [12]. *ICF* emphasizes the importance of environmental factors, including assistive devices, which enable persons with impaired function to conduct daily activities and participate in society [12]. However, assistive devices are often not available and expensive, so patients cannot afford specially in LMIC [13]. Acute and postacute rehabilitation services are crucial for improving the quality of life for stroke survivors and their caregivers [14]. To mitigate stroke-related disability and death, urgent priorities include scaling up prevention strategies, improving acute care capacity, and facilitating community-based rehabilitation to address the growing burden of stroke in situations where acute and postacute rehabilitation services are not accessible in health care facilities [1].



In LMIC, including Bangladesh, there is a lack of institutional acute, postacute, and long-term rehabilitation services available after receiving acute care management from the hospital [15]. Patients with disabilities who need rehabilitation face inadequate health care infrastructure and financial resources [16]. Moreover, poststroke function analysis is a lengthy process that begins with impairment evaluation, rehabilitation training, recovery monitoring, and providing the necessary support to carry out daily tasks [17]. Bangladesh faces a critical shortage of rehabilitation workforce compared to the number of patients with disabilities [18]. Rehabilitation services are limited and fragmented, concentrated in tertiary hospitals, where nongovernment organizations, such as the Centre for the Rehabilitation of the Paralyzed (CRP) and Bangladesh Rural Advancement Committee, provide community-based rehabilitation in some parts of the country [19]. As a result, patients with disabilities have no choice but to be cared for by nonprofessional family members in a nonsupportive and unequipped living environment, which makes it difficult to support their independence and participation in society [20]. Moreover, caregivers face significant challenges, including limited stroke knowledge, financial strain, psychological stress, and cultural expectations [21].

As there are insufficient poststroke institutional services available in Bangladesh, home-based stroke rehabilitation could be an alternative way to play a vital role in ensuring continuity of care and supporting functional recovery within patients' home environments [22]. Globally, it is delivered through multidisciplinary outreach teams, primary care providers, caregiver involvement, and increasingly telerehabilitation, which has proven effective in functional and activities of daily living (ADL) recovery [6,7,23].

Nurse-led rehabilitation is well-practiced globally [24]. They excel at coordinating necessary services and providing rehabilitation care integrated with disease management education for patients and their families. However, in Bangladesh, the role of nurses is limited to acute care nursing, and they do not participate in providing rehabilitation services to patients with poststroke disabilities. Therefore, the purpose of this study was to test the feasibility and efficacy of nurse-led rehabilitation programs focused on improving ADL among patients after stroke in Bangladesh (Figure 1).

Figure 1. Study conceptual framework.

Methods

Study Design and Participants

This was a parallel (1:1), open-label, prospective, randomized controlled trial that adhered to the CONSORT (Consolidated Standards of Reporting Trials) guidelines (Multimedia Appendix 1) [25]. In addition to evaluating the intervention quantitatively, we qualitatively explored the feasibility of home-based rehabilitation and the use of assistive devices for promoting functional independence among patients after stroke and their family caregivers. This study was conducted at the National Institute of Neurosciences & Hospital (NINS&H) in Dhaka, Bangladesh, between March 2025 and August 2025. As NINS&H is the only specialized referral hospital in Bangladesh, most of the patients with stroke are usually discharged within 15 days to 1 month due to overcrowding/high bed occupancy. Therefore, we included patients who were admitted within 5-14 days of the onset of their stroke and discharged within 1 month from the hospital. Patients with stroke and their family caregivers, both male and female individuals, aged ≥18 years, were included. Patients were enrolled irrespective of their time (first or any recurrent) and type (ischemic or hemorrhagic) of stroke, with a modified Rankin scale (mRS) score of 1-4. Patients who had a physician's advice for rehabilitation therapy and needed assistive devices for ADL were included. It is evident that within this time (1-2 weeks), if rehabilitation is initiated, the patient experiences a better prognosis [26]. We conveniently enrolled only participants living in the Dhaka district to ensure follow-up visits with minimal dropout.

Sample Size

Sample size was generated using statistical power of 80% at α=.05 (2-tailed), with an estimated medium effect size of 0.75 [27]. We used this effect size as we had sufficient power to detect a meaningful effect. The sample size was calculated to be 29 for each arm (a total of 58 for both arms). Considering a 10% dropout rate, the estimated total sample size was 64 (32 in each arm). We used G*Power software (version 3.1.9.4; Heinrich Heine University Düsseldorf) for Windows for this calculation.

Randomization and Allocation

Participants were randomized equally into intervention and control groups (CGs; n=32 in each group) using a simple random technique by computer-generated numbers, regardless of their age and sex. Participants were sequentially allocated to the intervention and CGs based on the randomization chart. Randomization was done, and the random allocation sequences were kept by a researcher who was not involved in this study to minimize bias.

Assessment of Eligibility and Recruitment Procedures

At first, patients who were admitted to the hospital were assessed by physicians and the research team to identify any physical impairment. The physiotherapist also assessed the range of motion and notified the physician who required rehabilitation based on their disabilities. After checking the eligibility criteria and verifying with the physician, research assistant (RA) nurses explained the study purpose, ensured home visits for follow-up, and obtained written informed consent from patients and their caregivers. The patient was assessed for functional independence using the Functional Independence Measure (FIM) by RA nurses to evaluate their level of functioning. They also assessed the patient's self-efficacy, social participation, and caregivers' burden.

XSL•FO
RenderX

Interventions

Nurse-Led Intervention

Intervention nurses assessed patients' needs, prepared and supported the use of assistive devices, provided rehabilitation education to patients and carers, used telenursing to monitor patients' recovery remotely, and coordinated multidisciplinary care. This comprehensive nurse-led approach empowered the stroke survivors to participate actively in their recovery, promoted independence in daily activities, reduced complications and carer burden, and ultimately improved self-care management.

Rehabilitation Education

Rehabilitation education was provided according to the researcher-developed health booklet, followed by established guidelines and textbook [28] and a published journal guideline [29]. This booklet includes environmental adjustment, self-care management guidelines with disability (eg, eating and mouth care, grooming, bathing, toileting, and mobility), tips to avoid falling, instructions to use assistive devices, changing dietary habits, health monitoring, strategies to manage stress, exercise instructions, and a daily exercise and medication intake record chart (Multimedia Appendix 2).

Assistive Devices

The research team provided assistive devices to improve ADL (eg, spoon holder, bottle opener, pen holder, and cup/mug holder) using a 3D printer and physical improvement–aiding instruments (eg, special adjustable spoon, walking cane, exercise ball, Thera belt, and massage ball) to help patients with poststroke disabilities with self-care. The 3D printers were used to produce the assistive devices, and these were designed and developed by an occupational therapist and adjusted according to the needs of patients with disabilities.

For the Intervention Group

After assessment, patients and caregivers were trained (for 30 minutes during their discharge from the hospital) in self-care with stroke disabilities (eg, eating, grooming, bathing, dressing, and toileting), physical exercise, lifestyle modification [28,29], and prevention of complications after stroke through a researcher-developed "Health booklet" by the RA nurses. The booklet was provided to patients to follow at home for daily practice and a record of exercise with medication intake. Based on their disabilities, adaptive and exercise devices were provided for use at home to promote functional independence. After discharge from the hospital, they were followed by RA nurses through home visits and teleservices biweekly for 3 months (a total of 5 times). The telehealth services include conversations with patients and caregivers and follow-up on adherence to the use of assistive devices provided by RA nurses. These services follow rehabilitation guidelines and health booklet-guided exercises for improving muscle strength. If needed, guidance on the use of assistive devices was also provided through video calls. During these follow-up visits, they assessed patients' regular self-care activities, adjustment to devices, exercise and adaptive behaviors. During the final follow-up, after 3 months of the initial assessment, researchers and RAs evaluated patient outcomes at the hospital. If the patient was unable to attend the hospital, a home visit was made for follow-up.

For the CG

The patients received the usual care from the RA nurses and physician to which they were entitled. They received hospital advice on treatment adherence for stroke prevention during discharge. During the 3 months, patients were requested to visit the hospital for follow-up visits and data collection. We were provided with a health booklet for all and assistive devices who needed after the final evaluation for ethical purposes.

Preparation for Data Collection

Making a Multidisciplinary Team

Upon starting the study, researchers formed a multidisciplinary team consisting of a physician, RA nurses, a physiotherapist, and an occupational therapist under the supervision of the co–principal investigator (neurologist). They collaborated to assess patients from recruitment through final follow-up for evaluation.

Training the Study Nurses

A total of 7 RA nurses, who were involved in this study, received 1 week of training through lectures and practice on self-care, physical exercise, mobility, and telenursing services by the principal investigator based on the health booklet. They also received protocol-specific hands-on training for data collection, performing study procedures about self-care, behavioral changes, including adaptation and motivation, and assembling assistive devices for patients with disabilities using a 3D printer. They had regular refresher sessions about the enlisted activities with the principal investigator before and during the study period.

Data Collection Procedures

After allocating study participants to either the intervention group (IG) or the CG, the RA nurses conducted a face-to-face interview to collect data about the sociodemographic characteristics and health conditions of stroke survivors and their family caregivers. At baseline (T0), the functional independence measurement, self-efficacy, social participation, and care burden of the family were assessed. The RA nurses periodically followed up with the patients of the IG through home visits (twice a month) and teleservice (twice a month) to check their motivation and cultural values to adjust to the intervention devices and health booklet.

In the community, the nurse visited the home setting to observe the home environment and adjust to patients' needs. If required, they suggested modifications to home settings. Moreover, they assessed the way of implementing assistive devices for performing ADL and rehabilitation for improving muscle strength. Nurses demonstrated the use of assistive devices if needed. They also demonstrated the exercise procedure using the health booklet and motivated patients and family caregivers to maintain the daily record book.

To prevent participant contamination, RA nurses obtained consent and collected data in 2 different rooms. They also maintained different schedules for the IG and CG. As the same

XSL•FO
RenderX

RA nurses collected data from both groups, they strictly maintained confidentiality to share the intervention procedures with the CG. For home-based data collection, RA nurses were divided into the IG and CG.

To evaluate the feasibility and chronological changes of adjustment of home-rehabilitation and assistive devices qualitatively, RA nurses interviewed participants through some open-ended questions and observed participants of the IG every time they contacted them. The interview was conducted for 20-30 minutes by RA nurses based on observation points and interview questions during home-based follow-up. The observation and interview points were as follows: "home environment, adjustment, motivation and use of assistive devices, lifestyle changes pattern with risk factors, level of required assistance after using assistive devices, adherence to rehabilitation regimen, mental status, communication, and social participation" after having a stroke (Multimedia Appendix 3).

Outcome Measures

Primary End Point: Functional Independence

Functional independence was assessed using the FIM scale. The FIM was developed in 1983 by a task force from the American Congress of Rehabilitation Medicine and the American Academy of Physical Medicine and Rehabilitation [30]. The Bengali version of the scale was implemented among the patients with functional disabilities in Bangladesh and found to be valid and reliable (α=.97) [31]. This scale has 18 items from level 1 (total assistance) to level 7 (complete independence). This scale consists of 2 subscales, including physical (13 items) and cognitive (5 items) domains. The physical domain score ranges from 13 to 91, and the cognitive domain score ranges from 5 to 35. The range of the total score is from 18 to 126. The higher the score, the better the level of independence.

Secondary End Points

Self-Efficacy

Self-efficacy was assessed by the Generalized Self-Efficacy Scale [32]. This scale assessed patients' self-efficacy after experiencing poststroke stress and the strength of an individual's beliefs in situations. It was translated into the Bengali version and was found valid and reliable (α=.7 to .91) [33]. It has a total of 10 items with a 4-point Likert scale that ranges from 1=not at all true to 4=exactly true. The lowest score is 10, and the highest score is 40. The higher score indicates better self-efficacy.

Social Participation

Social participation was measured using the Participation Scale based on the WHO *ICF* domain for assessing a person's interaction and participation in community life, which measures the severity of social participation restrictions. They standardized the Bengali version of the scale and found it to be valid and reliable (α=.91) [34]. The score ranges from 0 to 70. The higher the score, the worse the level of participation.

Caregiver Burden

Care burden was assessed by the Zarit Caregiver Burden Assessment (12-item) scale, short version, to assess the subjective burden of informal caregivers of patients with chronic diseases [35]. The Bengali version of the scale was implemented among patients with stroke in Bangladesh and was found valid and reliable (α=.85) [36]. The score ranges from 0 to 48. No cutoff point was assigned for classifying the care burden; a higher score indicated a higher care burden.

Qualitative Observations

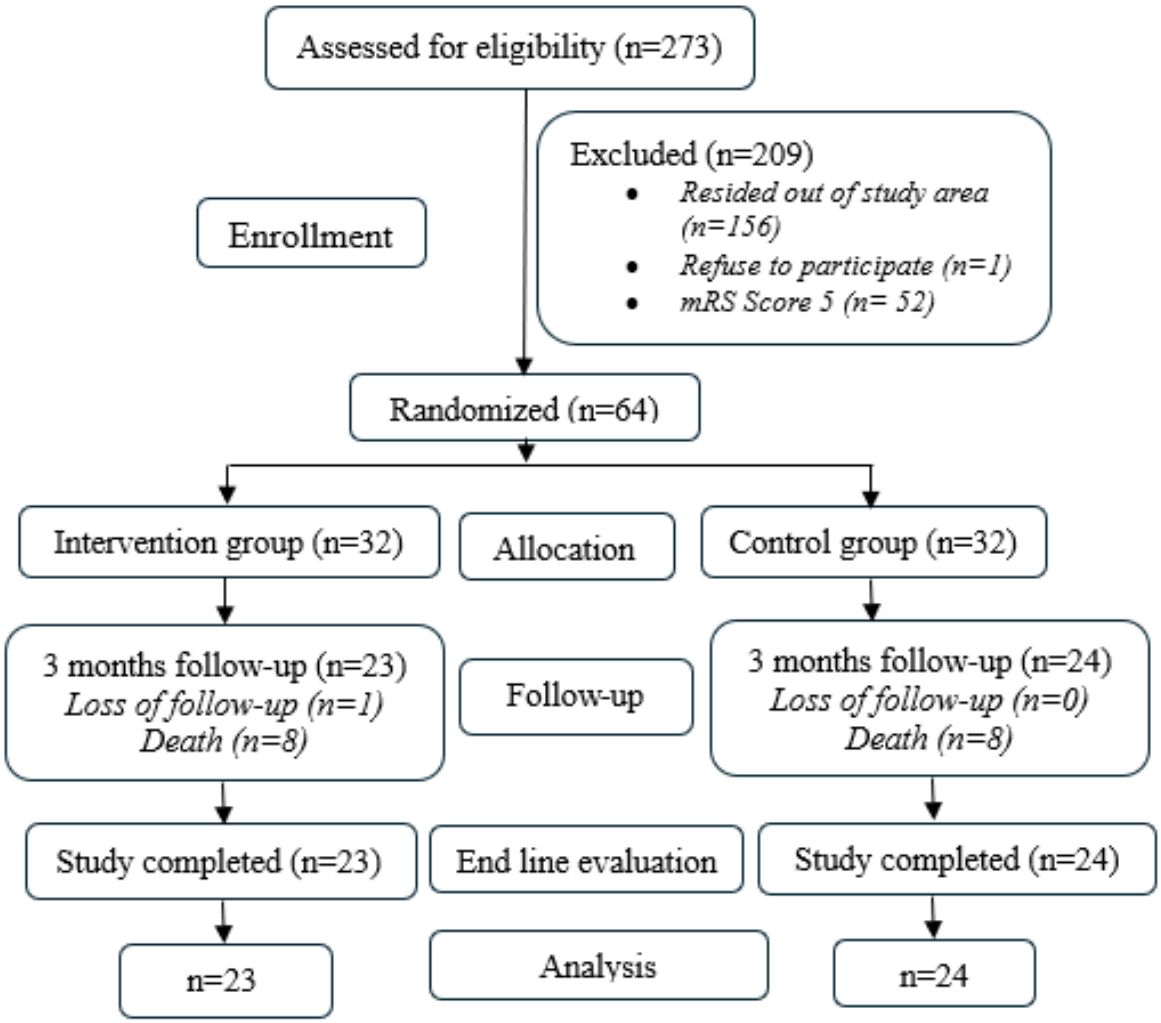
We qualitatively analyzed the assistive device-use rate, motivation to use, and unmet needs for physical improvement among participants who received our intervention (IG).

Analysis

To compare data between the 2 groups at different time points, we conducted a per-protocol set analysis to see the actual efficacy of the intervention. For baseline data, descriptive statistics were used after the normality test. The normal data distribution was examined using Shapiro-Wilk's test, histograms, box plots, and normal Q-Q plots for both the control and IGs, with $P>.05$. We used chi-square or the Fisher exact test to compare the IG and the CG using categorical variables, which were reported as frequencies and percentages. Since our data were not normally distributed, we performed the Mann-Whitney *U* test to report the continuous variables as the mean (SD). The mean differences between the 2 groups were compared by an independent *t* test at each time point (T0 and T1). In addition, to assess changes in outcomes within the groups over time, a 2-way repeated-measure ANOVA was used. The level of significance was set at $P<.05$. We conducted generalized linear models considering covariates such as age, residence, and mRS to examine the influence of additional rehabilitation activities (home-based and CRP). We used SPSS (version 31.0; IBM Corp). For the qualitative analysis, after transcribing and translating, we converged and coded the statements. Then we used Dedoose software (version 10.0.59; Socio Cultural Research Consultants, LLC), and the results were categorized into themes and subthemes.

Ethical Considerations

This study was conducted following the ethical principles of the Declaration of Helsinki after getting ethical approval from the institutional review board of NINS&H (approval number IRB/NINS/2024/392), Dhaka, Bangladesh. After an explanation of the study objective, procedure, risk, and benefit, written consent was obtained from participants and their caregivers. Patients' privacy and confidentiality were maintained throughout the study, and withdrawal was ensured without any consequences. Data were deidentified and assigned unique identification numbers for analysis, and no personal information was used in any publication or presentation resulting from this research. Data were stored and accessible by the principal investigator on a password-protected personal computer.



XSL•FO
RenderX

Results

Overview

A total of 273 participants were evaluated to determine their eligibility for the study. Among them, 209 of 273 did not meet the inclusion criteria; 156 of 273 resided out of the study area, 528 of 273 had an mRS score of 5, and 1/273 refused to participate in this study. Therefore, a total of 64 patients were enrolled equally in both groups (IG: n=32 and CG: n=32); 47 (73%) completed (IG: n=23 and CG: n=24) the study, and were analyzed. Among the participants who did not complete the study (n=17), 16/64 (25%) died during the first month of intervention (IG: n=8 and CG: n=8), and 1/64 (1.5%) was lost to follow-up (Figure 2).

Figure 2. Study flowchart based on the CONSORT (Consolidated Standards of Reporting Trials) statement. mRS: modified Rankin scale.

Sociodemographic and Clinical Characteristics of the Participants

The mean age of participants was 55.6 (SD 14.4) years, with a range of 20-82 years. Most of the participants were male (n=52, 81%) and resided in urban areas (n=55, 86%). A higher proportion of rural residents was noted in the CG (n=7, 22% vs n=2, 6%) compared to the IG.

Overall, no significant differences were observed between the IG and CG across sociodemographic and clinical characteristics and for comorbidity, indicating successful randomization (Table 1).

Preintervention FIM scores were compared with sociodemographic and clinical characteristics in Multimedia Appendix 4. The participants' age, religious status, residence, tobacco smoking, and mRS were significantly associated with FIM (all $P<.05$).

Outcomes

FIM

At baseline (T0), the mean FIM scores were 43.78 (SD 15.94) for IG and 43.79 (SD 14.10) for CG, with no significant difference (*P*>.99). FIM scores improved chronologically in both IG and CG, showing statistically significant improvements within groups; however, those changes were not statistically significant between groups or in the interaction (Table 2).

Table 2. Comparison of study outcomes between intervention and control groups at 4 time points.

	Baseline (T0), mean (SD)	After 1 month (T1), mean (SD)	After 2 months (T2), mean (SD)	After 3 months (T3), mean (SD)	*F* test (*df*)	*P* value
Functional Independence Measure[a]					37.23 (1)[b]	<.001[b]

[b]2-way repeated measure ANOVA.

[c]Independent *t* test was used to compare groups.

[d]2-way ANOVA.

[e]N/A: not applicable.

Self-Efficacy

At baseline (T0), self-efficacy scores of both groups showed a mean of 23.95 (SD 3.33) for IG and 24.12 (SD 4.59) for CG (*P*=.89). After 3 months (T3), IG showed a higher mean (IG: mean 27.04, SD 6.95; CG: mean 26.58, SD 7.14) than CG; however, the difference was not significant (*P*=.82; Table 2).

Social Participation

At baseline (T0) and end line (T3), the mean restriction in social participation was 39.13 (SD 13.17) and 30.35 (SD 21.44), respectively, for the IG and 36.17 (SD 13.18) and 28.21 (SD 17.19), respectively, for the CG. However, the differences were not significant (*P*=.45 and *P*=.71) at both points (Table 2).

Caregiver Burden

The means of caregiver burden were 31.35 (SD 4.5) for IG and 29.88 (SD 6.39) for CG (*P*=.37) at baseline. At end line (T3), the means were 24.91 (SD 13.58) for IG and 25.21 (SD 12.60) for CG (*P*=.94), and no significant differences were found (Table 2).

FIM Subdomain Scores

FIM domain scores were analyzed at baseline (T0) and end line (T3) between the intervention and CGs. There were no statistically significant differences between the groups at both time points in the following categories: self-care, sphincter control, mobility, locomotion, communication, social cognition, and overall FIM (all *P*>.05; Multimedia Appendix 5).

XSL•FO
RenderX

Regarding FIM scores, the CG demonstrated improvements comparable to those of the IG. To explore the reasons, we conducted further analyses and found that participants in both groups engaged in private rehabilitation services in addition to our intervention. As this was not part of the exclusion criteria, and for ethical reasons, we could not restrict their access to such services. We therefore examined how these additional rehabilitation activities influenced our results. Table 3 presents the FIM score changes by service in each group. The changes were inconsistent and showed no clear relationship with the services received.

To examine which additional rehabilitation services affected the FIM score, we conducted a general linear model with age, mRS, and residence as covariates and found no statistically significant effects**.**

Compared with the CG, participants in the IG showed no significant difference in outcomes (*B*=2.48, SE=10.04, 95% CI –17.21 to 22.16; Wald χ^2_1=0.06; *P*=.81). Similarly, home-based rehabilitation did not significantly predict the outcome relative to the research intervention (*B*=–2.64, SE=10.25, 95% CI –22.72 to 17.44; Wald χ^2_1=0.07; *P*=.80). CRP-based rehabilitation also did not differ significantly from the research intervention condition (*B*=17.22, SE=16.80, 95% CI –15.70 to 50.15; Wald χ^2_1=1.05; *P*=.31; Table 4).

Table 3. Comparison of rehabilitation services from baseline to end line (n=47).

[a]CRP: Centre for the Rehabilitation of the Paralyzed.

Use of Assistive Devices

Participants in the IG were significantly used in assistive devices (*P*<.001), with 21 (91%) in the IG compared to only 4 (17%) in the CG. These findings indicate that the intervention was associated with significantly greater adoption of assistive devices. In CG, participants purchased assistive devices (exercise ball and TheraBand) with the advice of their physical therapist or outside rehabilitation services.

Extremity Impairments

All (n=47) participants had extremity impairments, and 94% (44/47) had both upper and lower extremity impairments, and 6% (n=3) had only upper extremity impairments. There was no significant difference observed between groups regarding extremity impairment (*P*>.99).

Qualitative Findings

Overview

Among all the participants (n=32) who received the intervention, 23 were interviewed and observed for qualitative assessment. The qualitative data revealed 7 subthemes encompassing three key themes: (1) patients' adherence to rehabilitation, (2) improvement of physical functioning and independence, and (3) perceived improvement by patients and family caregivers. Each theme demonstrated positive transformation between the first month and the third month, supported by participants' perceptions and direct quotes (Multimedia Appendix 6).

Theme 1: Patients' Adherence to Rehabilitation

Acceptance and Motivation to Use Assistive Devices

During the first month, participants were in the process of adapting to assistive devices and integrating them into their daily life activities. By the end of the third month, most had accepted and used these devices independently without any assistance from caregivers, despite emotional and financial challenges.

> *My family spends more on me than they earn* [Male, 48 years, Case #2]

> *These devices feel like blessings, but sometimes I lose hope* [Female, 60 years, Case #6]

Following the Exercise Regimen

Participants initially depended on caregivers to carry out suggested exercises; however, they consistently followed rehabilitation guidelines independently (at least 2 times per day for 30 minutes) in later times. This shift illustrates increased motivation and adherence to recommended regimens of rehabilitation.

Theme 2: Improvement of Physical Functioning and Independence

Mobility and Balance

At baseline, participants required assistance for walking and balance from caregivers. After intervention, most had the ability to ambulate with minimal assistance or modified independence using assistive devices by their own efforts.

> *Nowadays I'm feeling good. I'm going out with a walking cane and walking on my own. My family is relieved* [Male, 20 years, Case #14]

This quote demonstrates regained confidence and functional ability.

ADL

Dependence on daily tasks reduced progressively, from total or moderate dependence to moderate or minimal levels. Initially, they used assistive devices to perform their ADL. Gradually, after gaining the ability, they reduced their use of assistive devices.

> *I do everything by myself (with the help of assistive devices), whatever I can* [Male, 65 years, Case #7]

> *Now I can do my daily activities like eating and going to the toilet on my own. I just need a little help, but not always* [Male, 48 years, Case #22]

Comorbidities and Risk Factors

Participants commonly experienced comorbidities such as diabetes, hypertension, and visual disturbances. While persistent, most reported reduced symptom severity over time.

Participants received health education to combat comorbidities. One participant with diabetes and hypertension felt better after receiving our intervention. He explained:

> *I'm seeing blurry, specially at night... headaches appear when I go to sleep* [Male, 20 years, Case #14]

Theme 3: Perceived Improvement by Patients and Family Caregivers

Physical Improvement

Participants' perceptions shifted from no or moderate improvement to substantial progress and functional independence using assistive devices. Another participant expressed:

XSL•FO
RenderX

> *I feel like I am improving day by day... this progress makes me feel very happy and hopeful* [Male, 48 years, Case #2]

Social Interaction and Participation

Initially, participants were socially withdrawn; they actively reengaged in community and family activities. After our intervention, they engaged more in social gatherings.

> *I go out and meet people. Being active has improved my condition* [Male, 65 years, Case #21]

This reflects enhanced self-efficacy and psychosocial well-being.

Discussion

Principal Findings

This study evaluated the feasibility of a nurse-led rehabilitation education with an assistive device to improve functional independence for self-care management, self-efficacy, social engagement, and reduction of caregiver burden among patients with poststroke disabilities. Over the 3-month study period, there was improvement after intervention; however, no significant differences were observed in any of the outcomes between the intervention and CGs.

Sociodemographic Characteristics

The participants' average age was 50 (range 20-82) years, which is consistent with the demographics of patients with stroke in LMIC, where strokes typically occur in early life compared to high-income countries [2]. Among the participants, male individuals were higher, which indicates that stroke is more common in men worldwide [37]. Therefore, it is essential to explore the underlying factors and comorbidities prevalent among male patients after stroke in that age group.

The majority of individuals came from families with moderate income or were employed, and educational attainment was consistent between groups. According to previous studies, socioeconomic and educational characteristics have an impact on stroke outcomes because decreased likelihood of receiving rehabilitation services and a worse long-term prognosis are associated with lower income and educational attainment [38].

The most prevalent comorbidities were diabetes mellitus and hypertension, which were found in almost a third of both groups, which are recognized risk factor profiles for stroke in Southeast Asian populations [39]. In the IG, we observed more ischemic strokes compared to the CG. As the prognosis of ischemic stroke is limited after intervention, this might affect our intervention, making it nonsignificant. Moreover, compared with ischemic strokes, hemorrhagic strokes are typically associated with higher early morbidity and mortality, resulting in more deaths, as reported in a previous study [40]. Despite persistent comorbidities, participants described adaptation and symptom control over time. This indicates resilience and coping strategies that help patients after stroke to survive with multimorbidity [7,41].

Functional Independence

We did not find any difference in FIM scores over time between the groups. However, if we observe the trend, the FIM scores improved at each time point for both groups. In the IG, we assumed that the FIM scores were increased due to our intervention. We explored the cause of the improvement in FIM scores in the CG and found that they received rehabilitation services from external sources (home-based and CRP), which we could not inhibit due to ethical considerations. CRP provides rehabilitation services with a very highly trained professionals using all conventional therapies (eg, physiotherapy, occupational, speech, and language) in our study areas. Therefore, we can consider our intervention to be effective in 1 arm. This study emphasizes the importance of adequate rehabilitation intervention for patients with poststroke disabilities. Other studies also explained that poststroke disability can be improved after health education and the use of assistive devices [42]. Though our short (3 months) study duration shows FIM improvement in individual groups, one study showed no significant differences in FIM evolution when compared to usual care alone during the short period of time (<10 weeks) [43]. Improvements in mobility, balance, and ADL performance reflect global evidence that structured poststroke rehabilitation fosters early recovery within 3-6 months [44]. The progression from dependence to modified independence, as reported by participants, reinforces the importance of consistent physiotherapy and guided home exercises [9,45]. Our study findings highlight the significance of comprehensive standard care following a poststroke disability.

Self-Efficacy, Social Participation, and Caregiver Burden

With respect to self-efficacy, social participation, and caregiver burden, we did not find any difference between the groups over time. To improve the self-efficacy of patients with stroke after discharge, we provided organized interaction and instruction that helped patients feel more confident and develop the skills they need to manage the aftermath of stroke. As in the CG, some of the patients received group interaction, education on health care and rehabilitation, and a community reintegration program from the CRP; therefore, we found improvement of self-efficacy in both groups. Recent research supports the importance of fostering self-efficacy through community services and standard care in patients, along with natural psychological adaptation [44].

The improvement of social participation and the decrease of caregiver burden were also observed in the IG and in the CG by the influence of CRP services. Despite prominent functional improvements, many patients after stroke report limitations in their ability to participate in the community, which raises concern [46]. Caregivers gradually adjust and become more confident as in the poststroke period, patients regain functioning ability, and families gain experience over time [47]. However, the persistently high levels of burden reported in recent surveys suggest that more focused and direct interventions, such as social support and behavioral education programs, may be effective [47].

The qualitative findings demonstrate how structured therapy promotes progressive recovery of patients after stroke, demonstrating significant gains in functional independence, adherence, and social reintegration. Additionally, patient

XSL•FO
RenderX

narratives enhance comprehension by clarifying contextual and personal factors influencing rehabilitation involvement.

Over time, patients demonstrated more motivation and continued use of assistive devices, which is consistent with earlier studies that focused on gradual adaptation to rehabilitation services [44,48]. However, participants acknowledged that financial and caregiving burdens highlight socioeconomic challenges common in low-resource settings [17,42]. These results are consistent with research indicating that long-term rehabilitation success depends critically on patient motivation and family support [18].

This study shows that nurse-led rehabilitation enhances psychological well-being and quality of life through perceived physical improvement and increased social engagement [44]. Self-efficacy's involvement in fostering recovery is supported by the expressed sense of hope and autonomy [21].

In resource-limited environments, barriers such as inadequate infrastructure, caregiver burden, and financial restraints reduce sustained engagement in rehabilitation [17,49]. These insights highlight the necessity of nurse-led, family-centered, community-based rehabilitation programs that tackle socioeconomic and clinical challenges [21].

Overall, the results show that, even in low-income settings, structured rehabilitation helps stroke survivors recover both physically and psychologically. To improve long-term adherence and social reintegration, future interventions should include systems of social support and monetary assistance.

Strengths and Limitations

This is the first nurse-led randomized controlled trial in Bangladesh to improve patients' ADL with disability by providing rehabilitation intervention. This study represents a proper allocation of participants through successful randomization. We provided assistive devices, education booklets, and follow-up through home visits. We carefully assessed patients and provided the appropriate assistive devices, ensuring that their usage was accurately measured. As this is a feasibility study, we observed that both the device and nurse education were well accepted by patients and family caregivers, indicating that this program could be feasibly implemented in the Bangladesh context.

Nevertheless, limitations must be acknowledged. High early mortality and attrition reflect the acute severity of illness in the study population. It causes underpowering of our study sample size. We conducted our study for a short period (3 months) of time with a small sample, which made it very difficult to interpret the findings. The study was conducted only in urban areas, which did not reflect the scenario of the whole country, which may limit generalizability. Further studies with multiple sites are needed to prevent participant contamination. More accurate measurements, rather than FIM, should be implemented to assess the influencing factors for self-care management. We also need to reconsider the mRS level (mRS-4) as there is a more severe disability that limits physical improvements.

Conclusions

In conclusion, this is the first nurse-led pilot randomized controlled trial aimed at improving the functional abilities of patients with poststroke disabilities in Bangladesh. However, our rehabilitative intervention (3 months) showed no impact on FIM, self-efficacy, social participation, and caregivers' burden for patients after stroke; obvious improvements were observed at each time point (baseline, monthly, and end line) of evaluation for both IG and CG. We assumed that this improvement occurred in the IG due to our intervention, and for the CG, improvement was observed due to the influence of rehabilitation received from home-based and institutional services. The result suggested that a comprehensive rehabilitation intervention is essential for the physical improvement of patients with poststroke disabilities. A future long-term interventional study with a large sample size will be guaranteed for better outcomes, considering all external influences to understand the underlying factors for the improvement of rehabilitative patients after stroke. Strengthening primary care facilities can be a strategic way for the community integration of patients with stroke disability. A government-led, systemic approach is essential to translate policy commitments into equitable access to rehabilitation services for all patients after stroke.

Acknowledgments

I would like to express my sincere gratitude to all the patients and their caregivers for their generous participation in this study. We acknowledge the enormous support from the medical staff at the National Institute of Neurosciences & Hospital (NINS&H) and research assistants for their tremendous effort. Special thanks to the Director of NINS&H for his excellent support of this study. We would like to express our gratitude to Mr Wataru Iwamori, OTR, Ai Reha Home-Visit Nursing Station, Ai Reha Co, Ltd, Hiroshima, Japan, for his guidance on staff training and the development of educational materials for stroke rehabilitation.

Abstract

Background: Access to physical rehabilitation services, including orthotics and wheelchairs, is recognized as a fundamental human right but remains limited in many low- and middle-income countries due to resource constraints, fragmented care, and a shortage of trained rehabilitation professionals. In Cambodia, where the health system still faces challenges from past conflict, these services are delivered through a mix of government, international, and nongovernmental organizations.

Objective: This study investigated the pathways to obtaining orthoses and wheelchairs in Cambodia and their impact on individuals with physical impairments.

Methods: Semistructured interviews were conducted to explore experiences and the impact of accessing physical rehabilitation and assistive products for orthosis and wheelchair users. Interviews were conducted face-to-face with translation support, audio recorded, transcribed, and analyzed using thematic analysis. Interviews were conducted with participants in Phnom Penh and the Kandal province in Cambodia. In total, 17 participants aged 18 to 65 years who were current or previous patients of the Exceed Worldwide physical rehabilitation center located in Phnom Penh took part in the study.

Results: Three themes emerged (early experiences of illness and health care seeking, pathways to assistive products, and the impact of these assistive products). Access to orthoses and wheelchairs often involved lengthy delays and inconsistent experiences with medical care and physiotherapy. Despite these challenges, assistive products played a vital role in improving mobility, independence, and social participation, contributing to greater confidence and emotional well-being. However, issues such as poor environmental accessibility and delays in repair or replacement limited their effectiveness.

Conclusions: The findings demonstrate that, while assistive products offer significant benefits, they do not fully address the systemic barriers faced by people with physical disabilities in Cambodia. Persistent challenges such as stigma, environmental constraints, and emotional strain demonstrate the need for integrated policy reforms and a robust continuum of care that ensures coordinated, ongoing support across all stages of rehabilitation.

Introduction

The United Nations Convention on the Rights of Persons With Disabilities states that access to physical rehabilitation services and assistive products constitutes a fundamental human right [1]. Consequently, individuals with disabilities must be guaranteed equitable access to these services. According to the World Health Organization [1], disability is caused by the interaction between health conditions or impairments and societal or environmental barriers that hinder full participation in society. Within this, impairment refers to issues in body function or structure, including significant deviations or losses. In many low- and middle-income countries (LMICs), physical rehabilitation centers providing prosthetic and orthotic (P&O) services and assistive products are limited, and those services that are available may be inaccessible to potential service users [2].

Assistive products, such as orthoses and wheelchairs, are external products that can be used to prevent impairments and can support individuals in many areas of life, such as education, employment, independent living, and social participation [1,3]. The provision of assistive products can bring socioeconomic benefits for governments and welfare systems, including increased labor force productivity [1,4]. Orthotics and wheelchairs help improve mobility, but they must be appropriate for the user's environment. If an assistive product is not well matched to the setting in which it is used, it may be abandoned [2]. This can result from poor-quality provision, limited user training, and a lack of local services for maintenance and repair [2].

Although population need for wheelchairs and orthoses is lower than the need for other assistive products such as spectacles or walking sticks, reflecting their use among people with more severe functional limitations [1], access remains limited. Only around one-third of those needing basic manual wheelchairs have access to them, with even lower access to more specialized devices. Orthotic provision is similarly low, meeting only 15% to 25% of needs [1].

Orthoses and wheelchairs are included in the World Health Organization Priority Assistive Products List, reflecting their important role in enabling mobility, independence, and participation for large and diverse user groups [5]. However, access to assistive products in LMICs remains limited due to factors such as a lack of political prioritization, insufficient funding and investment, limited awareness of the need for assistive products, market barriers, and shortages of trained rehabilitation workers, resulting in understaffed services and barriers to effective service delivery [6,7]. These challenges can contribute to lengthy delays in accessing physical rehabilitation, such as P&O services, which are further exacerbated by limited referral systems in place and the absence of well-established continuums of care across multiple stages, such as health promotion, preventive care, curative care, and rehabilitation [1,6,8].

This research focused on Cambodia, an LMIC in Southeast Asia. The health system in Cambodia has been heavily impacted by a turbulent past, including conflict and civil war, which has contributed to ongoing challenges [9]. Currently, the delivery of physical rehabilitation services in Cambodia is a joint effort among the Cambodian government, international organizations, and nongovernmental organizations (NGOs) [10]. The People With Disabilities Foundation, a department of the Cambodian Ministry of Health, operates 3 physical rehabilitation clinics and 2 repair workshops [10]. Other organizations, such as Exceed Worldwide, International Committee of the Red Cross, and Humanity & Inclusion, also provide physical rehabilitation and assistive products free of charge [11].

Although there is a growing body of qualitative research on prosthetic services in low-resource settings, including studies on access barriers [12,13], user experiences [11,14], and satisfaction with devices and service delivery [15], fewer studies focus specifically on orthosis or wheelchair users. Where included, these groups are typically examined alongside prosthetic users, limiting evidence on their specific experiences despite the scale and diversity of people who rely on these devices. This study included wheelchair users only, orthosis users only, and users of both to explore shared and divergent experiences across mobility-related assistive product use, enabling analysis of experiences related to rehabilitation access, assistive technology provision, participation, and disability-related stigma, as well as differences between groups. This study therefore explored pathways to accessing physical rehabilitation and obtaining orthoses and wheelchairs in Cambodia and examined how this access shapes the lives of people with physical impairments.

Methods

Design

This qualitative study used semistructured in-depth interviews to explore the pathways to physical rehabilitation services for orthotics and wheelchairs in Cambodia. As this study aimed to understand the pathways taken to receive services, we wanted participants to use their own words to describe their experiences rather than using a fixed survey, leading to the approach undertaken. Multimedia Appendices 1 and 2 contain the completed COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist and associated information about the interviewer.

Setting and Sampling

This study took place in Phnom Penh and the Kandal province, Cambodia, in partnership with a physical rehabilitation center operated by Exceed [16]. Exceed is an international NGO that provides physical rehabilitation services in 3 provinces of Cambodia. Participants included individuals who were currently using or had previously received an orthosis or wheelchair from Exceed's Phnom Penh clinic.

Participants were primarily recruited using a convenience sampling approach involving individuals who attended the clinic either for scheduled appointments or a walk-in visit. Additional recruitment took place during community visits conducted as part of Exceed's outreach activities, including repair workshops and wheelchair delivery events. Some participants were also identified through direct outreach, in which community workers

XSL•FO
RenderX

contacted potential participants to inquire about their interest in taking part in the study. A total of 9 participants were recruited at the clinic, and 8 were recruited either during community visits or through interviews that took place outside of the clinic arranged by community workers. Recruitment was conducted by Exceed staff, who presented the study and emphasized that participation was voluntary.

Interview Procedures

All interviews were conducted face-to-face in Cambodia at Exceed's clinic in Phnom Penh, during community outreach visits or at the homes of participants. For interviews conducted during community visits, a private area within the community space where outreach activities were held was used to ensure confidentiality. The interviews took place from April 2022 to June 2022.

A lecturer from the Cambodian School of Prosthetics and Orthotics in Phnom Penh served as the translator for the interviews. The translator was a native Khmer speaker with English as their second language and professional experience teaching P&O in English. Their clinical and educational expertise supported the translation of technical rehabilitation concepts; however, the absence of a professionally trained interpreter may have resulted in the loss of linguistic nuance or subtle shifts in meaning [17]. Consistent use of a single translator and advance translation of the interview guide were used to support translation consistency [18]. The English version of the interview guide can be found in Multimedia Appendix 3.

During the interviews, questions asked in English by the interviewer were translated into Khmer. Participant responses were then translated back into English using consecutive verbatim interpretation. The quotations presented in the Results section represent the words of the translator and were subsequently edited into readable English for clarity while preserving the original semantic meaning and tone, in line with recommendations within the qualitative research literature regarding translated data [19,20].

The interviews were also recorded using an audio device. Sample size was guided by the aim of generating in-depth accounts rather than achieving data saturation, in line with reflexive thematic analysis practice [21].

Ethical Considerations

All participant documents, such as participant information sheets and consent forms, were produced in English and translated into Khmer by a local team based at Exceed. These documents were provided to the participants before the interviews, and the translator read them to participants to ensure full agreement and explained that they could withdraw at any time and this would not impact the care or treatment they received from the P&O clinic. The potential risks and benefits of taking part and data handling procedures were also explained to participants.

Once the participants had understood and agreed to take part in the study, written informed consent was obtained from all participants prior to data collection. No participants withdrew from the study following consent. All identifiable information was removed from transcripts, and data were stored securely on university servers accessible only to members of the research team.

Ethics approval for this study was granted by the University of Southampton Ethics and Research Governance Online system (68254.A1) and the National Ethics Committee for Health Research in Cambodia (088). All study procedures were conducted in accordance with the ethical standards of the approving committee. Participants received a 12,000 Cambodian riel (US $2.97) token of appreciation for their time.

Data Analysis

The audio files from the interviews were transcribed verbatim by the lead author (CS). The data were analyzed using reflexive thematic analysis [21] to categorize them into themes and subthemes. Thematic analysis was carried out using an interpretivist epistemological framework, which views knowledge as coconstructed and embedded within social, cultural, and contextual settings [22]. From this perspective, findings are not considered objective truths but interpretations shaped through interaction between translated participant accounts and researcher analysis.

Data coding was completed by the lead author (CS) and discussed with the coauthors (AP, MD-H, and AAC). This study formed part of a wider project on barriers to and facilitators of health and rehabilitation services in Cambodia. The wider study informed the initial deductive coding framework; however, coding and theme development for this analysis were primarily inductive and grounded in participants' accounts. The wider study provided a guiding concept rather than a rigid coding structure, allowing additional meanings and interpretations to develop iteratively throughout the analysis through inductive coding [23]. After coding the interview data, codes were reviewed and iteratively developed into broader themes and subthemes through an ongoing process of comparison, refinement, and discussion among the research team. Multimedia Appendix 4 includes all the themes, subthemes, and codes that emerged in this study.

Results

Participant Characteristics

Table 1 presents participant information, including gender, age, type of assistive product, reason for use, and interview location. Seventeen participants were interviewed (n=12, 70.6% women and n=5, 29.4% men), and none dropped out before completing the interview. In total, 52.9% (n=9) of the participants used knee-ankle-foot orthoses, 29.4% (n=5) used ankle-foot orthoses, and 17.6% (n=3) used manual wheelchairs. The average interview length was 43 (SD 12.3) minutes (ranging from 19 to 62 minutes).

[a]KAFO: knee-ankle-foot orthosis.

[b]AFO: ankle-foot orthosis.

The interviews were coded into three themes: (1) early experiences of illness and health care seeking, (2) pathways to assistive products, and (3) impact of assistive products.

Early Experiences of Illness and Health Care Seeking

Most participants stated that the reason for orthosis or wheelchair use was fever, with the most common cause of this being polio. Nearly all participants experienced this before they were 5 years old. A minority were uncertain of the cause, with some of their parents being skeptical of medical explanations. For example, one participant reported that her mother believed that antibiotic or antipyretic injections received at a health center were responsible:

> *Before she got ill, she was able to walk right, so her mum doesn't believe that a fever for a night has led to her being unable to stand and walk.* [From interview with Samnang; female; aged 18 years]

As most participants were young at the time of diagnosis, health care decisions were made by parents and grandparents. Health care use varied; while some sought multiple treatments, others received no care despite sudden limb weakness or paralysis. Participants who reported never accessing health care at the time cited several reasons, including parental work demands, financial constraints, and limited health care availability. This was explained by 11.8% (2/17) of the participants, who described the lack of treatment options when they were children due to insecurity and civil unrest in the country:

> *During 1972, she said because the country is insecure or there were problems in the country, there was no medical treatment available, no nothing.* [From interview with Sophal; female; aged 51 years]

Khmer traditional treatments were used exclusively or alongside allopathic medicine, with parents often moving between different types of health care facilities.

Pathways to Assistive Products

Experiences of Medical Treatments or Physiotherapy

Participants learned of orthotic and wheelchair services, including those provided by Exceed and other facilities, through family, neighbors, and outreach by community health workers. Lengthy delays between the onset of impairment and receiving further medical treatment, such as surgery or physiotherapy from hospitals or physical rehabilitation services, were common. Surgery, typically to release lower-limb muscles and tendons to improve mobility, was followed by months of aftercare, although some participants were unable to adhere to it. One participant explained that it was recommended that she undergo surgery on her spine; however, her mother refused due to not believing it was necessary:

> *The physician in Kantha Bopha hospital mentioned that the most important thing is her trunk, her spine. They wanted to do the operation on her spine, but her mum didn't agree with the surgery.* [From interview with Chea; female; aged 28 years]

Although it was not explored in depth, these findings indicate the importance of parental trust in obtaining health care and ensuring that health care professionals can adequately explain information to foster trust between them and patients.

Experiences of Using P&O Services

Participants reported varied experiences with physical rehabilitation services and assistive products. Initial visits typically involved assessment for orthotics or wheelchairs followed by physiotherapy and/or limb casting for orthotic fabrication. Several participants recalled fear and distress during early fittings, particularly as children, due to limited understanding of the process. One participant, who was a child at the time of her first appointment, stated that she believed the orthosis would require cutting into her leg:

> *She said that first time she was scared because she thought that when they brought her to the center, they might cut into her leg or something.* [From interview with Daevy; female; aged 35 years]

Two wheelchair users reported no difficulties adapting; however, one wheelchair user expressed reluctance to use the wheelchair outside the home:

> *He uses the wheelchair just around the house, only indoors. He doesn't use it outdoors because he is afraid of cars and other transport, because they travel very fast, so he is worried about accidents.* [From interview with Narin; male; aged 65 years]

Pain during orthosis fitting and use was commonly reported, particularly by those fitted as children. Gender differences emerged, with men generally reporting minimal discomfort whereas women more often described pain and reported their orthoses as bulky, heavy, and causing blisters in the lower limbs. The 2 quotes below describe some of the experiences that female participants had with their orthoses:

> *She said that when using the device, she feels like it's difficult to walk and is painful. Sometimes she feels like the knee is soft, so she falls over often.* [From interview with Rotha; female; aged 18 years]

> *He said it's not very difficult, like he is able to adapt when he wears the orthosis.* [From interview with Sambath; male; aged 31 years]

Difficulties in adapting to an orthosis sometimes led to device abandonment, particularly when discomfort prevented use. However, many users persisted because they recognized potential functional benefits, although some required multiple orthoses to adapt:

> *She said that after she threw the first device away, she was afraid she would be shy (due to her impairment), so she wanted to try and get a second device and learn to walk with that device.* [From interview with Bopha; female; aged 40 years]

Impact of Assistive Products

Importance of Access to Assistive Products

Several participants reported the positive impact of using a wheelchair or an orthosis. These devices supported their mobility, independence, and inclusion within their communities. Access to assistive products improved participants' confidence and emotional well-being, contributing to a greater sense of happiness and facilitating social interaction. One participant explained that, since she received the orthotic device, she had been able to make friends and work with others:

> *She feels confident and can be herself when she got the new device, before when she didn't have the device, she didn't have friends and worked alone.* [From interview with Chhean; female; aged 30 years]

Independence and the ability to carry out household tasks were highly valued, influencing patterns of assistive product use. Orthoses were generally worn throughout the day and removed only for washing or sleep, although some participants managed short distances without them. This pattern of use contrasted with that of wheelchairs, which were less commonly used within the home environment:

> *For him if he just stays at home, he won't use the wheelchair, but if he travels outside for a short distance, he's going to use his wheelchair.* [From interview with Chanthou; male; aged 51 years]

Despite the significance of assistive products in participants' lives, many reported delays in repairs or replacements of their assistive products. One participant, for example, reported using the same orthotic device for over 10 years, far beyond the typical expected life span of 2 to 3 years. These delays often led participants to resort to temporary self-repairs:

> *He said that his orthosis was broken, so he tried to repair by wrapping plastic around it, but he knows that it is not strong and is only a temporary repair until he gets the new device.* [From interview with Sambath; male; aged 31 years]

Limits in Access to Assistive Products

While assistive products provided significant benefits, they did not eliminate all challenges associated with having a physical impairment in Cambodia. One participant noted that, after discontinuing the use of her orthosis, she felt that her lower limbs had become stronger and became more confident in her mobility:

> *She said that because she has stopped using the device, she feels stronger and more confident because when she was young, she fell over often, but now it's ok, she doesn't fall often.* [From interview with Chamroeun; female; aged 20 years]

Participants noted that environmental conditions affected the functionality of their assistive products. Uneven or sandy terrain increased the risk of falls and wheelchair entrapment, whereas the weather reduced durability and comfort. Flooding and heavy rains during the wet season caused rusting of wheelchair frames, whereas high temperatures affected orthoses by causing the plastic to expand, affecting the fit of the device:

> *Because of the heat right now, the plastic [on the orthosis] increases in size so it makes it loose for him. It doesn't cause pain, but there is less control.* [From interview with Savy; male; aged 35 years]

Despite access to assistive products, daily limitations persisted, varying across individuals. Participants reported avoiding community events such as weddings and religious ceremonies due to discomfort; anxiety; or practical barriers, for example,

XSL•FO
RenderX

concerns about not being able to sit on the floor (customary during temple visits) without removing an orthosis.

The interviews also found challenges with self-perception. Several participants expressed feelings of being a burden on their families due to their reliance on others. One participant, following a stroke, compared his current abilities with his prestroke abilities and described a reduced sense of self:

> *The people around him pity him. He feels like before he could do everything and worked hard, but now he can't do anything, so he feels like he is useless.* [From interview with Narin; male; aged 65 years]

Experiences of negative perceptions were common. Some participants reported being stared at in public, leading to a reluctance to leave their homes:

> *Other problems he faces when he goes out, people look at him like he is not normal and they stare at him.* [From interview with Chanthou; male; aged 51 years]

However, not all participants reported discrimination. Some felt that they were treated equally because they were able to perform daily tasks and contribute economically, aligning with societal perceptions of "normality":

> *She doesn't feel like anyone discriminates or criticizes her about her disability. Her family say that she is ok, she has an impairment, but she is able to get married, have a family and work like other normal people.* [From interview with Leap; female; aged 38 years]

Participants often described employment and contributing to family and community life as helping mitigate the impact of impairment. "Blending in" with people without disabilities was seen as a strategy to avoid discrimination. Some noted improving attitudes toward disability in Cambodia, attributed to greater awareness and education:

> *Nowadays he thinks that information about disability is shared to everyone and people understand more about disabled people, so they don't discriminate against him.* [From interview with Viseth; male; aged 32 years]

However, there was a shared recognition of the ongoing need for more information about disability to be disseminated through schools, television, and other media to reduce stigma.

Discussion

Principal Findings

This study found that early childhood illness, most commonly linked to polio, alongside delayed or absent access to health care and rehabilitation services, shaped long-term disability trajectories and pathways to assistive product use. Assistive products substantially improved mobility, independence, and psychosocial well-being but did not fully remove environmental, social, and attitudinal barriers experienced by users. Pain, fear, and adaptation challenges highlighted the limitations of provision models that focus solely on the device, emphasizing the need for more holistic approaches that address both individual needs and the wider social context.

These broader challenges are rooted in the underlying causes and understandings of impairment. Use of orthoses or wheelchairs in this study was largely attributed to contracting polio in childhood, although other causes included clubfoot, cerebral palsy, and stroke. Some participants with polio were uncertain about their exact diagnosis, with several attributing their impairments to treatments received in hospital. Evidence shows that, in polio-endemic settings, intramuscular injections administered during the incubation period of poliovirus can increase the risk of paralysis, a phenomenon known as provocation poliomyelitis [24-26]. This may help explain why some individuals linked their impairments to medical treatments they received as children.

Many participants reported significant delays in receiving their first assistive product, primarily due to limited awareness of P&O services and restricted service availability. Early rehabilitation is known to improve outcomes for conditions such as stroke and cerebral palsy [27,28]. However, access to physical rehabilitation in many LMIC settings remains constrained by inconsistent service provision and shortages of skilled rehabilitation professionals [29]. Pathways to assistive products can also be difficult to navigate due to fragmented referral systems, particularly where rehabilitation services are delivered by international organizations and NGOs operating separately from wider health systems [1]. Despite this, P&O and other rehabilitation services are essential components of the health care system and play an important role along the continuum of care, particularly in ensuring access during both the postacute and long-term phases of care [30].

Initial use of orthoses was frequently associated with pain, contributing to device abandonment in some cases. This study found that female users of orthotics described experiences of pain and discomfort with their orthoses more frequently than male users. This aligns with existing literature that showed that women's experiences with orthoses were more unpleasant and uncomfortable [31], with another study finding persistent, gendered disparities in access, design, comfort, and function outcomes of assistive products for women compared to men [32]. An analysis of data on orthosis users in Cambodia found that the proportion of current female users was nearly 10% lower than that of male users [33]. This highlights the need for more research specifically examining gendered outcomes of orthoses and wheelchairs. Addressing these gaps will require approaches that account for physiological differences, user experience, and the structural factors shaping women's rehabilitation outcomes [34].

The findings from this study highlight the role of assistive products in the lives of people with physical impairments. Participants reported that these products enhanced independence, enabled work, and supported daily activities, echoing findings from other studies involving P&O users [11,35]. However, access alone does not ensure use, nor do assistive products fully remove barriers, especially in contexts where the broader social and political environment remains restrictive or stigmatizing [3,36]. In such settings, ongoing barriers to education and

XSL•FO
RenderX

employment may constrain the potential of assistive devices to advance inclusion.

Experiences of discrimination or prejudice related to physical disabilities were reported by participants. Misconceptions about the cause of disability, often rooted in traditional or religious understandings, can help perpetuate disability stigma [37,38]. Such stigma can restrict access to employment, education, and community inclusion. However, not all participants experienced discrimination or identified as having a disability, and some described their ability to work and have a family as being the same as that of others. Additionally, it was reported that wearing an assistive product reduced negative treatment from others. Previous research has shown that access to resources that can be used to obtain assistive products, such as finances and knowledge, was an indicator of privilege [39]. This finding was linked to the notion that poverty stigma can be more discriminatory than disability stigma in LMICs. This may help explain why participants had more positive attitudes after receiving an orthosis or wheelchair.

Not all participants wore an orthotic device daily or at all, underlining that access alone does not guarantee use of assistive products or rehabilitation services. In many LMICs, limited design options may not suit users' environments, contributing to nonuse [1,2]. While this study did not examine device abandonment in depth, findings suggest that provided products may not always meet users' needs or preferences. Known contributors to abandonment include pain, discomfort, inadequate training, and personal preference [40,41]. These gaps highlight the need for a comprehensive service approach that goes beyond initial provision to include follow-up, context-appropriate design, user education, and sustained support across the continuum of care.

In Cambodia, P&O service provision has shifted over time, with changes in rehabilitation services, increased government involvement, and reduced international funding. Sustaining a continuum of care for those requiring physical rehabilitation depends on establishing standardized referral pathways across all levels of the health system [30]. This necessitates collaboration among a range of stakeholders, including the government, public and private hospitals and health facilities, and international organizations.

Reflexivity

As White, anglophone researchers based in a high-income country, we recognize that our professional backgrounds, experiences, and prior assumptions may have shaped the study design, data interpretation, and construction of meaning from the data. The absence of Cambodian researchers within the author team is an important limitation and reflects broader structural inequities in global health research and ongoing debates around decolonizing humanitarian and development work. This study was conducted as part of a PhD project, which influenced the research team composition and authorship structure and may have limited the extent to which locally grounded interpretations informed the analysis.

Data collection and interpretation were supported by Cambodian rehabilitation professionals who facilitated recruitment, translation, and contextual understanding. Although their contributions informed the research process and were remunerated, they were not involved in coauthorship or full thematic analysis, primarily due to limited availability alongside clinic responsibilities. This may have influenced how meaning was interpreted and themes were developed.

The interviewer, as an external researcher, also occupied an outsider position [42], which may have shaped participant responses and the coconstruction of interview data. To enhance reflexivity and minimize bias, the findings were discussed within the research team, and contextual input from in-country collaborators informed interpretation. Nevertheless, limited local analytical involvement remains a key limitation, and future research should prioritize more equitable coproduction, including shared analysis and authorship with Cambodian researchers.

Strengths and Limitations

This study has a number of strengths. First, it makes a unique contribution to the literature as there is limited empirical research examining access to physical rehabilitation services specifically among individuals who use orthoses and wheelchairs. While there is a growing body of work on assistive technology access in LMICs, most studies focus on prosthetics or broader disability populations, with relatively few exploring the distinct needs and barriers experienced by orthosis and wheelchair users. Second, the findings are situated within the social, cultural, and environmental contexts of participants. This contextual grounding is important in rehabilitation and assistive technology research as cultural perceptions of disability, social support networks, and environmental barriers shape access, use, and outcomes [1].

This study also has some limitations (beyond those noted above about reflexivity). Participants were exclusively current or former users of Exceed services in Phnom Penh, excluding those who accessed other Exceed centers or services from different rehabilitation organizations, who may have had different pathways to obtaining orthoses and wheelchairs.

The interviewer (CS) did not speak Khmer, requiring the use of a translator. While clarification was sought to ensure accurate interpretation, some loss of meaning may have occurred. The translations were conducted by a local colleague, who is a native speaker of Khmer without formal training in professional interpretation or translation. This is a limitation of the study as translation in qualitative research is an interpretive act and can influence the precision and nuance of participant meaning [17]. To mitigate this, the same translator was used throughout the study to support consistency, and the interview guide was translated in advance to reduce ad hoc interpretation during interviews [18]. The translator also had contextual familiarity with the study setting, which supported comprehension of local and physical rehabilitation terminology. However, it is recognized that these measures do not replace the role of a professionally trained interpreter and that limited formal linguistic training may have influenced the accuracy and richness of some translations. The translator's role at the Cambodian School of Prosthetics and Orthotics in Phnom Penh, which collaborates closely with Exceed, may have also

XSL•FO
RenderX

influenced participants' willingness to voice criticisms, although assurances were given that care would not be affected.

Conclusions

This study investigated the pathways to physical rehabilitation services for users of orthoses and wheelchairs in Cambodia. The experiences of participants offer valuable insights into how individuals find and engage with P&O services for physical rehabilitation and assistive products and how these interventions influence their mobility and livelihood. This study highlights the important role of assistive products in enhancing mobility, independence, and engagement in daily activities. However, it also shows that they cannot fully overcome broader environmental, social, and emotional barriers, including stigma, discrimination, and negative self-perception.

Assistive products must be part of a broader, continuous system of care. A functioning continuum of care requires standardized referral mechanisms, consistent follow-up, and integration across all levels of the health system. Without this, individuals risk falling through gaps in service provision, particularly during critical stages of life such as childhood and adolescence.

Future research should further investigate the causes of assistive product abandonment and explore the complex reasons why individuals may choose not to use assistive products. A holistic, person-centered approach, one that supports individuals across the full continuum of care and acknowledges both physical and sociocultural dimensions, is key for improving quality of life for people with physical impairments in Cambodia.

Acknowledgments

The authors would like to thank Exceed Worldwide for their support with the completion of this work in the facilitation of interviews and guidance. In particular, they want to thank Sisary Kheng and Sophary Met for their support.

Data Availability

The datasets generated and analyzed during this study are publicly available in the University of Southampton institutional research repository [43]. The repository contains the deidentified study data and accompanying documentation required to reproduce the analyses.

Funding

Funding for this project was provided by the UK Economic and Social Research Council through the South Coast Doctoral Training Partnership.

Authors' Contributions

CS, AP, and AAC conceived and designed the study. Data collection was carried out by CS. Data analysis and interpretation were performed by CS, AP, MD-H, and AAC. The manuscript was drafted by CS, with input from AAC, AP, and MD-H. All authors approved the final manuscript.

Conflicts of Interest

None declared.

Abstract

Background: People with severe to profound intellectual disability and visual or visual and motor impairments often experience passivity and isolation. This can lead to limited environmental stimulation, reduced physical activity, and the acquisition of incorrect body postures. Approaches to improve the situation have generally involved increasing environmental stimulation, which was regulated by the context or controlled by the people through adaptive responding and assistive technology.

Objective: This study assessed 2 intervention programs serving as extensions and advancements of previous approaches aimed at helping participants with intellectual and multiple disabilities control environmental stimulation through their own responses and assistive technology. The first program was designed to help 4 participants with severe intellectual disability and blindness alternate between periods of preferred music stimulation and mild physical activity. The second program was designed to help 5 participants with severe to profound intellectual disability, visual and motor impairments, and postural problems (ie, a tendency to tilt their torso and head forward). These participants were led to access preferred environmental stimulation, engage in mild physical activity, and increase correct posture.

Methods: Each of the 2 programs was implemented according to a single-case research design. The technology for the first program involved (1) a smartphone with the MacroDroid app, which regulated the intervention conditions; (2) pressure sensors that allowed the participants to activate music stimulation; (3) a proximity sensor that monitored the participants' physical activity responses (ie, placing objects in a container high up in front of them); and (4) a mini speaker. The same technology was also used for the second program. In this program, the participants' physical activity responses consisted of arm-stretching movements, and the smartphone also served for monitoring the participants' correct posture. Within each program, a session included 7 music periods and 6 activity periods.

Results: During programs 1 and 2, the mean percentage of music pieces activated independently of research assistants' guidance was between 94.7% and 99.4%. The mean percentage of objects placed in the carton and of shelf-touching responses performed independently was between 98.7% and 99.7%. The baseline mean percentages were between 0% and 24.5%. The mean percentage of session time in a correct posture (program 2) increased to 71.1%-89.6% from baseline values of 18.8%-36.5%. A total of 8 of the 9 participants involved in the 2 programs showed higher levels of indices of happiness during program sessions than control sessions.

XSL•FO
RenderX

Conclusions: The results suggest that the programs might be a useful resource for supporting people with severe to profound intellectual disability and visual or visual and motor impairments.

Introduction

Background

People with severe or severe to profound intellectual disability and visual or visual and motor impairments tend to be passive and isolated, with limited or no opportunities to control environmental events (and stimulation) around them [1-5]. Their situation may be largely shaped by their inability to locate, recognize, and operate conventional stimulation sources (eg, television and music devices), their lack of self-determination, their poor motor condition, and a general disinterest in activity engagement [4,6-8]. The negative implications of this situation can include a reduced level of environmental stimulation, limited physical activity, and possibly incorrect body postures, that is, a range of conditions that can further hinder people's rehabilitation prospects, general well-being, and quality of life [9-15].

The literature available suggests that several stimulation approaches may be potentially useful in curbing, at least partially, the impact of those negative implications. Two common stimulation approaches involve the use of environmental enrichment and multisensory rooms, respectively. Environmental enrichment consists of an increase in the level of environmental stimulation regulated by staff or other personnel in charge of the context [10,14,16-18]. This approach is considered functional for (1) countering the most feared of the negative implications mentioned above, that is, the risk of low stimulation input (with consequent personal impoverishment), and (2) improving the participants' quality of life [10,19]. Multisensory rooms are structured areas equipped with multiple stimulation sources that are designed to engage the participants' senses and thus enrich their sensory input and possibly provide them with a feeling of satisfaction [20-23].

A third stimulation approach is characterized by the fact that the stimulation is mediated by direct staff and caregiver involvement (intervention). One strategy used within this approach includes an increase in social (verbal and physical) contact between participants and personnel sharing the same context [24-27]. Another strategy exposes the participants to simple stories whose narration by staff is accompanied by the presentation of stimulation events that underline the content of the stories [28-31].

A fourth stimulation approach, contrary to those mentioned above, ensures that the stimulation is controlled by the participants through their own responses and the use of microswitch (sensor) technology [11,13,32,33]. Specifically, the participants are taught to activate a microswitch device through a specific response (eg, a simple hand movement or a hand-stretching movement involving the use of objects). Such a response becomes instrumental in enabling them to access brief periods of preferred stimulation. The distinctive aspects of this approach are that the participants (1) are actively involved in seeking stimulation (rather than being automatically exposed to it) and (2) are required to increase their physical engagement (ie, through their microswitch activation responses) and thus counter their passivity and detachment.

A final stimulation approach differs from the fourth in that its goal is not limited to bringing the participants to seek environmental stimulation through their own responses but also aims to promote their postural control [34]. For example, participants may be (1) taught to perform specific (functional) arm and hand responses to activate microswitch devices and access preferred stimulation and (2) required to maintain a correct posture during the stimulation to ensure that this continues without interruptions [34,35].

In light of the above, one might argue that the last 2 approaches can be considered advantageous because they allow the participants to have an active role in seeking environmental stimulation and because they promote the participants' physical engagement and possibly postural improvement. In essence, these approaches can be viewed as valuable complements to standard occupational therapy and physiotherapy within daily contexts [4,9,12]. With regard to this point, it may also be noted that these approaches rely on the use of basic technology and are only marginally demanding on staff time [4,36,37].

Objectives

The present study was aimed at assessing 2 intervention programs serving as extensions and advancements of the last 2 approaches described above. The first program was directed at 4 participants who presented with severe intellectual disability and blindness. These participants were led to alternate periods in which they could activate preferred music stimulation pieces with periods of mild physical engagement in which a functional response requiring some physical effort was to be repeated several times. Each music stimulation piece lasted 1 minute. Each physical engagement period required the participants to place 6 to 10 objects (ie, common and age-appropriate objects) in a tall carton, which was in front of them. The performance of every response involved forward and upward arm and shoulder stretching (ie, movements that physiotherapists had recommended as useful and appropriate for the participants).

The second program was directed at 5 participants who presented with severe to profound intellectual disability, visual and motor impairments, and postural problems (ie, a tendency to tilt their torso and head forward). These participants were led to alternate stimulation periods such as those described for the

XSL•FO
RenderX

previous group of participants with physical engagement periods. During the latter periods, the participants were required to perform upward and sideward arm-stretching responses (ie, responses that physiotherapists considered useful because of the nature of the movements involved and because they were antagonistic to the participants' postural problems). The participants' posture was monitored throughout the sessions. Loss of correct posture during a stimulation period made the stimulation inaudible until the correct posture was regained.

The programs were developed by the authors, who have long experience working with and developing technology-aided solutions for people with intellectual and multiple disabilities. The authors operated in continuity with previous research work in the area, as indicated above, and in collaboration with staff personnel and caregivers. Each of the 2 programs was implemented according to a single-case research design. The technology used for the programs included commercial components such as a smartphone, pressure and proximity sensors, an interface to connect the sensors to the smartphone, the MacroDroid app, and a mini speaker.

Methods

Ethical Considerations

Staff considered the participants' involvement in the study to be a beneficial and pleasant experience for them (ie, an experience that extended their daily rehabilitation and care treatment by promoting self-determination, enriching stimulation input, and facilitating physical activity). The participants' condition did not allow staff to ask them for or obtain their clear consent to be involved in the study. In light of this, their legal representatives read and signed a consent form on their behalf. The consent form specified that there was no compensation for the participants' involvement, that participants could be withdrawn from the study at any time, and that their data would be deidentified. The study was approved by the Ethics Committee of the Lega F. D'Oro, Osimo (AN), Italy (P031020252). All procedures applied during the study were in line with internationally recognized ethical standards and complied with the 1964 Helsinki Declaration and its later amendments.

Participants

Table 1 reports the chronological age, Vineland age equivalents for daily living skills (personal subdomain), and sensory-motor impairments for the 9 participants. The first 4 (identified with the pseudonyms of Eloise, Grace, Jackson, and Margot) were involved in program 1, and the last 5 (identified with the pseudonyms of Matias, Colton, Alina, Hazel, and Graham) were involved in program 2. Their chronological age ranged from 27 to 59 years. The Vineland age equivalents for daily living skills (personal subdomain) measured via the second edition of the Vineland Adaptive Behavior Scales [38,39] varied between 1 year and 7 months and 4 years. The participants had a diagnosis of congenital encephalopathy and intellectual disability, which was combined with blindness or severe visual impairment. Four of the last 5 participants also presented with motor impairments that precluded any ambulation or allowed only limited levels of supported ambulation. While no recent IQ scores were available, the psychological records of the rehabilitation and care centers that the participants attended reported the participants' level of intellectual disability to be in the severe range (first 4 participants) or the severe-to-profound range (last 5 participants).

The participants were included in the study based on a number of conditions, which had been preliminarily verified. First, they tended to be passive and dependent on staff to access environmental stimulation and engage in physical activity (eg, using objects or performing functional body movements). Second, they seemed to enjoy different types of music stimulation. Third, they were considered capable of responding to simple verbal instructions concerning basic actions such as touching or putting away objects. Fourth, staff were favorable to the programs and the technology involved, which had been illustrated to them in advance.

Table 1. Participants' chronological age, Vineland age equivalents for daily living skills (personal subdomain), and sensory-motor impairments.

Participant (pseudonym)	Chronological age (years)	Vineland age equivalents[a], years (months)	Sensory-motor impairments
Eloise	59	3 (10)	• Blindness
Grace	41	2 (7)	• Blindness
Jackson	35	3 (3)	• Blindness
Margot	50	4 (0)	• Low vision
Matias	58	2 (4)	• Minimal residual vision • Lack of ambulation
Colton	52	2 (8)	• Blindness • Lack of ambulation
Alina	27	3 (1)	• Blindness
Hazel	45	2 (4)	• Minimal residual vision • Lack of ambulation
Graham	48	1 (7)	• Blindness • Lack of ambulation

[a]Age equivalents are based on the Italian standardization of the Vineland Scales [38].

Setting, Sessions, Research Assistants, and Music Stimulation

A quiet room in the participants' daily contexts, fitted with a desk at which the participants sat, served as the setting for the baseline and the program sessions (see below). The participants' regular occupational room served as the setting for the control sessions (see below). Sessions were typically carried out once per day, 5 or 6 days a week. A total of 4 research assistants implemented the sessions. They had a university education and were experienced in applying technology-aided programs with people with extensive disabilities and using various data recording procedures.

Different music pieces (songs and other music stimuli) recommended by staff were evaluated to determine whether they would be used during the study. The evaluation was carried out via a stimulus preference screening procedure. The procedure required that 3 brief segments of each music piece suggested by staff for the individual participants be presented nonconsecutively (at least 10 times per segment) over different screening occasions. Only the music pieces whose segments were considered (ie, by the research assistant and staff member involved in the screening procedure) to produce positive reactions (eg, alerting and smiling) in at least 50% of their presentations were retained for use in the study [4,13].

Technology System: Components

The technology system used for the programs involved (1) a smartphone operating on Android and fitted with a light sensor, (2) a Bluetooth Encore Plus interface (leonardoausili.com), which was linked to 2 pressure sensors and a proximity sensor, and (3) a Bluetooth mini speaker (JBL Go 3) amplifying the smartphone's volume. The smartphone was connected to the internet and fitted with the Encore Plus and MacroDroid apps. The pressure sensors consisted of small Buddy buttons, circles with a diameter of 6.3 cm (leonardoausili.com). The proximity sensor consisted of a Big Candy Corn, a triangle with a side of about 10 cm (leonardoausili.com). In program 1, the pressure sensors were on the desk while the proximity sensor was fixed to the carton in which the participants were to place common, age-appropriate objects taken from a container (Figure 1). The smartphone was in the desk drawer. In program 2, the pressure sensors were on the desk, the proximity sensor was on a small shelf that the participants were to touch, and the smartphone was attached to the back of their chair (Figure 2) or to their wheelchair's headrest.

In program 2, the smartphone on the back of the chair or wheelchair's headrest served to record whether the participants' torso or head posture was correct or incorrect. The closer the participant's torso or head was to the smartphone's light sensor, the lower the level of light reaching the sensor. Based on this relationship, the smartphone was programmed to record the posture as correct up to a prefixed level of light reaching the sensor. Beyond that level, the posture was considered incorrect. This smartphone and light sensor functioning was successfully tested prior to the study by 2 judges (a staff member and a research assistant), who compared the smartphone's (correct or incorrect) posture recording with video images of the posture collected simultaneously. Testing was conducted for each participant under environmental illumination conditions that remained stable during the baseline and program sessions.

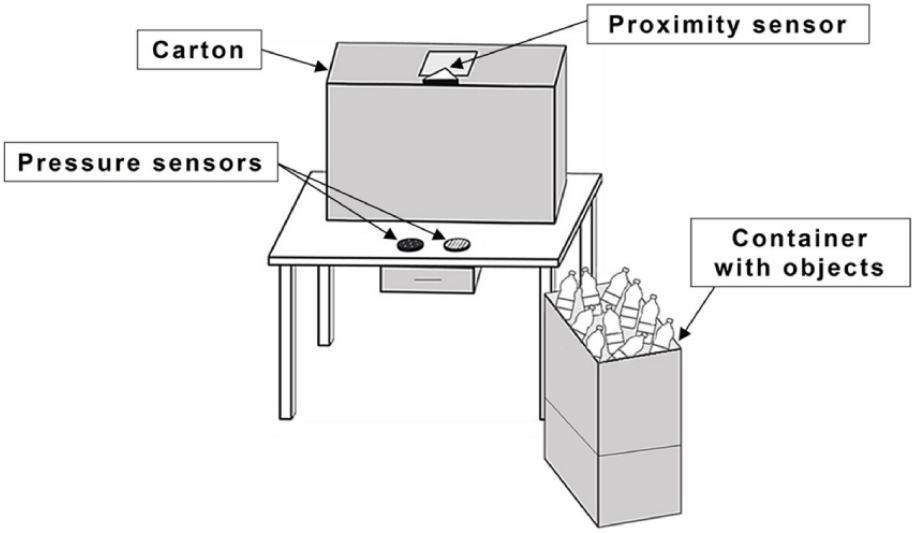
Figure 1. Schematic representation of the 2 pressure sensors placed on the desk, the proximity sensor fixed to the carton, and the container with objects.



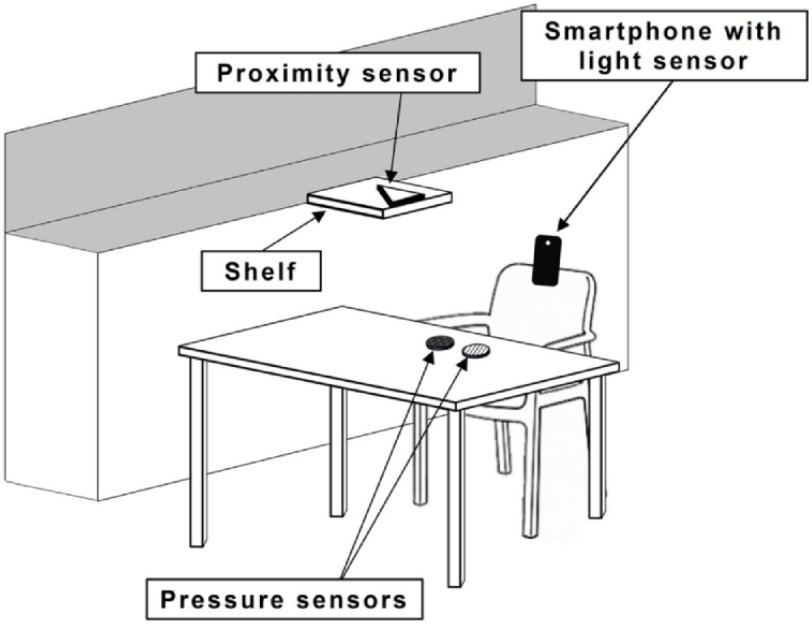


Figure 2. Schematic representation of the 2 pressure sensors placed on the desk, the proximity sensor fixed to the shelf, and the smartphone with the light sensor fixed to the back of the chair.

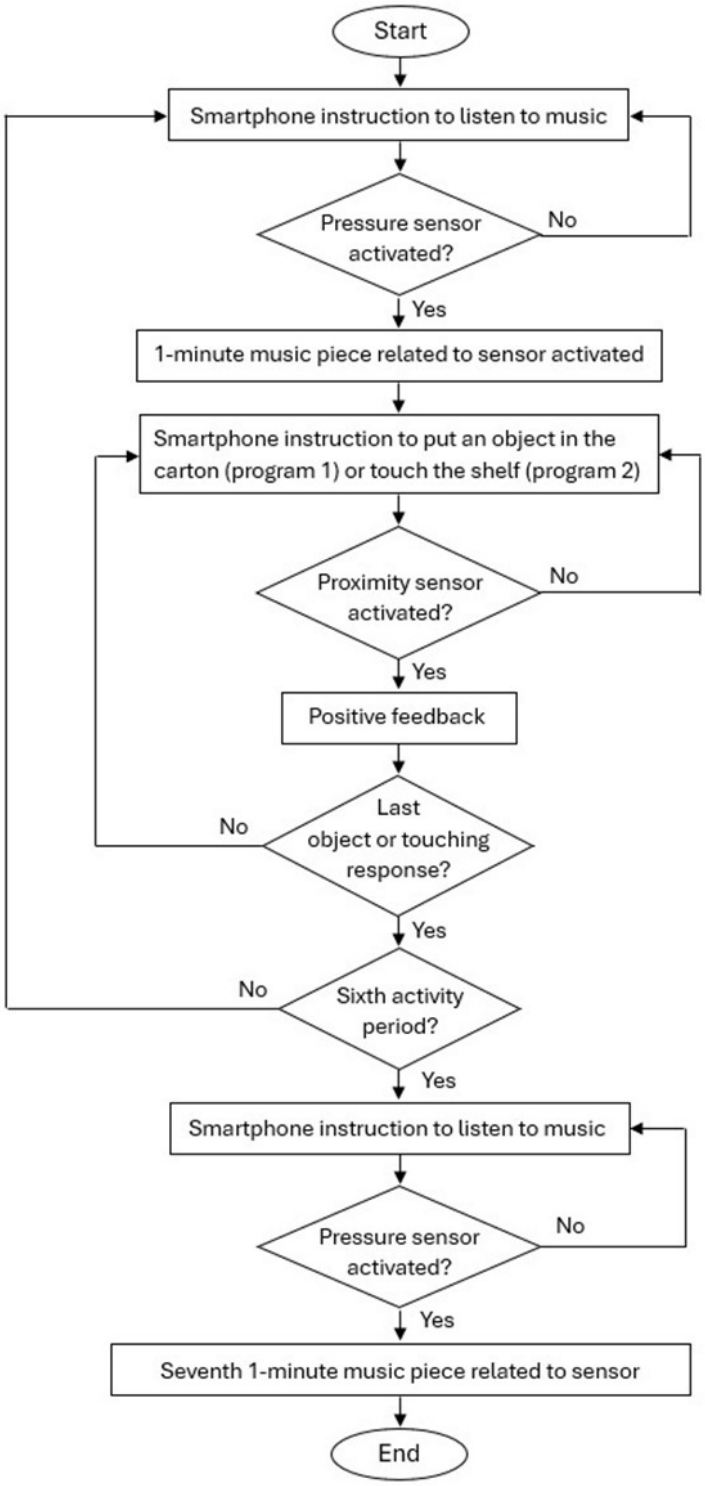
Technology System: Functioning



A session with either program started with the smartphone instructing the participants (via the mini speaker) to listen to music (eg, to select the name of a singer or the name of a band). Figure 3 provides a summary of the system's functioning. The participants could touch (activate) one of the pressure (music) sensors available in front of them, thus sending a signal to the smartphone. The smartphone, using the Encore Plus and the MacroDroid apps, (1) detected and discriminated the signal and (2) presented, via the mini speaker, a 1-minute music piece consistent with the sensor activated. In program 2, the piece was audible to the participants if their posture (as determined by the smartphone fixed on the back of their chair or headrest) was correct and inaudible if their posture was incorrect. In the latter case, the smartphone instructed them to straighten their body or raise their head. As the participants regained the correct posture, the music piece became audible again.

Following the end of the music piece, an activity period started during which the music sensors were unresponsive. The smartphone instructed the participants to put an object in the carton (program 1) or touch the shelf (program 2). These responses activated the proximity sensor fixed near the carton's opening (program 1) or on the shelf (program 2). Proximity sensor activation led the smartphone (supported by the Encore Plus and the MacroDroid apps) to (1) count each response (ie, an object placed in the carton or a shelf-touching response), (2) provide a one-word positive feedback statement for each response, (3) follow each feedback statement with the instruction to take another object (program 1) or touch the shelf again (program 2), and (4) determine when the participants had produced the number of responses programmed for the activity period (ie, had placed 6-10 objects in the carton or touched the shelf 6-9 times). Once the programmed number was reached, the smartphone instructed the participants to listen to music (ie, as above) and made the proximity sensor on the carton or shelf

XSL•FO
RenderX

unresponsive. The instruction to listen to music or to place an object in the carton or touch the shelf was repeated at intervals of 10 seconds until the participants responded to it. The session continued with new opportunities to access preferred music pieces followed by activity periods according to the conditions described above. A session was programmed to include 7 music pieces and 6 activity periods. During the 6 activity periods, the participants were expected to place a total of 36 to 60 objects in the carton or to touch the shelf a total of 36 to 54 times.

Figure 3. Flowchart summarizing the system's functioning.

Measures and Data Recording

The four measures recorded during both programs involved (1) the number of music pieces activated independently of research assistants' guidance, (2) the number of objects placed in the carton or of shelf-touching responses performed independently of research assistants' guidance, (3) the length of the sessions, and (4) the participants' indices of happiness (eg, behaviors

XSL•FO
RenderX

such as alerting or orienting to the music, smiling, and making music-based rhythmic movements [4,11,40-43]). The fifth measure, recorded only during program 2, concerned the amount of session time the participants spent in a correct posture. With the exception of indices of happiness, the measures were also recorded during the baseline phase that preceded the programs. Indices of happiness were recorded during 25-30 program sessions and as many control sessions (see below).

The first 2 measures were recorded by the research assistants during the baseline and by the technology system during the programs. During the programs, the system's recorded number of music pieces activated, of objects placed in the carton, and of shelf-touching responses performed would be modified (reduced) if research assistants' guidance had occurred in the process. The length of the sessions and the time spent in a correct posture were recorded by the technology system throughout the study. The indices of happiness were recorded from videos of the sessions using a partial-interval strategy in which 10-second intervals were used for observing and 5-second intervals were used for recording [4].

Interrater agreement was assessed over (1) all baseline sessions for the first 2 measures and (2) 50% of the program and control sessions for indices of happiness with the involvement of a reliability observer. The percentage of agreement on the first 2 measures (computed by dividing the number of sessions in which research assistants and the reliability observer had scores differing by no more than 1 unit by the total number of sessions and multiplying by 100%) was 100% for all participants. The percentage of agreement for indices of happiness (computed for the single sessions by dividing the number of intervals with agreement by the total number of intervals and multiplying by 100%) ranged between 87.5% and 100%, with means exceeding 93% for all participants.

Experimental Conditions and Data Analysis

Overview

The first 4 participants (ie, the group involved in program 1) and the last 5 participants (ie, the group involved in program 2) were initially exposed to a baseline phase without the technology system. Then, they entered the scheduled program during which the technology system described above was used. For each of the 2 groups, the program was implemented according to a nonconcurrent multiple-baseline design across participants (ie, the program started after the group members had received different numbers of baseline sessions) [44,45]. Parallel to 25-30 program sessions, both groups received control sessions. The latter sessions, which were implemented immediately before the program sessions, served to determine whether the program sessions had an impact on the participants' indices of happiness [4,46].

Two basic strategies were used to ensure high levels of accuracy in the research assistants' implementation of the sessions (ie, high levels of procedural fidelity [47,48]). First, the research assistants were involved in preliminary training through simulated sessions in which they were to apply the procedural conditions. Such training continued until they had shown the ability to manage those conditions. Second, the research assistants were provided with feedback about their performance during the study. The feedback (which they received from a study coordinator who had access to videos of the sessions) consisted of being informed as to whether their performance was accurate or included inaccuracies that needed to be amended (with the latter being virtually absent and thus confirming the research assistants' procedural correctness).

The Nonoverlap of All Pairs (NAP) method (ie, a method for the analysis of single-case research data [49,50]) was used to assess the effect size (1) of program 1 on the number of music pieces activated, objects placed in the carton, and indices of happiness, and (2) of program 2 on the number of music pieces activated, shelf-touching responses performed, session time spent in a correct posture, and indices of happiness displayed.

Baseline Sessions

The baseline phase included 5-10 sessions for the first 4 participants (who received program 1) and 5-11 sessions for the last 5 participants (who received program 2). The first four participants sat at a desk with (1) a smartphone that could be used for accessing preferred songs, (2) a carton placed in front of them, and (3) a container with objects placed to their right. The last five participants had (1) a smartphone that could be used for accessing preferred songs; (2) a smartphone with a light sensor and the MacroDroid app, fixed on the back of their chair or their wheelchair's headrest (Figure 2), which served to record the session time spent in a correct posture; and (3) a small shelf with a proximity sensor on it, which was fixed high up to their right.

The smartphone that the participants could use was set up to play music pieces from a YouTube playlist. The playlist had been preliminarily arranged for the individual participants based on their preferred music pieces. The playlist was regulated through a play and pause button on the smartphone's screen. To mark the button area for the participants (given their visual impairment), a small cotton ball was placed just below that area. Touching the smartphone screen above the cotton ball (ie, activating the play and pause button) would start or stop the music.

At the beginning of a baseline session, the research assistants helped the first four participants (1) touch the smartphone, locate the cotton ball, and activate the music briefly; (2) touch the carton's opening; and (3) take an object from the container and place it in the carton. The difference for the last 5 participants was that they were helped to touch the shelf, rather than to touch the carton and place an object in it.

After this introductory help, the research assistants instructed (encouraged) the participants to proceed on their own. If the participants managed to activate a music piece, place objects in the carton, or touch the shelf on their own, their responses were recorded as independent of research assistants' guidance. If the participants did not respond to the instruction (encouragement) for 25 seconds, the research assistants provided them with guidance (ie, verbal and/or physical support) to activate a music piece, which was then recorded as dependent on guidance. Any music piece was interrupted after 1 minute. If the participants remained passive for 25 seconds following

XSL•FO
RenderX

the end of the music piece, the research assistants provided them with guidance to put an object in the carton (first 4 participants) or touch the shelf (last 5 participants). The session continued until (1) the participants had activated 7 music pieces and had placed the objects in the carton or performed the shelf-touching responses programmed for them or (2) 4 consecutive instances of research assistants' guidance had occurred.

Program Sessions

Programs 1 and 2 included 59-73 and 61-80 sessions (with differences due to participants' availability), respectively. The participants were provided with the technology system, which worked as described in the Technology System: Components and Technology System: Functioning sections and Figure 3. The programs were introduced by 2 practice sessions during which the research assistants could repeat the smartphone's instructions and help the participants respond to those instructions. During the following sessions, the research assistants would provide verbal and physical guidance if the participants did not respond to a smartphone instruction after this had been presented 3 times. During 25-30 sessions spread over the central and final part of the programs, data recording also involved the participants' indices of happiness (eg, behaviors such as alerting or orienting to the music, making music-based rhythmic movements, smiling, or vocalizing [40-43]). Recording occurred within the first 10 minutes of the sessions so that the data could be compared to those of 10-minute control sessions.

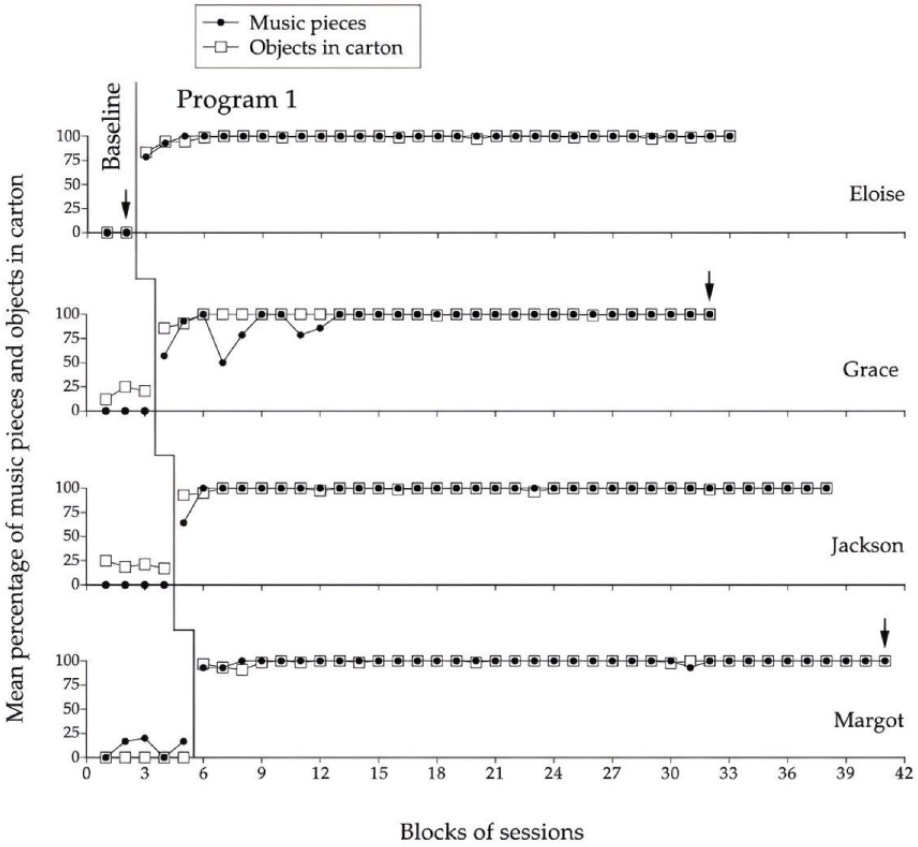
Control Sessions

Each of the 25-30 program sessions in which indices of happiness were recorded was preceded by a 10-minute control session involving the recording of the same indices. During the control sessions, the participants were not involved in specific activities but had objects available to them and could have some interaction with staff and listen to staff interacting with other individuals with intellectual and visual disabilities sharing the same context. Recording the participants' indices of happiness during program sessions and parallel control sessions served to determine whether the programs had an impact on those indices.

Results

Figure 4 reports the data for the first 4 participants on music pieces activated and objects placed in the carton independently during program 1 and the preceding baseline sessions. Figure 5 reports the data for the last 5 participants on music pieces activated and shelf-touching responses performed independently and for session time spent in a correct posture during program 2 and the preceding baseline sessions. The data points appearing in the figures are mean percentage values computed over blocks of 2 sessions (blocks of 3 sessions are marked with an arrow). Percentage values were computed over (1) the music pieces played, (2) the objects used or shelf-touching responses completed during the activity periods, and (3) the session durations (ie, for correct posture). During the program sessions (which were never interrupted), 7 music pieces were played and 6 activity periods were regularly completed (involving totals of 36-60 objects or 36-54 shelf-touching responses). During the baseline sessions (which were always interrupted), the music pieces played and activity periods started could vary between 2 and 6 (with variable numbers of response opportunities).

During the baseline sessions preceding the introduction of programs 1 and 2, the mean percentage of music pieces activated independently of research assistants' guidance was 0% except for Margot and Hazel. Their mean percentage was 10.7% and 3.5%, respectively. The mean percentage of objects placed in the carton (Figure 4) varied between 0% (Eloise and Margot) and 20.5% (Jackson), with the values of the last 2 or 3 sessions never exceeding the highest values reached in the phase. The mean percentage of shelf-touching responses (Figure 5) ranged between 8.7% (Matias) and 24.5% (Colton). The mean percentage of session time spent in a correct posture (Figure 5) was between about 18.8% (Colton) and 36.5% (Alina). All baseline sessions were interrupted after 4 consecutive instances of research assistants' guidance. Their mean length was always below 9 minutes.



During programs 1 and 2, the mean percentage of music pieces activated independently of research assistants' guidance was between 97% and 99.4%, except in the case of Grace, whose level was 94.7%. The mean percentage of objects placed in the carton and shelf-touching responses performed independently was between 98.7% and 99.7%. It may be noted that the lower percentage values were basically concentrated in the initial sessions of the programs, except in the case of Grace (Figure 4). Her lower values for music pieces activated independently spread beyond the initial sessions as she (1) could continue placing objects in the carton without responding to the smartphone's instruction to listen to music and thus (2) would receive research assistants' guidance. The mean percentage of session time spent in a correct posture (Figure 5) increased to between about 71.1% (Hazel) and 89.6% (Matias). The mean length of the sessions for the 9 participants ranged between about 12 minutes (Jackson) and 16 minutes (Colton and Hazel).

The NAP method used to compare the program and baseline data on the aforementioned measures showed indices of 1 (as the program data on each measure showed percentage values higher than the baseline values for all participants). These indices, together with the fact that the change from the baseline to the program sessions was rapid and clearly visible, may be taken to confirm the large effect size of the programs.

Figures 6 and 7 report the percentage of intervals with indices of happiness during program and control sessions for the first 4 participants and the last 5 participants, respectively. The mean percentage ranged from 7.3% (Eloise) to 64.3% (Margot) during the sessions of program 1 and from 16.8% (Colton) to 37% (Graham) during the sessions of program 2. The mean percentage during the control sessions was below 10% except for Graham (whose mean percentage was 10.2%). The NAP method used to compare the data from the program sessions with the data from the control sessions showed that the programs had a strong effect (with indices of 0.93 to 1) for Jackson, Margot, Matias, Alina, and Graham, a moderate effect (with indices of 0.82 and 0.90) for Colton and Hazel, and no effect (with an index of 0.56) for Eloise.

Discussion

Principal Findings

The findings suggest that the programs assessed in this study were helpful in improving the situation of people with intellectual disability and visual or visual and motor impairments. All participants learned to activate music stimulation and to engage in recommended forms of mild physical activity. The participants involved in program 2 also showed an improvement in body posture. Taken as a whole, these findings seem to confirm and extend previous data in the area [33,35,51,52] and to provide new encouraging evidence about the possibility of developing technology-aided programs to help participants with extensive disabilities become responsible for increasing their stimulation input and enhancing their physical activity and postural control. In light of these findings, several considerations are in order.

First, helping people with extensive disabilities manage their access to environmental stimulation and the performance of functional physical actions may be considered relevant from a rehabilitation standpoint and from a practical standpoint. Regarding the rehabilitation aspect, one can argue that the participants' behavioral activation and self-determination not only curb the risks of stimulation impoverishment and limited physical activity but also likely provide a basis for the participants' developmental progress, well-being, and satisfaction [15,53-57]. Regarding the practical aspect, one may consider the findings a demonstration that relevant participants' achievements can be ensured (1) through the support of rather simple and easily accessible technology and (2) with relatively small staff time investment [3,9,36,58-60].

Second, interspersing physical activity with access to preferred music stimulation was thought to be a useful strategy to (1) deal with the participants' low level of interest in and tendency to avoid such activity (ie, a generally nonpreferred type of engagement) and (2) create a link between the activity and the following preferred stimulation with the likelihood that this would become a reinforcing (motivating) factor for the participants' activity engagement [61-64]. Pursuing an improvement in body posture could be considered a useful supplement to the goal of increasing physical activity in participants with motor impairments and postural problems. Bringing participants to control their posture through motivational strategies may be the only way to ensure the independence of such control from external supervision [62,64-67]. The aforementioned hypotheses on promoting physical activity and postural control seem to find support in the participants' performance during the 2 programs. Interpretation of the data reported on postural control may require some caution as the sensor (ie, the smartphone's light sensor) used to record body posture is not a conventional (validated) instrument for use in that specific assessment area.

Third, while the importance of increasing physical activity in people with extensive disabilities is largely acknowledged [9,10,36,37,51,58-60], the evaluation of the beneficial effects of such an increase is difficult or practically impossible when the activity is mild and lasts for relatively short periods of time. In this case, in fact, one cannot rely on any specific assessment criteria and tools. A similar consideration can be extended to the issue of postural control. Identification of functional assessment criteria and tools may be viewed as an important research objective in this area.

Fourth, the data on indices of happiness show that 8 of the participants found their involvement in the program sessions more satisfactory (enjoyable) than their involvement in the control sessions (ie, sessions featuring common conditions in periods of no specific activity or direct supervision). This evidence, together with the findings that all participants had high and stable levels of performance throughout the program sessions, suggests that (1) the program conditions were largely motivating, (2) the positive impact of the stimulation available in the program sessions exceeded the cost (efforts) of the physical activity or postural control pursued within those sessions, and (3) technology-aided programs such as those reported might help promote participants' initiative and functional occupational engagement and foster their developmental progress, with possibly positive implications for their quality of life [4,33,37,40,43,57,61,63].

Fifth, the components of the technology system used in the programs, that is, the smartphone, the Encore Plus interface and app, the pressure sensors, the proximity sensor, the mini speaker, and the MacroDroid app, are commercially available and easily affordable. Commercial availability and affordability make the acquisition of the technology and the application of the programs reported in this study feasible for daily contexts [68,69] as well. One clarification that should be provided at this point is that the acquisition of the technology components does not allow one to have a readily usable system. In fact, the usability of the system depends on the programming of its functioning through the MacroDroid app. This programming, albeit not particularly complex, requires a certain level of familiarity with technology issues. A similar point could be made regarding the implementation of the programs. Although not difficult, it requires staff to acquire a clear understanding of the procedural conditions and the technology arrangement. The authors of this study are willing to provide assistance to any context interested in adopting and using the technology system and programs reported.

Sixth, the fact that the system does not require adjustments from one session to the next and the evidence that the participants can be independent of any external assistance during the sessions can lead one to basic considerations about program applicability and sustainability [70-72]. For example, one might argue that (1) the participants involved in this study could continue to use the programs reported over time with relatively small staff time investment, and (2) the same programs could represent a realistic treatment opportunity for other people with extensive disabilities and limited access to stimulation and physical activity (ie, a treatment opportunity that their daily contexts might be able to afford in terms of time cost and technology requirements).

Limitations and Future Research

While the results appear promising, some caution may be required in interpreting them given the limitations of the study. The most obvious limitations are the relatively small number

XSL•FO
RenderX

of participants, the unavailability of maintenance and generalization data, and the absence of social validation of the programs and the technology system involved. An additional limitation may be the use of an experimental sensor (ie, the smartphone's light sensor) to record the participants' posture. With regard to the small number of participants, 2 points may need to be clarified. The first point is that the single-case research designs used with the participants involved in program 1 and the participants involved in program 2 can be considered adequate to support the internal validity of the data reported [44,45,73]. The second point is that new studies (ie, single-case replication studies and/or group-design studies) would be critically important to determine the external validity of the data and thus their level of representativeness [73-76].

To deal with the issues of maintenance and generalization, more comprehensive studies are needed. Those studies would have to (1) extend the data collection periods and include follow-up checks to verify whether the participants' gains remain stable over time, (2) test the effects of the programs with different groups of people so as to verify whether those effects can be reproduced across participants, and (3) include different contexts in the evaluations (eg, homes, schools, and community and rehabilitation settings) to ascertain the applicability and effectiveness of those programs across settings as well as the sustainability of the programs within those settings [61,63,70,77,78].

To address the social validation question, new studies may need to gather the opinions of staff, family members, and service providers about the acceptability, relevance, and usability of the programs and the technology system on which they rely [79,80]. The process of gathering such opinions may involve 2 steps. The first step would consist of presenting all these personnel with videos of program sessions in which participants use the technology system. The second step would consist of presenting the same personnel with a series of questions concerning the programs and the technology (eg, their impact, social relevance, and applicability) [81-83]. The aforementioned process may be complemented by formal scales assessing the usability of technology (eg, the System Usability Scale) [84,85].

With regard to the recording of body posture, new studies may need to evaluate the usability and practicality of accelerometers, depth cameras, or infrared optical tracking sensors [86-88]. New studies may also consider ways of measuring (1) the impact of mild physical activity such as that adopted in the 2 programs of this study and (2) the level of purposefulness in the participants' selection of the music pieces (ie, in their decision about the pressure sensor to activate at each music opportunity). To address the first issue, one might need to identify evaluation criteria and instruments more sophisticated than those presently available [9,51,58,64]. To address the second issue, one may need to associate highly preferred music pieces with one sensor and moderately preferred music pieces with the other sensor and verify whether the activation of the former sensor is more frequent than the activation of the latter sensor [13,89-91].

Conclusions

The findings suggest that the programs assessed in this study were helpful in improving the situation of people with intellectual disability and visual or visual and motor impairments. All participants learned to activate music stimulation and to engage in recommended forms of physical activity. The participants involved in program 2 also showed an improvement in body posture. These findings provide new evidence of the possibility of developing technology-aided programs to improve the situation of participants with extensive disabilities. Notwithstanding this evidence, caution is required in making general statements and drawing conclusions based on these findings given the limitations of this study, which need to be addressed through new, carefully planned research efforts.

Abstract

Background: Loss of self-feeding ability due to severe bilateral upper extremity motor impairment (BUEMI) limits functional independence with a critical activity of daily living, increases medical risks, reduces social participation, and affects overall well-being. Robotic feeding devices are an emerging category of assistive technology. Obi3 is a third-generation, robotic feeding device, regulated in the United States as a Class I medical device and CE marked as a Class I device under the European Union Medical Device Regulation. The device is designed to enable people with BUEMI to independently select and safely consume food and liquid using accessible switches or interfaces while maintaining culturally normative dining practices. Although earlier Obi generations showed promise, comprehensive usability data across multiple stakeholder groups remains limited.

Objective: This study evaluated the usability, safety, and clinical relevance of Obi3 in real-world use from the perspectives of people with BUEMI, caregivers, and rehabilitation providers. The findings were intended to generate evidence to inform clinical decision-making and determinations of medical necessity for potential DME coverage, consistent with the device's intended use and clinician-assessed implementation.

Methods: A mixed methods usability study provided a 1-week home trial of Obi3. Quantitative measures included the System Usability Scale (SUS), survey items adapted from the Matching Person and Technology (MPT) framework, and self-feeding ratings based on the *International Classification of Functioning, Disability, and Health* impairment scale. Paired-sample *t* tests, Wilcoxon signed-rank tests, and effect sizes (Cohen *d*) assessed changes in self-feeding scores. Qualitative data from open-ended survey responses and follow-up semistructured interviews were analyzed thematically to complement quantitative findings.

Results: A total of 50 participants were enrolled, of whom 42 completed follow-up surveys. Participants included 15 people with BUEMI (pediatric and adult), 14 caregivers, and 13 providers. Participants' mean self-feeding impairment scores decreased significantly from 3.80 (SD 0.41) at baseline to 0.60 (SD 0.74) post trial (n=15; t_{14}=10.75; P<.001; Cohen d=3.40). All patient participants demonstrated improvement in functional self-feeding ability. Mean SUS scores exceeded the benchmark for acceptable usability (≥68) across stakeholder groups: 82.8 (SD 17.2) for people with BUEMI, 85.2 (SD 12.6) for caregivers, and 85.0 (SD 10.7) for providers. Responses to MPT items indicated strong alignment between user goals and device capabilities, perceived safety, and low complexity. Caregivers reported reduced feeding-related workload and stress, and providers endorsed ease of clinical integration. No adverse events or device malfunctions occurred.

Conclusions: Obi3 demonstrated high usability, safety, and clinical use in restoring self-feeding independence among individuals with severe BUEMI. Findings across people with BUEMI, caregivers, and providers support Obi3 as an effective DME that may

XSL•FO
RenderX

enhance user autonomy and reduce caregiver burden. Lengthier longitudinal studies are needed to establish long-term clinical efficacy and health outcomes.

(JMIR Rehabil Assist Technol 2026;13:e86338) doi:10.2196/86338

Introduction

Background

Self-feeding is a fundamental activity of daily living that supports autonomy, nutritional health, and social participation. Within the *International Classification of Functioning, Disability, and Health* (*ICF*) and the *Occupational Therapy Practice Framework*, self-feeding is recognized as a core activity linked to independence, dignity, and quality of life [1,2]. For clarity, this manuscript uses the term self-feeding to refer specifically to bringing food to the mouth, distinguishing it from eating and swallowing, as defined by the American Occupational Therapy Association [3]. Loss of self-feeding ability due to bilateral upper extremity motor impairment (BUEMI) affects more than nutritional intake, contributing to reduced autonomy, dignity, and social participation [4,5]. BUEMI arises from conditions such as cerebral palsy, amyotrophic lateral sclerosis, muscular dystrophy, spinal cord injury, and traumatic brain injury, all of which may disrupt voluntary arm and hand function [6-11]. Although caregiver-assisted feeding can maintain nutrition, it does not restore independence and may introduce variability in feeding pace, technique, and safety [12-15]. Over time, reliance on caregiver assistance can increase caregiver burden and reduce quality of life for both individuals and their caregivers [16]. In addition to physical limitations, loss of self-feeding reduces participation in the social and cultural aspects of eating. Mealtimes are important social activities, and dependence on others may limit engagement and contribute to a reduced sense of identity and belonging. Assistive and robotic feeding technologies aim not only to restore physical function but also to support social participation and emotional well-being [17-21].

Powered feeding systems are an emerging class of assistive technology (AT) designed to restore self-feeding ability in individuals with BUEMI [22,23]. In the United States, these devices are regulated as Class I medical devices under US Food and Drug Administration (FDA), as a daily activity assist device, indicating low risk when used as intended [24]. Several powered feeding devices are commercially available, including the Mealtime Partner [25] and Neater Eater systems [26]. Earlier devices typically rely on limited motor control and produce less fluid movement. In contrast, Obi incorporates a 6–degree-of-freedom (DOF) robotic arm designed to enable smoother, more adaptive utensil motion and individualized positioning, reflecting advances in human-centered assistive robotics [27].

Evidence from Al-Halimi and Moussa [28] supports the functional validity of such multi-DOF robotic approaches, demonstrating that individuals with severe BUEMI were able to perform complex daily tasks, including self-feeding and drinking, using a 6-DOF robotic arm mounted on a wheelchair. Their study highlighted individualized control strategies and adaptive movement patterns, underscoring how increased robotic dexterity can restore meaningful interaction and autonomy while self-feeding.

Obi is designed for repeated use, serves a medical purpose, and is appropriate for home use. These characteristics are consistent with the Centers for Medicare & Medicaid Services (CMS) definition of durable medical equipment (DME). Its design for home use further supports its use in long-term care settings. Obi has been widely used in clinical and home settings, with no reported adverse events in major regulatory databases. It has been prescribed by clinicians and reimbursed through multiple funding sources, supporting its role as a clinically recognized intervention for self-feeding impairment [31]. Despite these advances, limited research has evaluated the real-world usability of newer robotic feeding systems across multiple stakeholders. Usability is a key determinant of adoption and sustained use, particularly for devices intended for long-term home use.

Obi has been prescribed by physicians, deemed medically necessary by occupational therapists, and reimbursed by multiple sources, including the Veterans Health Administration, state Medicaid programs, private insurers, and international health systems. These patterns of prescription and funding highlight Obi's recognition as a legitimate medical intervention to restore self-feeding independence. A recent descriptive study reported that 19 individuals with BUEMI, ranging in age from 8 to 60 years, successfully used an earlier version of Obi in homes, schools, and clinics, achieving independence in food delivery with positive impacts on nutritional intake, autonomy, and social participation [33]. Obi's third-generation model (Obi3) incorporates user-informed enhancements, including new and expanded utensil options, improved utensil-arm retention, new software features ("reward mode" and "patient power-on"), a 2-inch increase in reach, and faster speeds from scooping to mouth delivery.

The literature and regulatory evidence highlight a critical clinical and societal need for safe, effective, and user-centered technologies that restore self-feeding independence among individuals with BUEMI. The systematic evaluation of Obi3's usability over a 1-week period, including the enhanced features and perspectives of multiple stakeholders, including participants with BUEMI, caregivers, and providers, has not been conducted previously. Addressing this gap is essential because usability is a key determinant of the adoption and sustained use of assistive technologies in real-world contexts. Usability, defined as the effectiveness, efficiency, and satisfaction with which users achieve goals in specific environments [33], remains

XSL•FO
RenderX

particularly critical for devices classified as DME given their intended long-term use.

Study Purpose and Hypothesis

Building on prior descriptive findings [32], this study conducted a mixed methods usability evaluation of the Obi3 robotic feeding device to assess its performance, safety, and clinical relevance across multiple stakeholder groups in real-world settings. We hypothesized that Obi3 would demonstrate high usability, safety, and clinical use, reflected by System Usability Scale (SUS) scores exceeding the industry benchmark of 68 [34,35], significant improvements in self-feeding impairment scores, and positive qualitative feedback related to satisfaction and integration into daily routines. This approach aimed to generate both quantitative and qualitative evidence to inform iterative device refinement, guide clinical implementation, and support broader adoption through real-world clinical evidence.

Methods

Study Design and Oversight

This mixed methods usability study evaluated the Obi3 Robotic Feeding Device across 3 stakeholder groups: people with BUEMI, caregivers, and rehabilitation providers. Quantitative and qualitative methods were combined to determine whether Obi3 fulfills its intended purpose of restoring self-feeding ability for individuals with severe upper-extremity motor impairments and whether it meets formally defined user needs. The study was designed in accordance with the International Organization for Standardization (ISO) 14155:2020 Clinical Investigation of Medical Devices for Human Subjects: Good Clinical Practice and was approved by the WCG Clinical Institutional Review Board (Protocol #20251472).

A target sample of up to 60 participants (20 people with BUEMI, 20 caregivers, and 20 providers) was based on the FDA guidance recommending ≥15 participants per user group for usability or design-validation testing of medical devices [36,37]. The study was coordinated by the device manufacturer, DESĪN LLC, as a single-sponsor remote investigation. All consent procedures, survey administration, and survey data collection were conducted electronically using the HIPAA (Health Insurance Portability and Accountability Act)–compliant Qualtrics platform [38].

Recruitment and Enrollment

Recruitment followed a structured, multistage process to ensure broad representation while maintaining ethical compliance. Recruitment materials, including flyers and digital notices, were distributed nationally. A triadic recruitment model (patient-caregiver-provider) was prioritized but not required. Providers were eligible if they held professional credentials (eg, occupational therapist, speech-language pathologist, or AT professional [ATP]) and had experience recommending or evaluating assistive technologies for individuals with self-feeding limitations. Caregivers were qualified if they directly assisted an individual with mealtime activities. People with BUEMI were eligible if aged ≥5 years, required assistive feeding technology to increase self-feeding independence, and could provide consent or assent.

Exclusion criteria included residency in California for new Obi users (due to state-mandated 30-day device-trial requirements), inability to provide informed consent, cognitive impairments preventing meaningful participation, or non-English fluency. Certified ATPs employed by DESĪN LLC prescreened potential participants using standard operating procedures aligned with routine clinical practice.

Informed consent (and assent when applicable) was obtained electronically via Qualtrics. Adults, caregivers, and providers electronically signed consent forms; pediatric participants (aged <17 years) provided assent with parental or guardian consent. Verbal consent was documented when physical signing was not feasible. Participants were informed of study procedures, potential risks, and withdrawal rights.

Obi3 Trial Procedures

Following consent and baseline screening, providers completed the Obi Medical Device Needs Assessment (MDNA) form [38]. The MDNA captured demographics, diagnosis, and self-feeding impairment at baseline and follow-up using the Self-Feeding Impairment Scale. This scale was not intended to serve as a standardized outcome measure and has not undergone formal psychometric validation. Rather, it is a study-specific clinical rating scale embedded within the Obi MDNA form and is conceptually informed by the *ICF* framework. Specifically, the scale reflects levels of functional self-feeding performance ranging from complete dependence to independent performance and was developed to pragmatically characterize the degree of self-feeding impairment observed during routine clinical assessment and device trials. Because the scale was developed internally for clinical use, there are no published studies on its validity, reliability, or responsiveness.

People with BUEMI and their caregivers received an Obi3 unit for a 1-week home trial. The Obi3 (third generation) device incorporated user-informed hardware and software enhancements, expanded utensil options, increased reach, improved utensil-arm retention, and new features such as reward mode and patient power-on (Figure 1).

XSL•FO
RenderX

Figure 1. Obi3 robotic feeding device and new features. The Obi3 robotic feeding system includes several user-informed enhancements, such as expanded utensil options, stronger utensil attachment, additional 2-inch horizontal reach, faster delivery speed, reward mode, patient power-on mode, in-bowl collision detection, new switch color, and improved labeling and aesthetic design.

The trial was conducted in participants' customary real-world environments, including private homes, outpatient clinics, schools, rehabilitation facilities, and other community-based settings where meals would ordinarily occur, to evaluate how effectively the Obi3 robotic feeding device could be integrated into routine daily activities rather than under controlled laboratory conditions. This approach emphasized ecological validity, allowing researchers to capture authentic user experiences, environmental influences, and contextual factors that affect real-world usability. Each caregiver and patient used the device for a minimum of 5 meals within a 1-week period, providing repeated exposure sufficient to assess learning effects, ease of setup, and consistency of performance across multiple sessions. Providers introduced the Obi3 system using the manufacturer's *Quick Start Guide* [39], ensuring standardized orientation while permitting flexibility for individualized instruction. Remote technical and clinical support was available throughout the trial to mirror the level of assistance users might receive during early adoption in home or community settings.

Participants interacted with the device in its standard configuration, which included power controls, utensil selection options, and the reward mode feature designed to enhance motivation and engagement. Meals were self-selected to align with each participant's typical diet, cultural food preferences, and mealtime routines. This design allowed the study to capture performance across a diverse range of food consistencies, environmental contexts, and social settings, thereby providing a more comprehensive understanding of the device's usability, adaptability, and potential for integration into everyday life.

Outcome Measures

Electronic surveys were administered to people with BUEMI, caregivers, and providers, with developmentally appropriate adaptations for pediatric participants. Surveys combined standardized and nonstandardized items assessing usability, satisfaction, and integration of Obi3 into daily routines. The primary outcome was the SUS, a 10-item instrument scored 0-100, with 68 as the benchmark for average usability [34,35]. The SUS was administered to adult patients, caregivers, and providers; pediatric participants were excluded because the SUS has not been validated for children. Secondary measures included items adapted from the Matching Person and Technology (MPT) framework, which evaluates personal predisposition, psychosocial fit, and environmental support [40,41]. Adults and teen people with BUEMI (aged ≥15 years) completed the SUS and MPT-based items verifying ≥5 meal exposures and answered nonstandardized questions about instruction clarity, ease of operation, utensil satisfaction, and

XSL•FO
RenderX

perceived independence and safety. People with BUEMI aged 15 years and older were grouped within the adult patient category because the survey instruments used in the study included self-report items requiring a higher level of reading comprehension, abstract reasoning, and self-reflection regarding device usability, satisfaction, and independence. These constructs align more closely with adolescent and adult cognitive and communicative abilities than with those of younger children. Grouping patient participants aged 15 years and older with adults allowed for consistent interpretation of survey responses and ensured that the usability and satisfaction data reflected meaningful self-reports.

Younger people with BUEMI (aged 5-14 years) were analyzed separately, as their perspectives were often supplemented or interpreted through caregiver feedback due to differences in literacy, attention span, and cognitive maturity. This stratification thus enhanced the validity and comparability of responses across age groups while maintaining clinical and developmental appropriateness. Pediatric participants with BUEMI (aged <15 years) used simplified, emoji-based Likert items evaluating confidence, enjoyment, and safety.

Caregivers completed survey questions designed to capture both their experience using the Obi device and its impact on daily caregiving demands. These included the SUS [34] to assess perceived ease of use and overall satisfaction; the Zarit Caregiver Burden Scale [42] to evaluate potential changes in emotional, physical, and time-related strain; and a series of custom items addressing device setup, cleaning procedures, and perceived reductions in hands-on feeding time. Together, these instruments provided a comprehensive view of how Obi influenced caregiver workload, stress, and independence for the individual being served.

Providers completed a separate set of survey items, including measures capturing professional background characteristics and impressions of Obi3. They rated the device's usability and clinical use, including the clarity and completeness of its instructional materials, setup guides, and documentation tools. These data were intended to evaluate the device's practicality for integration into routine clinical assessment and intervention processes, as well as its suitability for recommendation and long-term use across diverse care settings.

Participants who completed the survey received a US $25 electronic gift card as approved compensation. Optional semistructured interviews were offered to participants following survey completion, whose responses required clarification or elaboration.

Qualitative Interviews

To complement quantitative data, semistructured virtual interviews were conducted by a researcher independent of DESĪN LLC. Interviews captured lived experiences and stakeholder perspectives, addressing the risk that excluding user voices can yield ineffective technologies. A total of 12 participants were contacted via email, phone, and/or text to elaborate on survey themes. Initial contact with participants who completed the follow-up interviews began the week following survey completion, with recruitment and reminders occurring over a 3-week period. Follow-up interviews were conducted during a limited 4-week period. Early sessions included both provider and pediatric user perspectives, followed by adult user and caregiver interviews later within the 1-month data collection window to ensure accurate recall of the Obi3 trial. Sessions were conducted via Google Meet, with verbal consent to record and transcribe. Transcripts were anonymized and analyzed qualitatively as described in the next section.

Data Analysis

All statistical analyses were conducted using IBM SPSS Statistics for Windows (version 31.0.0). Descriptive and inferential procedures were used to summarize participant characteristics and evaluate changes across study measures. Continuous variables, including SUS scores, MPT alignment ratings, Zarit Caregiver Burden scores, and self-feeding impairment ratings, were analyzed using descriptive statistics, including means, SDs, medians, and 95% CIs to describe central tendency and variability. Categorical variables, such as demographic characteristics, professional discipline, and prior AT experience, were summarized as frequencies and percentages.

Assumptions of normality were evaluated using Shapiro-Wilk tests and visual inspection of score distributions, given the relatively small sample sizes within stakeholder groups. Shapiro-Wilk test statistics (W values) and exact *P* values were calculated and are reported for primary outcome measures. Within-subject changes from baseline to post trial were analyzed using paired-sample *t* tests, with *t* values, degrees of freedom, exact *P* values, and 95% CIs reported. For variables that did not meet assumptions of normality, or because of the ordinal nature of the self-feeding impairment ratings and small sample size, confirmatory nonparametric analyses were conducted using Wilcoxon signed-rank tests, with corresponding *Z* statistics and exact *P* values reported.

Effect sizes (Cohen *d*) were calculated to quantify the magnitude of change, using conventional benchmarks (0.2=small, 0.5=medium, and 0.8=large) [43]. Missing data were reviewed descriptively to confirm whether the missing data appeared to occur at random or if they reflected systematic withdrawal-related patterns. Given the low proportion of missing data and absence of identifiable systematic patterns, analyses were conducted using available-case data without imputation. Data were screened for potential outliers by inspecting distributions and performing range checks; no implausible values or data-entry errors requiring removal were identified.

Open-ended survey responses and interview transcripts were analyzed using thematic content analysis. Two researchers independently coded the data, iteratively refined categories, and resolved discrepancies through consensus. To support consistency in the coding language, a generative AI tool (Google Gemini, version 2.5) was used in a preliminary stage to assist with organizing the raw text and suggesting candidate theme labels. The researchers critically reviewed all AI-assisted outputs, confirmed or revised them through manual coding, and determined the final themes. Triangulation with quantitative findings and weekly audit meetings further enhanced methodological rigor [44].

RenderX

Ethical Considerations

All procedures adhered to Good Clinical Practice and ethical standards for human research. The study protocol was reviewed and approved by the WCG Clinical Institutional Review Board (IRB; Protocol #20251472). All participants, or their legal guardians in the case of minors, provided informed consent or assent prior to participation. Data collection and handling followed HIPAA-compliant procedures through the Qualtrics electronic platform. Participants who completed the follow-up survey received a US $25 electronic gift card as IRB-approved compensation for their time and effort.

Results

Participant Enrollment and Retention

In total, 50 individuals enrolled in the study across the stakeholder groups, reflecting a balanced distribution among providers, caregivers, and people with BUEMI. Of these, 42 (84%) participants completed posttrial surveys. Overall attrition was at 16% and was limited to posttrial survey completion rather than participation in the Obi trial itself. Participants who did not complete posttrial surveys were considered lost to follow-up after they could not be reached despite multiple contact attempts over a 2- to 3-week period following the expected survey completion date. This time frame was established to ensure that participants' experiences with the device remained recent enough to support accurate recall.

Among providers, 13 (76%) of 17 completed all study requirements, with attrition primarily due to missed posttrial surveys. Caregivers demonstrated a comparable completion rate of 82% (14/17), with 1 early withdrawal prior to trial initiation and 2 incomplete follow-up surveys. Participants with BUEMI aged 15 years and older demonstrated full retention and 100% completion of study procedures, suggesting high engagement and feasibility of participation in this subgroup. Participants aged 5-14 years also demonstrated strong engagement, with 6/7 (86%) completing the surveys. Overall, these results indicate excellent adherence and acceptability across participant groups, particularly among patient stakeholders, with minimal losses attributable to study-related factors. Enrollment, completion, and attrition rates by stakeholder group are summarized in Table 1.

Table 1. Stakeholder enrollment, survey completion, and attrition.

Stakeholder groups	Participants enrolled, n	Surveys completed, n	Total dropouts and reasons for attrition
Providers	17	13	4 (1=no patient available; 3=did not complete posttrial surveys)
Caregivers	17	14	3 (1=dropped before trial; 2=did not complete posttrial surveys)
People with BUEMI[a] (aged ≥15 years)	9	9	None—100% survey completion
Participants aged 5-14 years	7	6	1 (completed trial but no survey)
Totals	50	42	8 lost to attrition

[a]BUEMI: bilateral upper extremity motor impairment.

Patient Demographics

Demographic and descriptive data were obtained from provider-completed Obi MDNA forms. For 1 pediatric participant whose original provider withdrew from the study, the MDNA form was instead completed by a certified ATP. In accordance with standard clinical procedures, the ATP reviewed the participant's existing clinical documentation, including therapy notes, prior evaluations, and progress reports, and conducted a detailed video review of feeding sessions. This approach ensured that the MDNA data accurately reflected the child's functional abilities, feeding performance, and support needs, consistent with how such assessments are typically conducted in clinical practice when direct observation by the evaluating therapist is not feasible.

Among adult and adolescent participants aged ≥15 years (n=9), the mean age was 33.9 (median 18, range 15-67) years. Gender distribution was balanced (4 males and 5 females). The most common diagnosis was cerebral palsy (n=4), followed by other neurological or neuromuscular conditions, as summarized in Table 2.

The pediatric patient cohort (n=6) ranged in age from 7 to 11 (mean 9.2, SD 1.83) years and included 4 females and 2 males. Rett syndrome was most prevalent (n=3), followed by cerebral palsy (n=2) and Charcot-Marie-Tooth disease (n=1) as listed in Table 3.

Caregiver Characteristics

Caregiver participants (n=14) were primarily mothers (n=11), with additional representation from spouses/partners (n=2) and 1 paid caregiver. Participants were predominantly middle-aged, with varied household income levels and generally high educational attainment. Burden ratings indicated moderate to high stress, particularly related to balancing caregiving with employment and family responsibilities (9/14, 64%). Half of caregivers reported a high overall burden. Descriptive data related to the caregiver results are summarized in Table 4.

Caregiver Burden

Selected items from the Zarit Caregiver Burden Scale were used to descriptively characterize caregiver experiences and caregiving demands among participants. Caregivers reported moderate to high levels of burden across multiple domains. The greatest burden was associated with balancing caregiving responsibilities with work and family obligations (mean 2.64, SD 1.01), followed by insufficient personal time due to caregiving demands (mean 2.57, SD 1.09). Caregivers also reported that their health had been affected by caregiving responsibilities (mean 1.93, SD 1.07). Overall perceived caregiver burden averaged 2.07 (SD 1.14), with 50% (7/14) of caregivers reporting very high levels of burden. These findings suggest that participants providing feeding assistance frequently experienced substantial caregiving demands, highlighting the potential value of interventions that promote greater self-feeding independence.

Provider Characteristics

Of 17 providers enrolled, 13 completed the study. Most were occupational therapy practitioners (n=12), and 1 was a speech-language pathologist. Providers represented outpatient clinics, private practice, and rehabilitation centers, with experience ranging from <3 to >20 years. Half of the providers were recommending Obi for the first time, and most reported limited prior integration of AT into clinical workflows. Descriptive data related to the providers who participated in this study are highlighted in Table 5.

Participants With BUEMI Self-Feeding Outcomes

Changes in self-feeding ability were measured using the Self-Feeding Impairment Scale (0=no problem to 4=complete impairment). Pediatric participants (n=6) showed significant improvement, with mean impairment decreasing from 3.83 (SD 0.41) at baseline to 0.83 (SD 0.98) post trial (t_5=5.38; P=.002; Cohen d=2.37). Adult participants (n=9) demonstrated a similar pattern, improving from 3.78 (SD 0.44) to 0.44 (SD 0.53; t_8=10.22; P<.001; Cohen d=4.71). Across all people with BUEMI (n=15), mean impairment decreased from 3.80 (SD 0.41) to 0.60 (SD 0.74), representing a mean reduction of 3.20 points (t_{14}=10.75; P<.001; Cohen d=3.40). All participants demonstrated improvement in functional self-feeding ability following the use of Obi3 as represented in Figure 2.

XSL•FO
RenderX

Figure 2. Pre- and postintervention self-feeding impairment scores using Obi3. Bar chart showing baseline and postintervention self-feeding impairment scores. Pediatric group (aged <15 years): 3.83 → 0.83; adult group (aged ≥15 years): 3.78 → 0.44; combined group: 3.80 → 0.60. All groups demonstrated large, statistically significant improvements.

SUS Results

The SUS was administered to adult participants with BUEMI, caregivers, and providers; pediatric participants were excluded because the SUS has not been validated for children. Adult participants with BUEMI reported a mean SUS score of 82.78 (SD 17.16). Caregivers reported a mean score of 85.18 (SD 12.58), and providers reported a mean score of 85.00 (SD 10.73). Detailed results are presented in Table 6.

Table 6. System Usability Scale scores by stakeholder group.

Stakeholder group	n	Mean (SD)	Range	Score ≥68[a], n (%)
Adult participants with BUEMI[b]	9	82.78 (17.16)	47.5-100	8 (88.9)
Caregivers	14	85.18 (12.58)	60-100	13 (92.9)
Providers	13	85.00 (10.73)	72.5-100	13 (100)

[a]System Usability Scale scores ≥68 are considered above the benchmark for acceptable usability. Pediatric participants did not complete the System Usability Scale.

[b]BUEMI: bilateral upper extremity motor impairment.

Modified MPT Findings

Participants With BUEMI Perspectives

Survey items adapted from the MPT framework demonstrated strong alignment between Obi and user goals, competencies, and environmental supports. Adult participants (n=9) rated most items highly (*M*=4.11-4.56 on a 5-point scale) but reported lower comfort integrating Obi into daily routines (*M*=3.44) and social settings (*M*=2.50-3.78). Pediatric participants (n=6) provided consistently higher ratings (*M*=3.50-4.75), with the greatest agreement for the statements “Obi helps me achieve my feeding goals” (*M*=4.17) and “Obi improves my quality of life” (*M*=4.75). Across both groups, participants endorsed ease of use (*M*=4.50-4.56) and environmental support (*M*=4.44-4.67), indicating strong usability and goal alignment. However, additional research is warranted to examine how Obi can further facilitate integration into daily routines and community participation.

XSL•FO
RenderX

Caregiver Outcomes

Caregivers reported reduced burden and stress, with increased time for personal responsibilities and less physical fatigue during meals. Open-ended feedback emphasized Obi's dual benefit, enhancing user independence while easing caregiver workload. Common suggestions included improving portability for travel, stabilizing switch ports, adding visual or auditory cues for users with sensory impairments, and optimizing utensil scooping performance. While "reward mode" was praised by some for motivation, others found it confusing, suggesting clearer instructions or customization options. Overall sentiment was highly positive, with several caregivers describing Obi as "life-changing" for both users and families.

Provider Perspectives

Providers described Obi3 as highly beneficial, easy to use, and clinically valuable. They highlighted smooth operation, intuitive setup, and clear instructional materials, particularly the Quick Start Guide and online tutorials. Suggested refinements included utensil geometry, bite consistency, and environmental adaptability. Several providers emphasized that Obi3 promoted measurable independence and engagement among participants with BUEMI, with one describing it as "a necessary tool for promoting autonomy."

Safety Findings

No adverse events, device deficiencies, or unanticipated problems were reported during the study. The absence of safety incidents supports Obi's favorable safety profile, consistent with its FDA Class I designation and regulatory history.

Follow-Up Qualitative Interviews

Overview

To complement the survey data and gain a deeper understanding of usability experiences, follow-up virtual interviews were conducted. Qualitative data from these semistructured interviews were analyzed to enrich, validate, and extend the quantitative findings. Interview participants included caregivers, health care providers, and clients who had previously used the Obi3 feeding device and completed the corresponding surveys. A total of 7 participants (3 participants with BUEMI, 1 caregiver, and 3 providers) completed follow-up virtual interviews to expand on survey findings.

Participants with BUEMIs ranged in age from 11 to 48 years, with primary diagnoses of spinal cord injury (quadriplegia), cerebral palsy, and Charcot-Marie-Tooth disease. Two participants were adults (aged 35 and 48 years), and 1 was a minor (aged 11 years) who participated with support from her mother; all clients completed follow-up interviews. The caregiver participant was a mother aged 31-40 years with a doctoral degree and an annual household income exceeding US $150,000; she also completed a follow-up interview. Providers included an occupational therapist and a speech-language pathologist, both with master's degrees. Their years of practice ranged from 2-3 years to more than 20 years, and their current settings included an outpatient clinic, private practice, and a state developmental disabilities resource center. Overall, 2 providers worked in Louisiana and 1 in Nebraska; 2 had prior experience recommending Obi. Time dedicated to AT varied, with one provider spending less than 50% but more than 20% of their time on AT, another about 20%, and the speech-language pathologist 50%-75%.

The following themes emerged from this analysis:

Theme 1: Enhanced Independence and Quality of Life

This theme highlights the significant positive impact of Obi3 on the lives of users and their families. Clients, including a client with quadriplegia and a young child, reported a newfound sense of autonomy and freedom during mealtimes. One adult client appreciated being able to eat on their own terms and time, rather than relying on a caregiver for every bite, which provided a mental and emotional boost. A provider noted that their client became tearful at the thought of the device being taken away, indicating a profound improvement in their quality of life. Furthermore, the device facilitated social interaction during meals, as it allowed a client and their caregiver to sit and talk together while eating, transforming mealtimes from a task into an enjoyable, social experience.

> *The timing was perfect for the feeding because I was capable of pressing the button and giving the bite when I wanted it.* [adult patient]

Theme 2: Usability and Ease of Setup

Participants generally found the Obi3 to be user-friendly and easy to set up. A caregiver described the initial setup as "not frustrating" and straightforward after calibrating it with the manual. A provider, who is a therapist, reported that they learned to use the device in under 30 minutes and found it "super easy" and "very user-friendly," even for caregivers who may not have extensive technical knowledge. The *Quick Start Guide* and online resources were also praised for being helpful. However, some participants, including a provider, experienced challenges with certain button functionalities, such as getting the device to start or enter training mode, suggesting a need for clearer instructions.

> *It was very, very user-friendly. I was able to show three of his caregivers...And it took us less than 10 minutes to get it set up.* [provider]

Theme 3: Portability and Design Limitations

Both caregivers and clients identified the device's size and lack of portability as a major limitation. A caregiver expressed a need for a smaller, more portable version for use outside the home, such as at restaurants, church dinners, or school. An adult client shared a similar sentiment, stating they would not feel comfortable taking the large device into a public restaurant. The client likened bringing the device to a "briefcase" that takes up half the table, which they felt detracted from the social experience. A provider also mentioned challenges in finding a suitable table to accommodate the device in a clinical setting.

> *Obi was a little too big for the wheelchair tray. Like, we made it work, but um if it were a little smaller, I think it would have worked better.* [caregiver]

XSL•FO
RenderX

Theme 4: Functional Improvements and Feature Suggestions

Participants offered specific suggestions to improve the device's functionality and versatility. The need for additional utensils, such as a fork, a spoon, and a dull knife for cutting food, was raised by a caregiver. Another client and a caregiver noted the issue of the spoon frequently coming up empty, suggesting that the device should be programmed to always use the bowl's edge to ensure a successful scoop. Different plate sizes, including a larger bowl option, were also recommended. A provider highlighted the benefit of the smaller spoon in the Obi3 version for a client with a small mouth and choking concerns. The device's ability to handle liquids was also a significant benefit for clients with dehydration issues.

> *The machine was easy to use, but the spoon couldn't scoop food from the edge, so I think it needs a larger circumference.* [adult patient]

Theme 5: Motivating Impact and Self-Advocacy

The device was found to be highly motivating for both clients and their families. A pediatric patient loved using the device and was excited to show it to others, even wanting to make a YouTube video about it. A provider noted that the device was motivating for both a child user and their parent, helping them feel that success with the device was achievable at home. One client even used the device to express their food preferences by immediately dumping food they did not want and giving a different choice. This demonstrates that the device empowers users to exercise greater control and self-advocacy over their mealtimes.

> *The Obi device helped reduce my caregiving workload during mealtimes by allowing my child...to self-feed. The Obi device has the potential to be a 'game changer' for our family, as we have been hand-feeding our child three meals a day for ten years.* [caregiver]

Discussion

Principal Findings

Obi3 demonstrated high usability and short-term functional improvements in self-feeding performance under real-world conditions. Statistically and clinically significant gains were observed across all patient participants, who progressed from severe or complete self-feeding impairment at baseline to mild or no impairment after a 1-week home trial. These improvements indicate that Obi3 successfully fulfills its intended medical function, compensating for the loss of voluntary upper-limb movement and enabling users to independently select and consume food and liquid. These findings support the feasibility of the device as an assistive intervention; however, longer-term and controlled studies are needed to establish sustained clinical efficacy, nutritional outcomes, and psychosocial impact.

Quantitative outcomes were reinforced by qualitative and observational data. SUS scores exceeded the industry benchmark of 68 across participants with BUEMI (mean 82.8, SD 17.2), caregivers (mean 85.2, SD 12.6), and providers (mean, SD 10.7), demonstrating a consistent pattern of high perceived usability, reliability, and ease of clinical integration. Complementary survey findings aligned with the MPT framework revealed strong alignment among device capabilities, user goals, and environmental supports, including key predictors of sustained adoption in real-world contexts. Triangulation with interview data further confirmed that participants experienced enhanced autonomy, dignity, and reduced caregiver burden. Collectively, these findings demonstrate that Obi3 meets essential design and performance criteria for DME, addressing not only the physical restoration of self-feeding but also the psychosocial and participatory dimensions of independence.

Participant feedback regarding utensil options and food handling underscores the importance of caregiver and provider education on optimal food presentation when using robotic feeding devices. Although a caregiver suggested adding utensils such as forks or dull knives to facilitate food cutting, this feedback reflects a potential misunderstanding of the device's intended use. As with most adaptive feeding interventions, foods presented for robotic delivery should already be prepared in appropriately sized, manageable portions consistent with each user's swallowing safety and motor abilities. Proper meal preparation, including cutting food into uniform, bite-sized pieces and selecting suitable textures, ensures safe, reliable spoon loading and reduces the risk of choking or aspiration.

The *Instructions for Use* provided with Obi3 include guidance on food size, placement, and consistency to promote optimal performance; however, these directions may not always be sufficiently emphasized or understood by all users. Some caregivers may benefit from more explicit visual examples or in-person demonstrations to reinforce these principles and ensure consistent adherence to safe feeding practices. Integrating this training into initial device setup, clinician-guided instruction, and follow-up sessions could enhance device performance, minimize user frustration, and strengthen caregiver confidence. Ultimately, reinforcing food-preparation education is essential to achieving safe, effective, and independent mealtime participation with robotic feeding systems.

Comparison With Prior Work

Unlike other commercially available powered feeding systems, Obi3 uses a 6-DOF robotic arm that produces naturalistic utensil trajectories and customizable positioning, allowing accommodation for diverse user anatomies and dining environments. These technical advancements correspond with prior evidence from Al-Halimi and Moussa [28], who demonstrated that users with severe motor impairments could complete complex activities of daily living, including self-feeding, using a 6-DOF robotic arm. This study also builds upon earlier work by Burgos [33], which reported improved independence among 19 Obi users in home and clinical contexts, by expanding the sample to a larger, more diverse group and incorporating caregiver and provider perspectives.

The observed reductions in caregiver workload and stress mirror findings from studies of adaptive eating devices and robotic assistance in neurological populations [12,13], underscoring the dual benefit of such technologies for users and care partners alike. In addition, the absence of adverse events aligns with

XSL•FO
RenderX

existing safety records in the FDA's Manufacturer and User Facility Device Experience [31] and the European Database on Medical Devices [32], supporting Obi3's favorable benefit-to-risk profile. Consistent with principles of human-centered design [36], the findings affirm that usability, environmental fit, and psychosocial relevance are critical determinants of long-term adoption and meaningful engagement with assistive technologies.

Limitations

Several limitations should be considered when interpreting these findings. First, data collection primarily relied on self-report surveys, which are well-suited for capturing perceptions of usability, satisfaction, and caregiver burden, but are inherently subject to recall bias, social desirability bias, and individual differences in self-awareness or communication ability. Follow-up interviews were incorporated to contextualize these responses and reduce misinterpretation.

Although 50 participants were enrolled and 42 completed all study requirements, the sample size remains relatively small, limiting the ability to detect subgroup differences or perform multivariate analyses. Although the target enrollment of 60 participants was not achieved, the final sample of 50 participants exceeded typical sample sizes reported in usability studies and was considered sufficient to address the study objectives. While the number of participants aligns with the FDA's guidance for formative and summative usability testing, larger multisite studies would enhance the external validity and representativeness of findings. Future research should include greater demographic, diagnostic, and cultural diversity, as well as participants using alternative switch interfaces or mounting configurations to evaluate device performance across varied clinical and environmental contexts.

The self-feeding impairment rating scale used in this study was a study-specific clinical measure embedded within the MDNA assessment process and has not undergone formal psychometric validation or interrater reliability testing. Although structured scoring anchors, clinician-guided assessment procedures, and repeated ratings by the same provider were used whenever feasible to support consistency, the measure was intended primarily to descriptively characterize functional change during the Obi3 usability trial rather than to serve as a definitive clinical outcome instrument. Consequently, the observed improvements in self-feeding performance should be interpreted as preliminary evidence of functional feasibility rather than conclusive evidence of clinical efficacy. In contrast, the SUS, which served as the primary standardized usability outcome measure, is a well-established, psychometrically validated instrument widely used in health and AT research.

The study was conducted over a short-term trial period (1 week), which may not fully capture the effects of sustained device use on long-term outcomes such as user satisfaction, skill acquisition, changes in muscular strength or tone, or caregiver burden. Extended longitudinal and home-based evaluations are warranted to understand the potential impact on health outcomes, maintenance needs, and adherence over time.

The device manufacturer sponsored this study, and several authors maintain professional or financial relationships with the sponsor. Although these relationships were fully disclosed and reviewed by the IRB, they introduce a potential risk of bias in study design, data interpretation, and reporting. To mitigate this risk, data collection followed standardized protocols. Ratings of participants' self-feeding performance were completed by licensed therapists, who were also study participants, using a structured clinical data collection instrument (Obi MDNA) consistent with routine practice. All survey data were collected remotely via the Qualtrics platform, with participants entering responses independently and without direct interaction with the researchers responsible for data analysis. Qualitative interviews were conducted by a researcher independent of the sponsor, and data analysis incorporated dual independent coding, triangulation, and audit procedures. Additionally, all authors had access to aggregated study data, and statistical analyses were independently verified. Finally, this investigation did not include objective nutritional or biomechanical measures (eg, meal duration, food intake volume, posture, or reach analysis), which could strengthen the interpretation of functional and clinical outcomes. Integrating such measures in future studies would allow for a more comprehensive understanding of the device's impact on independence, health, and participation across stakeholder groups.

Acknowledgments

This study was supported by DESĪN LLC, the manufacturer of the Obi Robotic Feeding Device. The sponsor provided financial support for study coordination, device provision, and participation in the decision to submit this manuscript for publication. DESĪN LLC also contributed to aspects of study design and data interpretation; however, all analyses were conducted in accordance with Good Clinical Practice, and the authors retained full responsibility for the accuracy, integrity, and presentation of the data.

The authors thank the people with disabilities, caregivers, and rehabilitation providers who participated in this study, as well as the assistive technology professionals who assisted with recruitment and device setup.

A generative AI tool (Google Gemini, version 2.5) was used under the researcher's supervision to assist with the organization of qualitative text and preliminary theme labeling during analysis. All final coding, thematic interpretation, and manuscript writing decisions were conducted and verified by the authors.

Authors' Contributions

Conceptualization: ADF, JPD

XSL•FO

Methodology: ADF, HK, JPD
Formal analysis: ADF, RBO
Investigation: RBO, HK
Project administration: ADF, RBO, HK
Supervision: ADF
Writing—original draft: ADF, RBO, JPD
Writing—review and editing: ADF, RBO, HK, JPD
ADF served as the principal investigator and oversaw adherence to the institutional review board–approved protocol. To minimize potential bias, ADF did not participate in data collection or have direct contact with research participants. JPD directed activities related to International Organization for Standardization (ISO) 14155 compliance and the Clinical Investigation Plan. Due to his ownership interest in DESĪN LLC, JPD did not have access to identifiable participant data and did not participate in data analysis. All authors reviewed, revised, and approved the final manuscript.

Conflicts of Interest

ADF discloses significant financial interests and relevant financial relationships with DESĪN LLC, the developer and manufacturer of the Obi robotic feeding device. She currently serves as Director of Clinical Affairs at DESĪN LLC, where she oversees clinical research, evidence development, and reimbursement strategy for the device. During the implementation of the study, she was contracted by DESĪN LLC as an independent consultant. RBO reports no direct financial relationship with DESĪN LLC. He received compensation for his contributions to this study through part-time employment with The Driving Doctor: Adaptive Driving and Rehabilitation Solutions under the supervision of ADF. HK discloses significant financial interests and relevant financial relationships with DESĪN LLC. She is a paid employee of DESĪN LLC and served as a subinvestigator on the research activities related to the Obi3 described in this manuscript. JPD discloses a significant financial interest through equity ownership in DESĪN LLC, which constitutes a potential financial conflict of interest. To manage this conflict, he was restricted from access to subject identification, data collection, and analysis activities. All conflicts of interest were reviewed and approved by the WCG Institutional Review Board, which provided independent oversight to ensure compliance with US Food and Drug Administration regulations (21 CFR Part 54) and International Council for Harmonization E6 Good Clinical Practice guidelines.

Abstract

Background: Socially assistive robotics (SAR) is an emerging field integrating robotics, medicine, cognitive and social sciences, and neuroscience. Its potential in multiple sclerosis (MS) remains largely unexplored, although MS affects sensory-motor, cognitive, and psychological domains where SAR could offer substantial benefits.

Objective: This study aimed to evaluate the usability of a humanoid robot in people with MS, compare it with age-matched healthy individuals (HIs), and explore usability predictors. Automated written-language analysis was tested as a complementary approach.

Methods: In this 2025 cross-sectional study at the Italian MS Foundation laboratory, 20 people with MS (mean age 51.4, SD 11.0 years; n=13, 65% female; mean education 13.0, SD 3.4 years) and 20 age-matched HIs (mean age 47.3, SD 10.1 years; n=12, 60% female; mean education 14.8, SD 2.2 years) completed 4 predefined tasks with the robot Pepper. Usability was assessed using the System Usability Scale (SUS). Attitudes toward robots, robot-related factors, and task-related effort were measured with the General Attitudes Towards Robots Scale (GAToRS), Godspeed questionnaire, and NASA-TLX, respectively. Psychological variables (eg, personality traits from the Italian Ten-Item Personality Inventory [I-TIPI]) and clinical characteristics for people with MS (eg, cognitive functions via the app DIGICOG-MS, upper-limb difficulties with the Arm Function in Multiple Sclerosis [AMSQ]) were collected. Written responses to open-ended questions were analyzed using natural language processing (NLP).

Results: SUS scores exceeded the standard cut-off in both groups, with no between-group differences (people with MS: mean 81.00, SD 12.31; HIs: mean 77.75, SD 11.24; r=0.14, 95% CI 0.01-0.42; P=.39), indicating high usability. People with MS reported more negative attitudes toward robots at the societal level (GAToRS S–: r=0.36, 95% CI 0.08-0.63; P=.02) and judged Pepper as more anthropomorphic (r=0.42, 95% CI 0.15-0.67; P=.007) and intelligent (r=0.37, 95% CI 0.09-0.61; P=.02) than HIs. Anthropomorphism was strongly associated with visuospatial memory (DIGICOG-MS: ρ=–0.632, 95% CI –0.84 to –0.26; P=.003) and relatively strong with both verbal memory (DIGICOG-MS: ρ=–0.504, 95% CI –0.77 to –0.08]; P=.02) and agreeableness (I-TIPI: ρ=0.491, 95% CI 0.06-0.77; P=.03). Exploratory forward stepwise regression showed that conscientiousness (I-TIPI: B=2.064, 95% CI 0.679-3.449), negative personal attitudes toward robots (GAToRS P–: B=0.169, 95% CI 0.033-0.306), and perceived upper-limb difficulties (AMSQ: B=0.169, 95% CI 0.033-0.306) explained 64% of SUS variance (adjusted R^2=0.568); task-related frustration (NASA-TLX: B=–1.497, 95% CI –2.276 to –0.719) explained 48% (adjusted R^2=0.451). NLP analyses revealed no between-group differences in lexical productivity or sentiment-lexicon coverage.

Conclusions: This study provides first preliminary evidence that people with MS perceive a social robot as highly usable, comparably to HIs, suggesting MS-related challenges may not hinder human-robot interaction. Psychological factors, prior attitudes toward robots, and clinical characteristics were associated with user experience in the MS group. Future research should explore whether integrating these measures with language-based approaches informs tailored interventions in MS.

socially assistive robotics; multiple sclerosis; usability; technology acceptance; anthropomorphism; human-robot interaction; natural language processing; Pepper

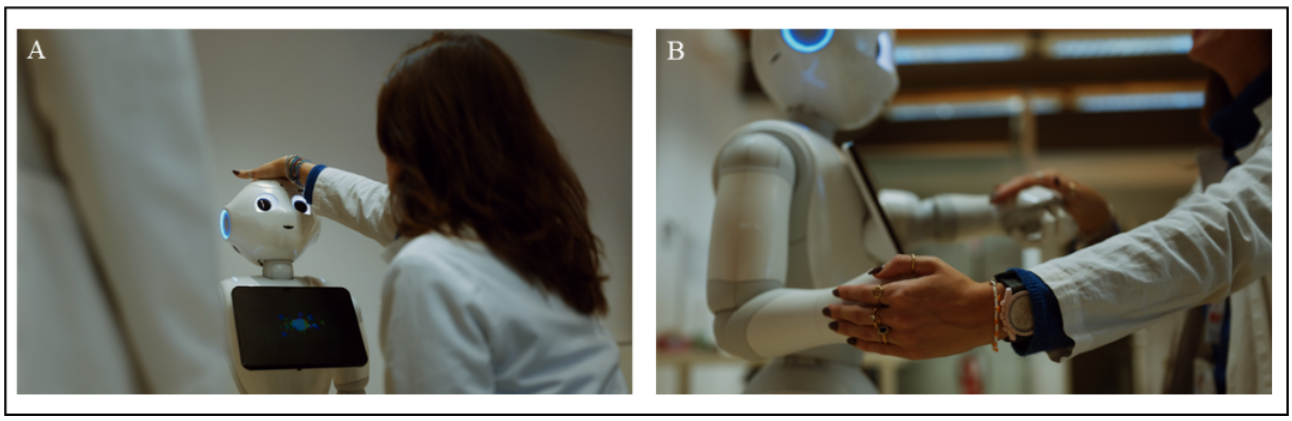
Introduction

Socially assistive robotics (SAR) is a growing interdisciplinary research field aiming at supporting people in different social situations through robot-based solutions [1]. This area integrates robotics, medicine, social and cognitive sciences, and neuroscience. Social robots are used in various domains, such as health care, education, business, industry, and culture [2], where interaction between individuals is essential. One of the main challenges of human-robot interaction applied to different research areas, such as physical and cognitive rehabilitation or emotional support, lies in ensuring a fluid and effective interplay so that users have the subjective impression that they are interacting with an intelligent agent. In this context, achieving a positive user experience (UX) is crucial, as it directly influences engagement, acceptance, and the overall impact of SAR on human life [2]. SAR has demonstrated its value to promote people's well-being by creating new avenues to access services and resources for mental health in real-world contexts [3], offering numerous possibilities for the innovation and implementation of robots in education, medicine, rehabilitation, and psychotherapy, improving treatment compliance in children with specific clinical conditions such as autism spectrum disorder [4-8] and in reducing anxiety among older adults, with subsequent improvements in their quality of life [9]. As indicated in a recent review [10], SAR has been used with promising success specifically in supporting everyday life, providing interaction, and facilitating cognitive and physical training in the older population. Despite these advances, the use of SAR in other neurological populations [11-13], such as people with multiple sclerosis (MS), remains largely unexplored. This is surprising given that MS is characterized by a heterogeneous combination of sensory-motor impairments, cognitive deficits, and psychological symptoms, all domains in which SAR could potentially offer substantial benefits [14,15]. The impact of MS extends into work roles, economic status, and social relationships. It is reasonable to surmise, therefore, that MS and its manifestations make those living with this disease vulnerable to the experience of loneliness and social isolation [16,17]. In this context, SAR may offer a promising avenue not only for physical and cognitive rehabilitation but also for addressing the social and emotional needs of people with MS—a gap that has received little attention in the existing literature. However, before implementing such interventions, it is crucial to understand how people with MS perceive and interact with social robots. To date, there is no empirical evidence on how this clinical population perceives key social dimensions of human-robot interaction, such as robot anthropomorphism. Without this foundational knowledge, deploying SAR in MS rehabilitation risks being ineffective or misaligned with people's needs.

Based on these premises, the aims of this study were to (1) evaluate the usability of humanoid robot Pepper (SoftBank Robotics) in people with MS; (2) investigate any differences with an age-matched group of healthy individuals (HIs) in both perceived usability and task-related effort; and (3) exploratorily examine potential predictors of usability, including psychological variables, prior attitudes toward robots, and clinical characteristics. Furthermore, as a complementary component of the study, we applied natural language processing (NLP) techniques to participants' written responses to open-ended questions with the aim of examining whether automated language analysis could serve as a proxy for evaluating user appreciation of the social robot alongside the primary quantitative measures. This analysis was not intended as a substitute for qualitative inquiry, but rather as a preliminary, hypothesis-generating exploration of the linguistic correlates of UX in this population.

Methods

Study Population



This cross-sectional study was conducted in November 2025 at the laboratory of the Fondazione Italiana Sclerosi Multipla (FISM) in Genoa (Italy). The study sample consisted of people with MS, followed as outpatients at the Italian Multiple Sclerosis Society (AISM) Rehabilitation Service of Liguria (Genoa, Italy). Potential participants were identified by the AISM clinical staff and approached directly during routine clinical appointments or contacted by telephone by the FISM Secretariat. All individuals contacted agreed to participate, except for 1 individual who expressed willingness but was unable to attend due to work commitments. Eligibility criteria included an age of 18 years and older; a confirmed MS diagnosis [18]; any disease course (relapsing-remitting, secondary progressive, primary progressive MS); the absence of relapses in the last 3 months; an Expanded Disability Status Scale (EDSS) [19] of 6.5 or below; and adequate visual, hearing, and motor capabilities to complete the experimental tasks. Exclusion criteria were a Montreal Cognitive Assessment score of 18 or below [20], neurological and major psychiatric illness, past serious head trauma, and alcohol or drug abuse. Inclusion criteria were intentionally broad to reflect the heterogeneity of the real-world MS population; eligible individuals were first identified by the clinical staff in collaboration with the research team, ensuring that only those meeting all eligibility criteria and able to safely complete the experimental tasks were approached. A healthy control group was included to provide a reference for comparison, allowing us to determine whether people with MS respond to the robot differently from HIs, and to identify usability patterns and attitudes that may be specific to the MS population rather than common to all users. HIs were recruited on a voluntary basis among AISM employers through institutional email distribution, matched by age, and were required to have no history of neurological or psychiatric diseases. All participants provided written informed consent prior to enrollment.

The Social Robot and Software Used in the Experiment

The device used in this study was the humanoid social robot Pepper. Pepper is designed to interact with people and is capable of autonomous navigation, face recognition, scripted dialogue, and adopting life-like human poses, such as performing arm and hand gestures. In this study, Pepper was programmed with a small and simple set of behaviors: greeting participants, providing instructions for each experimental task, and guiding participants through the tasks themselves, as detailed in the next section (Figure 1). The software controlling the robot's behaviors in the study was developed by Engineering Ingegneria Informatica S.p.A. (EII) as part of their long-term Socially Assistive Robotic Solution for Ambient (SARA)–assisted living, a complex distributed home automation and robotics system providing health monitoring and (socially interactive) assistance in daily living tasks to older adults and their caregivers at home, with the aim of prolonging their autonomy and delaying their institutionalization. Following [21], the SARA has the ambitious goal to develop robots that provide physical assistance, for example, rehabilitation robots, wheelchair robots, mobility aids, manipulator arms), and are able to engage humans in interaction, for example, from [22] engaging in high-level dialog, using and understanding natural cues (gaze, gesture, etc), expressing/perceiving emotions, and establishing and maintaining social relationships (among other competencies).

Figure 1. Participant-robot interaction with the humanoid social robot Pepper (SoftBank Robotics, Tokyo, Japan). (A) All interactions started with a head-touch gesture to activate the robot's social engagement mode. (B) Keyframe from 1 experimental task, showing the reciprocal movement dynamics between the participant and the robot.

Experimental Procedures: Human-Robot Interaction

Prior to the experimental sessions, a preliminary focus group was conducted with a multidisciplinary team, including clinicians with a high experience in MS (eg, psychologists, physiotherapists, occupational therapists) and engineers, to identify the most appropriate and meaningful tasks for the study. Insights from this focus group were used to select and refine task scenarios that were engaging and feasible for interaction with the robot. This collaborative approach ensured that the activities included in the experiment were ecologically valid and aligned with both abilities and practical considerations of people with MS for the robot's implementation.

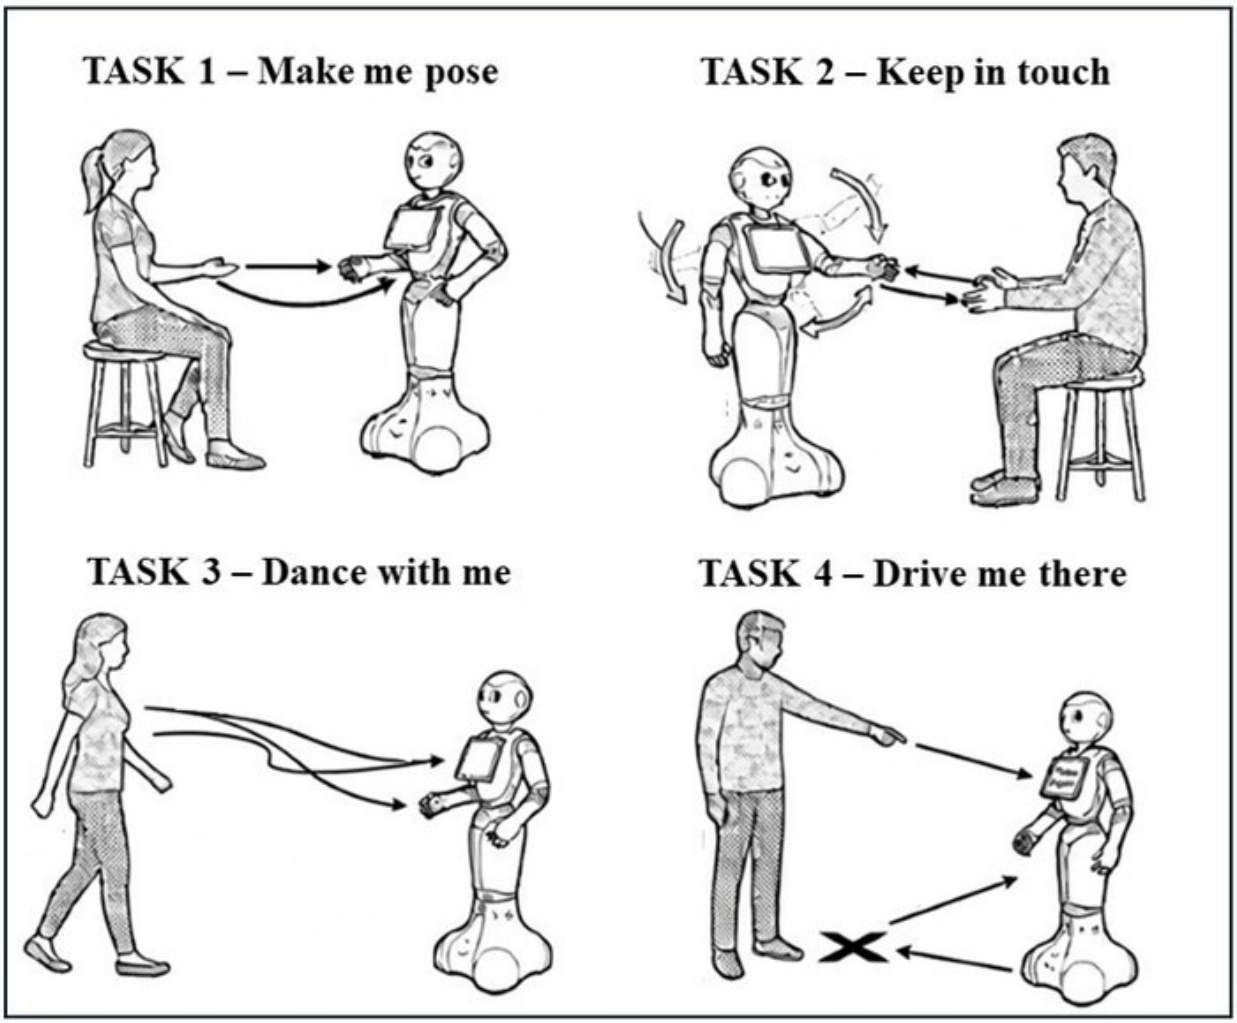
Each participant, in a structured setting, was invited to engage in 4 predefined interaction sequences with the robot (inspired by Tleubayev et al [23]), served to document engagement levels and usability perceptions of the robotic system, under the supervision of a trained health care professional (ie, a psychologist). The first 2 tasks were "static," with the participant sitting in front of the robot, which remained docked (in a standing pose) on its recharging station throughout. Both tasks relied principally on the robot's touch sensors and its upper body motion capabilities. The tasks were as follows:

- Task 1—Make me pose: The goal for the participant, seated in front of Pepper, was to make the robot adopt a target pose (demonstrated by the robot at the beginning of the interaction). Starting from a random initial pose, the robot moved into a new pose each time the participant touched the robot's hands. The task stopped when the participant recognized that Pepper reached the target pose, indicated by the participant touching the robot's head. The aim of this exercise was to stimulate the participant's memory ability.
- Task 2—Keep in touch: The objective for the participant, again seated in front of Pepper, was to maintain physical contact between her/his hands and the robot's hands while the robot executed a slow preplanned sequence of arm movements. The task stopped at the end of the sequence. The aim of this exercise was to stimulate participants' focused attention while engaging in controlled upper body movements.

The remaining tasks were more dynamic, with both Pepper and the participant free to move around. The robot's behavior in these tasks relied on its autonomous navigation capabilities and used proximity sensors (infrared, sonars, and lasers) embedded within its mobile base to detect the relative location of the participant. The final task also depended on the native visual localization functions of the robot. The 2 dynamic tasks were as follows:

- Task 3—Dance with me: The participant stood at 1 m or so in front of Pepper. The goal was to guide the robot through a short sequence of locomotive movements (forward, backward, and turning). The robot moved in response to changes in the relative positions of the participant and the robot—for example, if the participant stepped backward, Pepper moved forward—to maintain a

XSL•FO
RenderX



constant relative distance and orientation. The aim of this exercise was to stimulate working memory and spatio-temporal orientation with the participant engaging in simple locomotion.

- Task 4—Drive me there: Once again the participant was standing, but now the objective was to guide the robot to a nearby location (a few meters away). The robot moved in response to the participant's movements in the same way as in the previous Task 3. The aim of this exercise was to stimulate spatio-temporal orientation and planning abilities with the participant engaging in simple locomotion.

Each task was introduced and explained to the participant by the robot itself. During the task, the robot also offered occasional encouraging remarks and provided feedback on the participant's progress, which were all accompanied with appropriate hand/arm and head gestures to favor communication and avoid ambiguity.

The experimental session lasted 45 minutes, comprising interaction with Pepper (20 min) and test and questionnaire administration (25 min). Figure 2 shows an overview of the 4 experimental tasks illustrating human-robot interaction.

Figure 2. Overview of the 4 experimental tasks illustrating human-robot interaction. Participants performed 4 tasks with Pepper. In Task 1 (Make me pose), a seated participant guided the robot to a target pose via touch. In Task 2 (Keep in touch), a seated participant maintained continuous contact with the robot's hands while it executed a sequence of movements. In Task 3 (Dance with me), a standing participant led the robot through locomotor movements using a "follow-the-leader" approach. In Task 4 (Drive me there), a standing participant guided the robot to a target location.

Demographic and Clinical Outcomes

Sociodemographic data (ie, age, sex, educational level) were collected for all participants, while disease-related information (ie, MS course, disease duration, and disability level as indicated by EDSS) was gathered only for people with MS. Furthermore, MS cognitive functioning was tested using DIGICOG-MS, a mHealth app including digital tests that measure visuo-spatial and verbal memory, information processing speed, and semantic fluency [24]. Patient-reported outcomes (PROs), routinely used in MS clinical practice and well-established in this population, were administered to people with MS to assess upper-limb functionality (Arm Function in Multiple Sclerosis [AMSQ] [25]), perceived fatigue (Modified Fatigue Impact Scale [MFIS] [26,27]), perceived cognitive deficit (Multiple Sclerosis Neuropsychological Questionnaire [MSNQ] [28]), and impact of MS (29-item Multiple Sclerosis Impact Scale [MSIS 29] [29]). State and trait anxiety (State-Trait Anxiety Inventory [STAI] [30]), risk of depression (9-item Patient Health Questionnaire [PHQ-9] [31,32]), and personality traits (Italian Ten-Item Personality Inventory [I-TIPI] [33]) were collected

XSL•FO
RenderX

for both people with MS and HIs. All questionnaires were administered in paper-and-pencil format, except for DIGICOG-MS, which was completed digitally. Participants completed all measures independently, with a psychologist available to clarify any questions. All instruments have been validated in Italian, with the exception of the MSIS-29, for which no formal Italian-language validation study has been published to date; however, its Italian translation is widely used in MS research internationally.

Human-Robot Interaction Outcomes

Before starting the experiment, all participants completed the General Attitudes Towards Robots Scale (GAToRS) [34] to explore positive and negative attitudes toward robots at a personal and societal level. After the task, the following questionnaires were administered: System Usability Scale (SUS) [35] for overall usability (primary outcome); Godspeed questionnaire [36,37] for robot-related factors such as Anthropomorphism (ANTR), Animacy (ANIM), Likeability (LIKE), Perceived Intelligence (INT), or Perceived Safety (SAF) of robots; the National Aeronautics and Space Administration Task Load Index (NASA-TLX) [38] for mental and physical workload.

After the interaction with the robot, participants responded to three open-ended written questions: (1) “How would you describe your experience with the social robot during the activity?” (2) “What kind of feelings or thoughts did the interaction with the robot evoke?” (3) “Was there anything that struck you or surprised you about the way the robot interacted with you?”

Statistical Analysis

Given the absence of prior SAR studies in people with MS, no formal a priori power analysis was feasible. The sample size of 20 per group was chosen in line with established practice in pilot SAR research, where small samples are commonly adopted when exploring novel populations or contexts [39,40]. Descriptive statistics including means, SDs, SEs, and medians with IQRs were calculated to summarize the data. Depending on the distribution of the data, parametric tests, nonparametric tests, or chi-square tests were used to compare demographic, psychological, and technological/robotic factors between people with MS and HIs, as appropriate. To explore factors associated with the group differences, exploratory bivariate correlations with clinical, psychological, and functional variables were run. Pearson or Spearman correlation analyses, as appropriate, were performed to examine associations between variables, with correlation coefficients interpreted as follows: 0.20-0.39 were interpreted as moderate, 0.40-0.59 as relatively strong, 0.60-0.79 as strong, and ≥0.80 as very strong correlation [41]. Effect sizes for Mann-Whitney *U* tests were reported as *r* ($Z/\sqrt{N}$) and interpreted as small (<0.30), medium (0.30 - 0.50), or large (>0.50). Effect sizes for χ^2 tests were reported as Cramér *V*. Given the lack of evidence on factors influencing the usability of social robots in people with MS and the small sample size (n=20), 2 exploratory stepwise linear regressions were conducted—one examining psychological factors, the other technological/robotic factors—to identify possible predictors, both using a forward selection procedure, entering all candidate predictors simultaneously and retaining only those meeting the p-to-enter threshold of .05 and p-to-remove threshold of .10. Particularly, the first stepwise multiple linear regression analysis was conducted to explore the extent to which personality traits (I-TIPI), attitudes toward robots (GAToRS), and other clinical variables such as perceived upper-limb difficulty (AMSQ), depression (PHQ-9), perceived cognitive abilities (MSNQ), impact of MS (MSIS), and perceived fatigue (MFIS) predicted SUS scores. The second analysis was run with workload as measured by NASA-TLX subdomains and Godspeed. Both R^2 and adjusted R^2 were reported to account for the number of predictors. Influential-case diagnostics were conducted for both regression models using Cook distance, with a threshold of 4/n=0.20. Prior to interpretation, model assumptions were verified through visual inspection. Normality of residuals was assessed using P-P plots, and homoscedasticity was examined through residual scatterplots, which revealed no systematic patterns, supporting the assumption of homoscedasticity in both models. Multicollinearity was evaluated using tolerance statistics and variance inflation factor (VIF) values. Given the exploratory nature of this study, no formal corrections for multiple comparisons were applied. While this increases the risk of type I error, applying corrections such as Bonferroni or FDR in exploratory analyses raises the risk of type II error and may obscure potentially meaningful patterns worthy of further investigation in confirmatory studies. Our analytical strategy aimed to capture the widest possible range of behavioral and clinical predictors, allowing for a more inclusive exploration of the factors shaping robot-assisted interaction in this clinical population.

In addition, participants provided short written responses to 3 open-ended questions about their experience interacting with the social robot. These responses were analyzed using a lightweight NLP pipeline aimed at extracting basic lexical and evaluative features. This analysis was conceived as exploratory and complementary to the primary quantitative outcomes, rather than as a stand-alone qualitative investigation.

Text preprocessing and lemmatization were conducted using the Italian language model in the spaCy NLP library [42]. Punctuation, numbers, and Italian stopwords were removed before analysis. Stopword lists were based on standard Italian Snowball resources [43] and were supplemented with additional context-specific terms related to the experimental setting to avoid artificially inflating lexical counts. The additional terms excluded were the following Italian words: *robot* (“robot”), *pepper* (“Pepper”), *esperienza* (“experience”), *interazione* (“interaction”), *attività* (“activity”), *esercizio* (“exercise”), *studio* (“study”), *compito* (“task”), *task* (“task”), *persona* (“person”), and *paziente* (“patient”). Lemmatized tokens were then used to compute basic lexical features, including total word count (NumWords) and the number of unique lemmas. To capture evaluative language, tokens were matched against the Sentix Italian sentiment lexicon [44,45]. For each participant, we calculated the number of tokens appearing in the sentiment lexicon (SentN). Because longer responses naturally increase the likelihood of lexicon matches, we derived an additional measure to estimate sentiment-lexicon coverage independently of response length. Specifically, SentN was regressed on total

XSL•FO
RenderX

word count, and the residuals from this model were extracted. This residualized measure reflects whether a response contains more or fewer sentiment-lexicon matches than would be expected given its length. Responses to the 3 questions were concatenated to obtain a single text sample for each participant. The corpus therefore comprised 120 written responses from 40 participants (3 responses per participant). After preprocessing, 648 lemmatized tokens were retained for analysis, corresponding to a mean of 16.2 tokens per participant (SD 11.9; median 11.5; range 2‐50). Given the exploratory nature of the NLP component, no between-group test was formally prespecified. Both Welch 2-tailed *t* tests and Mann-Whitney *U* tests were conducted as complementary robustness checks. Within the MS group, exploratory associations between linguistic variables and UX measures (SUS and GAToRS) were examined using Kendall tau (τ), which is suitable for small samples and variables with tied ranks. To assess the sensitivity of the association between residualized sentiment-lexicon coverage and SUS to individual observations in the small MS sample, leave-one-participant-out and leave-two-participants-out analyses were additionally performed, reestimating the residualization model at each iteration. No formal multiplicity correction was prespecified for the exploratory NLP analyses. For the 4 reported NLP associations, Benjamini-Hochberg FDR-adjusted *P* values were calculated post hoc as a sensitivity analysis.

Ethical Considerations

The study has been approved by the Regional Ethics Committee (229/2022 - id 12330), and participants provided their written consent to participate after reading information about the study in accordance with the revised Declaration of Helsinki. Data collected were stored in an anonymized format to properly protect the privacy and confidentiality of participants, ensuring that no individual can be identified from the data provided. Participants have been informed that data collection could be used only for research purposes.

Results

Sample Characteristics

Twenty people with MS and 20 HIs were enrolled and completed the study. As indicated by Mann-Whitney *U* tests, the groups did not differ in terms of demographic variables (all *P* values >.05), including sex distribution (χ^2_1 =0.107, *P*=.74, Cramér *V*=0.052; Table 1). Considering psychological variables, MS groups showed higher depressive symptoms compared to HIs (*P*<.001, *r*=0.70). This finding is consistent with evidence showing a higher prevalence of mood disturbances in people with MS compared to the healthy population [46]. No other differences have been observed between groups (all *P* values >.05). See Table 1 for a detailed summary of descriptive analysis of both groups considering demographic and psychological variables and Table 2 for clinical and disease-related information from people with MS.

Results on UX, Usability, and Human-Robot Interaction

Table 3 shows a detailed summary of results from Mann-Whitney *U* tests. The average SUS score exceeded the standard cut-off of 68 and was comparable in both groups (MS: mean 81.00, SD 12.31; HI: mean 77.75, SE 2.51, r=0.14; P=.39), indicating that participants reported a highly positive experience with Pepper.

[b]SUS: System Usability Scale.

[c]GAToRS *P*+: General Attitudes Towards Robots Scale—Personal Positive subscale.

[d]GAToRS P–: General Attitudes Towards Robots Scale—Personal Negative subscale.

[e]GAToRS S+: General Attitudes Towards Robots Scale—Social Positive subscale.

[f]GAToRS S–: General Attitudes Towards Robots Scale—Social Negative subscale.

[g]NASA-TLX: National Aeronautics and Space Administration Task Load Index.

[h]Godspeed (Anthropomorphism).

[i]Godspeed (Animacy).

[j] Godspeed (Likeability).

[k]Godspeed (Perceived Intelligence).

[l]Godspeed (Perceived Safety).

As shown by the score obtained at GAToRS S– (General Attitudes Towards Robots Scale—Social Negative subscale), people with MS perceived the introduction of robots into daily life at a community level with greater apprehension than HIs, with more focusing on the potential risks that SAR could pose at a societal level (MS: mean 25.90, SD 6.95; HI: mean 21.20, SD 5.5, r=0.36; P=.02).

Considering the mental and physical workload measured by the NASA-TLX, no differences were found between the groups (all P values >.05), suggesting that the proposed tasks were feasible and not excessively demanding. On the Godspeed scale, differences in ANTR and INT subscales were found. People with MS tended to perceive the robot as more anthropomorphic (natural, human-like, realistic, and fluid) than HIs (MS: mean 3.10, SD 0.79; HI: mean 2.38, SD 0.79, r=0.42; P=.007). Additionally, the INT subdomain differed between the groups (MS: mean 4.16, SD 0.69; HI: mean 3.49, SD 0.93, r=0.37; P=.02), suggesting that people with MS considered Pepper to be more competent, well-educated, responsible, and judicious. The results of Spearman correlation analyses between ANTR, INT, and psychological and clinical variables showed that ANTR was strongly associated with visuospatial memory (DIGICOG-MS: ρ=–0.632, 95% CI –0.84 to –0.26; P=.003), relatively strong with both verbal memory (DIGICOG-MS: ρ=–0.504, 95% CI [–0.77 to –0.08]; P=.02), and moderate with Agreeableness (I-TIPI: ρ=0.491, 95% CI 0.06-0.77; P=.03). Besides the correlation between ANTR and INT (ρ=0.645, P=.002, 95% CI 0.29-0.85), no other meaningful associations were observed (Ps>.05). See Table S1 in Multimedia Appendix 1 for the full results of the correlation analyses.

The first exploratory stepwise multiple linear regression on psychological factors was conducted to predict SUS scores. Conscientiousness (I-TIPI), negative personal attitudes toward robots (General Attitudes Towards Robots Scale—Personal Negative subscale [GAToRS P–]), and perceived upper-limb difficulty (AMSQ) explained 64% of the variance in usability (R^2=0.637, adjusted R^2=0.568; $F_{3,16}$=9.342; P=.001). As shown in Table 4, higher conscientiousness was associated with greater perceived usability, whereas lower negative personal attitudes toward robots correlated with higher perceived usability—a finding consistent with prior literature suggesting that people with more open and positive dispositions toward technology tend to rate it as more usable and accessible. In addition, people with MS with higher perceived difficulties in upper-limb function reported greater usability. The second exploratory stepwise multiple linear regression on technological/robotic factors revealed that the final model with task-related frustration from NASA-TLX was retained as the sole predictor. Higher frustration was associated with lower perceived usability (B=−1.497, 95% CI −2.276 to −0.719, SE 0.367, β=−.693; t_{1} =−4.077; P=.001). The model was significant ($F_{1,1}$ =16.620; P=.001) and explained 48% of the variance in SUS scores (R^2=0.480, adjusted R^2=0.451), suggesting that, among people with MS, lower levels of task-related frustration were associated with higher perceived usability of the robot. Visual inspection of P-P plots and residual scatterplots supported the assumptions of normality and homoscedasticity in both models.

XSL•FO
RenderX

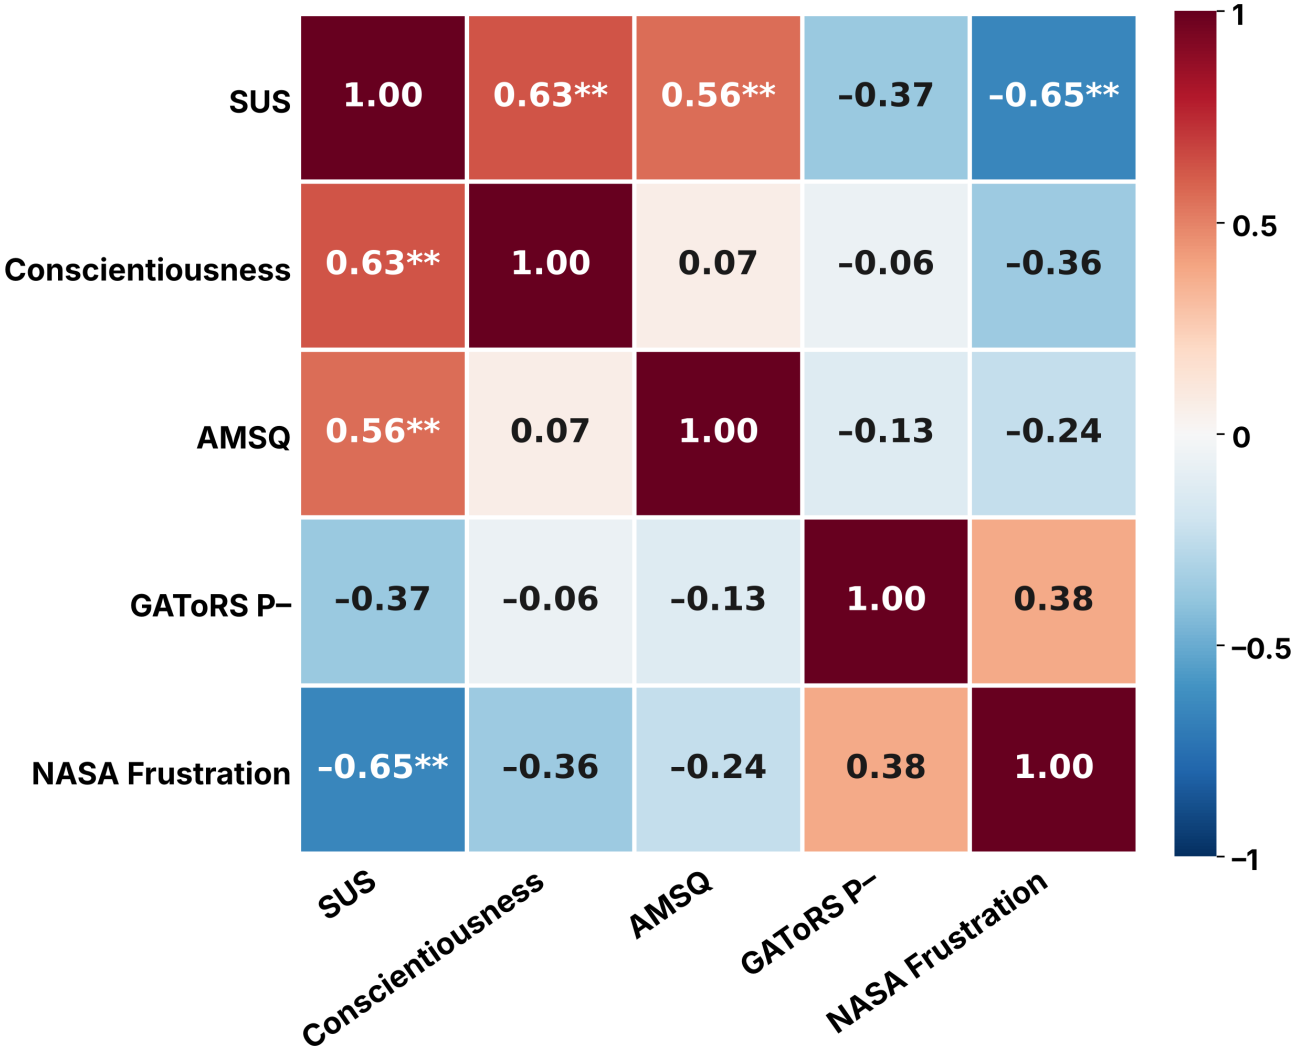
Influential-case diagnostics were conducted for both regression models using Cook distance, with a threshold of 4/N=0.20. In the first model, 9 cases exceeded this threshold (Cook *D* range: 0.00 - 0.72, mean 0.126, SD 0.196), and in the second model, 2 cases exceeded the threshold (Cook *D* range: 0.00 - 0.365), confirming that both models should be interpreted with caution given the sensitivity to individual observations inherent in small samples. No multicollinearity was detected (model 1: VIF range 1.005 - 1.022, tolerance range 0.979 - 0.995; Model 2: VIF=1.000, tolerance=1.000). See Figure 3 for the heatmap of Spearman coefficients from regression analyses.

Table . Results of the first exploratory forward stepwise linear regression model predicting System Usability Scale (SUS) in people with multiple sclerosis (MS)[a].

Predictors	B[b] (95% CI)	SE	ß	*t* test (*df*)	*P* value
I-TIPI[c]-Conscientiousness	2.064 (0.679 to 3.449)	0.653	0.481	3.159 (16)	.006
AMSQ[d]	0.169 (0.033 to 0.306)	0.064	0.398	2.631 (16)	.02
GAToRS P–[e]	–0.937 (–1.694 to –0.180)	0.357	–0.400	–2.625 (16)	.02

[a]The final model included Conscientiousness (I-TIPI), negative personal attitudes toward robots (GAToRS P–), and perceived upper-limb difficulty (AMSQ) as predictors. *P* values and effect sizes with 95% CIs are reported for each comparison. R^2=0.637, adjusted R^2=0.568, $F_{3,16}$=9.342; *P*=.001.

[b]Nonstandardized coefficient.



[c]I-TIPI: Italian Ten-Item Personality Inventory.

[d]AMSQ: Arm Function in Multiple Sclerosis.

[e]GAToRS P–: General Attitudes Towards Robots Scale—Personal Negative subscale.

XSL•FO
RenderX

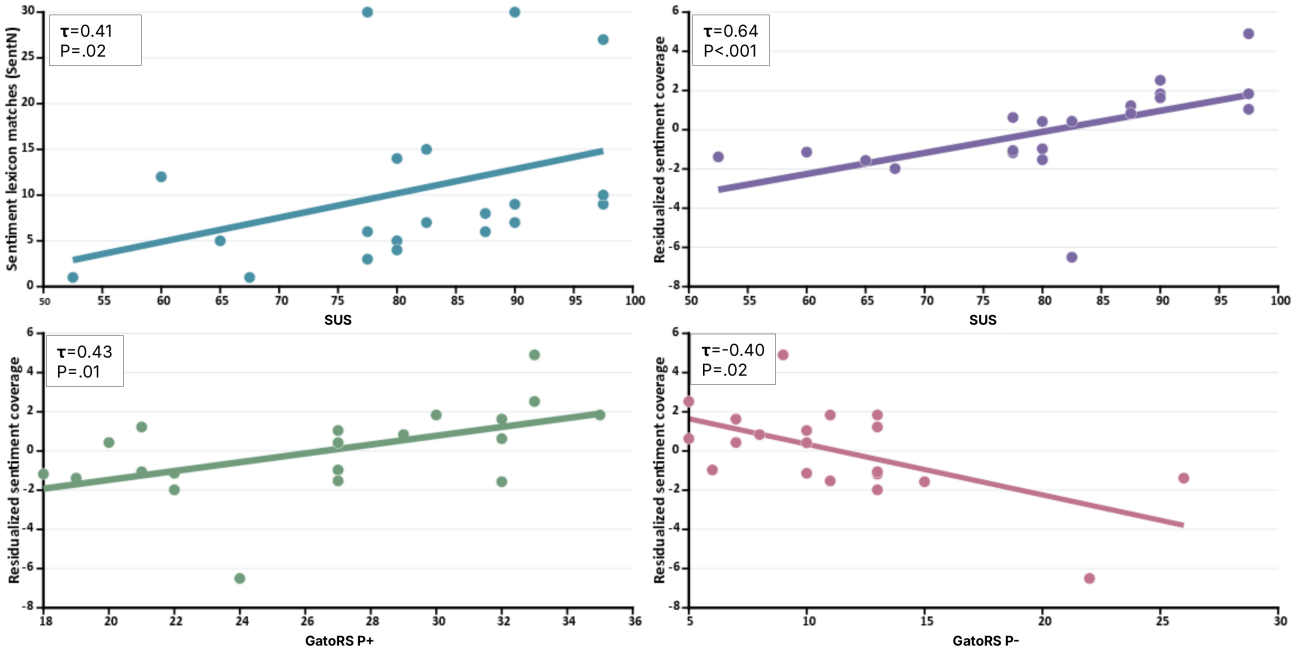


Figure 3. Heatmap showing Spearman correlation coefficients between meaningful predictors and System Usability Scale (SUS) scores from exploratory forward regression analyses. Color intensity represents the strength of the correlation, with darker colors indicating stronger correlations. *P* value is reported for each comparison. Positive correlations (ρ>0) are shown in red, and negative correlations (ρ<0) are shown in blue. **P<.01. AMSQ: Arm Function in Multiple Sclerosis Questionnaire; GAToRS P–: General Attitudes Towards Robots Scale—Personal Negative subscale; NASA: National Aeronautics and Space Administration.

From the exploratory NLP analysis, no meaningful differences emerged between people with MS and HIs in the extracted linguistic features (all *P* values >.05), including lexical productivity and sentiment-lexicon coverage. Within the MS group, exploratory analyses revealed meaningful associations between evaluative lexical content and psychological and user-experience measures. The number of sentiment-lexicon matches (SentN) was positively associated with SUS (τ=0.411; *P*=.02). After controlling for response length, residualized sentiment-lexicon coverage was positively associated with usability (τ=0.642; *P*<.001). This association was stable to case deletion: leave-one-participant-out Kendall's τ values ranged from 0.592 to 0.669, while leave-two-participants-out values ranged from 0.515 to 0.715, indicating that the association was not attributable to any single participant or pair of participants. Residualized sentiment-lexicon coverage was also positively associated with GAToRS P+ (General Attitudes Towards Robots Scale—Personal Positive subscale) (τ=0.431; *P*=.01) and negatively associated with GAToRS P– (τ=–0.403; *P*=.02; Figure 4).

XSL•FO
RenderX

Figure 4. Natural language processing (NLP) associations with attitudes toward robots and perceived usability in people with multiple sclerosis. Sentiment lexicon matches and residualized sentiment coverage are reported on the *y*-axes, whereas System Usability Scale (SUS), GAToRS P+, and GAToRS P– are reported on the *x*-axes. GAToRS P–: General Attitudes Towards Robots Scale—Personal Negative subscale; GAToRS S–: General Attitudes Towards Robots Scale—Societal Negative subscale.

Discussion

Although SAR has shown promising results in supporting everyday life, providing interaction, and facilitating cognitive and physical training in neurological and older populations, its application in MS remains largely unexplored. Our findings bridge this gap, demonstrating that Pepper was perceived as highly usable not only by HIs but also, and notably, by people with MS, a population often characterized by significant motor, cognitive, and psychological challenges. Critically, SUS scores in both groups consistently exceeded the standard cut-off of 68, and the absence of between-group differences indicates that, at least in this pilot study, MS-related challenges may not substantially hinder human-robot interaction. These preliminary findings indicate that Pepper was perceived as usable, even in the presence of MS-related challenges, and support the rationale for further investigation of SAR in MS rehabilitation contexts. These results align with Technology Acceptance Model (TAM) [47] and Unified Theory of Acceptance and Use of Technology (UTAUT) [48], 2 of the most widely used frameworks to understand why people adopt or reject new technologies, in which perceived ease of use and low effort are considered key drivers of acceptance. The high SUS scores and the absence of workload differences observed in both groups suggest that Pepper met these basic requirements, laying a favorable ground for its integration in clinical settings. Despite this high technical evaluation, meaningful differences emerged regarding social integration. People with MS expressed more cautious attitudes toward the introduction of robots in daily life, as measured by GAToRS S–, suggesting that while the robot's functional usability is well accepted, people with MS could have greater concerns about the broader social and practical implications of SAR. This finding is consistent with studies reporting that negative attitudes and avoidance tendencies toward robots may hinder their acceptance across various societal contexts [49] and resonates with the Social Influence construct in UTAUT, which highlights how perceived community norms and collective attitudes can affect individual acceptance of new technologies. Addressing these broader social narratives around robots in health care will therefore be essential to support long-term adoption [44]. To favor a smooth introduction of SAR into human lives, it is essential to explore effective strategies targeting the reduction in negative attitudes toward robots or the fear of potential harm from their extensive use, highlighting the importance of addressing trust, transparency, and perceived risks when introducing such technologies in clinical settings.

The absence of between-groups differences in mental and physical workload, as measured by NASA-TLX, indicates that the tasks were generally manageable for both people with MS and healthy controls. This aligns with TAM and UTAUT constructs, especially with the principle that good usability relies on systems that are intuitive and efficient, minimizing the learning curve and reducing potential user frustration [50]. Surprisingly, people with MS tended to perceive the robot as more human-like (anthropomorphic) and intelligent compared to HIs, as reflected in the ANTR and INT subscales of the Godspeed questionnaire, respectively. ANTR was further associated with cognitive abilities and personality traits. Participants with lower visuospatial and verbal memory scores perceived the robot as more human-like. This pattern could be interpreted in 2 ways. First, as posited by Epley [51], anthropomorphism, as the process of attributing human-like qualities and characteristics to nonhuman agents and objects [52], may function as a cognitive compensatory strategy for individuals facing reduced processing resources [51]. Under this framework, individuals with reduced cognitive capacities may rely more heavily on heuristic social attributions, perceiving

XSL•FO
RenderX

the robot as more human-like to simplify the understanding of its behavior. Second, the positive correlation between ANTR and Agreeableness from I-TIPI suggests a dispositional influence. Consistent with Epley et al [53], individual differences in anthropomorphizing nonhuman agents are often rooted in stable prosocial traits and sociality motivation—the fundamental human drive for interpersonal connection. Consequently, those who self-identify as kind, sympathetic, and cooperative may be more naturally inclined to extend these social categories to robotic partners. The finding that people with MS attributed higher levels of anthropomorphism and perceived intelligence to Pepper compared to HIs may be interpreted considering the heightened social needs commonly reported in this population. People with MS experience higher rates of social isolation and loneliness than healthy adults [16]. Building on social identity theory and research on human-robot interaction, it may be speculated that for individuals who perceive themselves as belonging to a socially marginalized group, such as people living with a chronic condition like MS, anthropomorphism may not merely humanize the robot, but symbolically reposition it as an ingroup partner, potentially attenuating intergroup boundaries between human and artificial agents [49,50]. While speculative, this interpretation is consistent with evidence that social needs and group membership influence the attribution of human-like qualities to nonhuman agents [53]. Understanding these psychological factors is crucial for tailoring interventions, improving user engagement, and optimizing the effectiveness of robot-assisted in MS.

Exploratory multiple linear regression analyses revealed that Conscientiousness (I-TIPI), personal negative attitudes toward robots (GAToRS P–), and upper-limb difficulties (AMSQ) were associated with perceived usability. Specifically, higher levels of Conscientiousness and less negative personal predispositions toward robots were associated with enhanced usability ratings. These findings also resonate with TAM and UTAUT constructs. Conscientiousness, which reflects a tendency toward goal-directed and organized behavior, may foster a more positive performance expectancy, another key driver of technology acceptance according to UTAUT. Similarly, negative personal attitudes toward robots closely mirror the concept of Behavioral Intention in TAM—that is, the degree to which an individual is predisposed toward a technology influences how they ultimately experience it. Furthermore, increased perceived difficulty in upper-limb function positively predicted usability. This suggests that individuals facing greater motor limitations may perceive assistive technologies as more indispensable, leading to a more favorable evaluation of the social robot's use. This finding aligns with prior research indicating that participants with significant challenges in activities of daily living express a stronger preference for robotic support [54]. Finally, lower task-related frustration, as measured by the NASA-TLX, was associated with higher usability, suggesting that people with MS who experienced the interaction as less frustrating tended to evaluate the robot more favorably.

Overall, these findings highlight that human-robot interaction in MS is not uniform; psychological, prior attitudes, and functional abilities which jointly influence how people with MS perceive and interact with social robots should be considered when developing personalized rehabilitation approaches. Understanding these factors is crucial for tailoring interventions, improving user engagement, and optimizing the effectiveness of robot-assisted rehabilitation in MS. Exploratory NLP analyses revealed no between-group differences in the lexical measures examined. Within the MS group, however, associations emerged between evaluative lexical content and UX measures: participants whose written responses contained a higher density of sentiment-lexicon matches relative to response length tended to report higher usability scores and more favorable attitudes toward robots. These findings suggest that free-text language may provide information complementary to structured UX measures, although this interpretation should remain cautious given the exploratory nature of the analysis, the small sample, and the brevity of the written responses. In particular, sentiment-lexicon coverage reflects evaluative lexical density rather than positive emotional valence and should not be interpreted as evidence of a positive emotional tone. Future work using longer spoken or written responses may help determine whether linguistic signals can provide reliable complementary indicators of user experience in clinical populations. Such studies could also investigate whether richer language measures may contribute to the development of more responsive and user-centered human-robot interactions and may help clarify the role of linguistic signals as complementary indicators of UX in clinical populations. The results from NLP are further in line with key recommendations in the literature about the importance of implementing empathy-driven design in SAR, particularly ensuring that social robots can recognize and respond to human emotions through language and behavior, as discussed by Park and Whang [55]. SAR must move beyond basic functionality to provide meaningful and personalized interactions. This is confirmed by studies in autism spectrum disorders, dementia, and psychiatric disorders that emphasized that the effectiveness of SAR is linked to its ability to adapt to users' specific needs and behavioral cues.

To our knowledge, this study represents the first preliminary exploration into the usability of social robots specifically within the MS population. By identifying the multifaceted predictors of perceived usability, spanning cognitive, personality, and clinical domains, this work marks a foundational step in understanding how these individuals perceive and evaluate SAR. These insights are instrumental for the design of tailored, ethically grounded, and user-accepted interventions, ensuring that robot-assisted rehabilitation is optimized for the unique needs of those living with MS. SAR can offer real-time feedback, maintain patient engagement, and reduce the need for continuous human supervision, thereby improving the scalability and efficiency of rehabilitation programs [13,56]. In principle, given the observed high appreciation toward robots, SAR could be strategically used in MS care as motivational agents, real-time feedback providers, or digital companions that help sustain adherence and engagement. From a rehabilitation perspective, these preliminary findings provide an initial indication that social robots may warrant further exploration as complementary tools in MS rehabilitation, though firm conclusions about their role and implementation require replication in larger and more representative samples.

XSL•FO
RenderX

Addressing concerns identified by GAToRS, including perceived social risks and apprehension toward robotic integration, will be essential to foster acceptance and long-term adoption of social robots in rehabilitation contexts.

Several limitations should be acknowledged. In the absence of prior studies about the use of SAR in the MS population, no formal sample size calculation was available to conduct a formal a priori power analysis. The limited sample size, while consistent with pilot SAR studies in neurological and older populations [39,40], may reduce the statistical power to detect small effects, limiting the generalizability of the findings and precluding causal interpretations. Future studies should replicate these findings in larger samples to confirm and extend the present results. Additionally, the study focused on a limited set of tasks, and the robot did not capture other potentially informative measures of human interaction, such as gaze, number of touches, or facial expressions, due to privacy considerations. This issue is in line with Song and Luximon [56] that discussed that ethical considerations around privacy and consent in the context of human-robot interaction should be carefully managed to ensure these technologies are used responsibly and effectively. As SAR becomes more advanced, understanding how they can be seamlessly integrated into clinical workflows is crucial.

The NLP approach was selected to provide a transparent and replicable method for extracting evaluative features from a small corpus, with the explicit aim of capturing dimensions of UX not fully covered by structured questionnaires. Given the limited number of participants and the brevity of the written answers, a full qualitative content analysis was beyond the scope of the present work. Moreover, NLP results may have been influenced by response modalities: recording oral responses could have facilitated participants' performance while reducing fatigue, particularly among people with MS. The absence of between-group differences may also reflect the limited sensitivity of lexical metrics when applied to very short texts. Future studies with larger samples and richer verbal or written data should consider complementing NLP approaches with systematic qualitative or content analysis methods to provide a more comprehensive picture of participants' subjective experience with social robots. In this study, verbal interaction between Pepper and participants was limited and restricted to instructions. However, as indicated by [57], even minimal speech is generally well received, suggesting that the mere presence of verbal communication can enhance engagement.

Acknowledgments

The authors would like to thank Maria Madera for her help in participants' enrollment and Simone Boccardo for his support in data acquisition. Finally, special thanks go to all the people with multiple sclerosis that took part in the study.

During the preparation of this manuscript, the authors used ChatGPT (OpenAI) and Claude (Anthropic) to ensure linguistic accuracy and readability. Figure 2 was generated with the assistance of Gemini (Google). After using these tools, the authors reviewed and edited the content as needed and take full responsibility for the content of the manuscript.

Funding

Abstract

Background: Improving exercise self-efficacy (ESE) is a key strategy for promoting sustained physical activity among older adults with frailty. The lumbar-type Hybrid Assistive Limb (HAL), a wearable device that supports voluntary movement through bioelectric signals, may facilitate mastery experiences in individuals with low baseline self-efficacy via adjustable assistance. However, its effects on ESE remain unclear.

Objective: This study evaluated the effects of lumbar-type HAL exercise on ESE in older adults with frailty and examined whether responsiveness differed according to baseline readiness for exercise.

Methods: A retrospective pooled analysis was conducted using data from 2 prospective studies of a lumbar-type HAL–based frailty prevention program: a feasibility study (n=20) and a randomized controlled trial (RCT; n=76; lumbar-type HAL group: n=38; waitlist control: n=38). Participants aged 50 to 84 years performed sit-to-stand and squat exercises using the lumbar-type HAL twice weekly. ESE was assessed using a validated 4-item questionnaire (range 4‐20). The prespecified primary analysis examined within-person changes in ESE in the lumbar-type HAL group (2-tailed paired *t* test; n=96). A secondary analysis compared changes in ESE between the lumbar-type HAL and waitlist control groups in the RCT using the Welch *t* test and baseline-adjusted analysis of covariance. A prespecified subgroup analysis compared participants in stages 1 to 4 of the transtheoretical model of behavior change (exercise habit not established) with those in stage 5 (maintenance). All statistical tests were 2 sided, with significance at $P<.05$.

Results: The primary pooled paired analysis demonstrated a significant increase in ESE of 1.05 points (95% CI 0.41-1.69; $P=.002$). The subgroup analysis was also significant: those in stages 1 to 4 (n=56) improved by 1.73 points vs 0.05 points for those in stage 5 (n=38), a difference of 1.68 points (95% CI 0.41-2.95; $P=.01$). The largest within-group improvement was observed in stage 1 (precontemplation: +3.50 points, 95% CI 0.27-6.73; $P=.04$; Cohen $d=1.14$); 4 of 6 participants improved and none deteriorated. In the secondary RCT between-group comparison, the lumbar-type HAL group showed a directionally favorable improvement (between-group difference=1.21 points, 95% CI −0.33 to 2.75; $P=.12$; Cohen $d=0.36$). The subgroup differences were 2.10 points in stages 1 to 4 ($P=.07$; Cohen $d=0.58$) and 0.02 points in stage 5 ($P=.99$). Sensitivity analyses confirmed robustness to source-related heterogeneity (heterogeneity test: $P=.74$; source-adjusted regression: $P=.76$).

Conclusions: The pooled analysis demonstrated significant within-person improvement in ESE among older adults with frailty following lumbar-type HAL training, with the greatest improvement in individuals without established exercise habits. The RCT indicated a favorable but inconclusive between-group effect, and adequately powered confirmatory RCTs remain necessary. The

XSL•FO
RenderX

exploratory response among precontemplators—typically difficult to engage in interventions—suggests that HAL-supported mastery experiences may support disengaged older adults at high risk of frailty in starting physical exercise.

Introduction

Frailty and Exercise Self-Efficacy in Older Adults

Frailty is a common clinical syndrome in older adults and is associated with increased risk of hospitalization, falls, and disability, highlighting the need for targeted interventions [1,2]. Exercise self-efficacy (ESE), a psychological construct linked to frailty [3], reflects confidence in maintaining exercise despite barriers [4]. Lower ESE is associated with reduced physical activity (PA) [3], supporting its relevance as an outcome in exercise interventions. According to the social cognitive theory by Bandura [5], self-efficacy is shaped by mastery experiences, vicarious experiences, verbal persuasion, and physiological and affective states, with mastery experiences being most influential [5,6]. Mastery experiences involve successful performance in challenging tasks. In rehabilitation, task difficulty is adjusted to enable success, supporting motor learning and improving efficiency [7]. Thus, appropriate task adjustment may facilitate mastery experiences and enhance ESE.

Challenge of Reaching Disengaged Older Adults

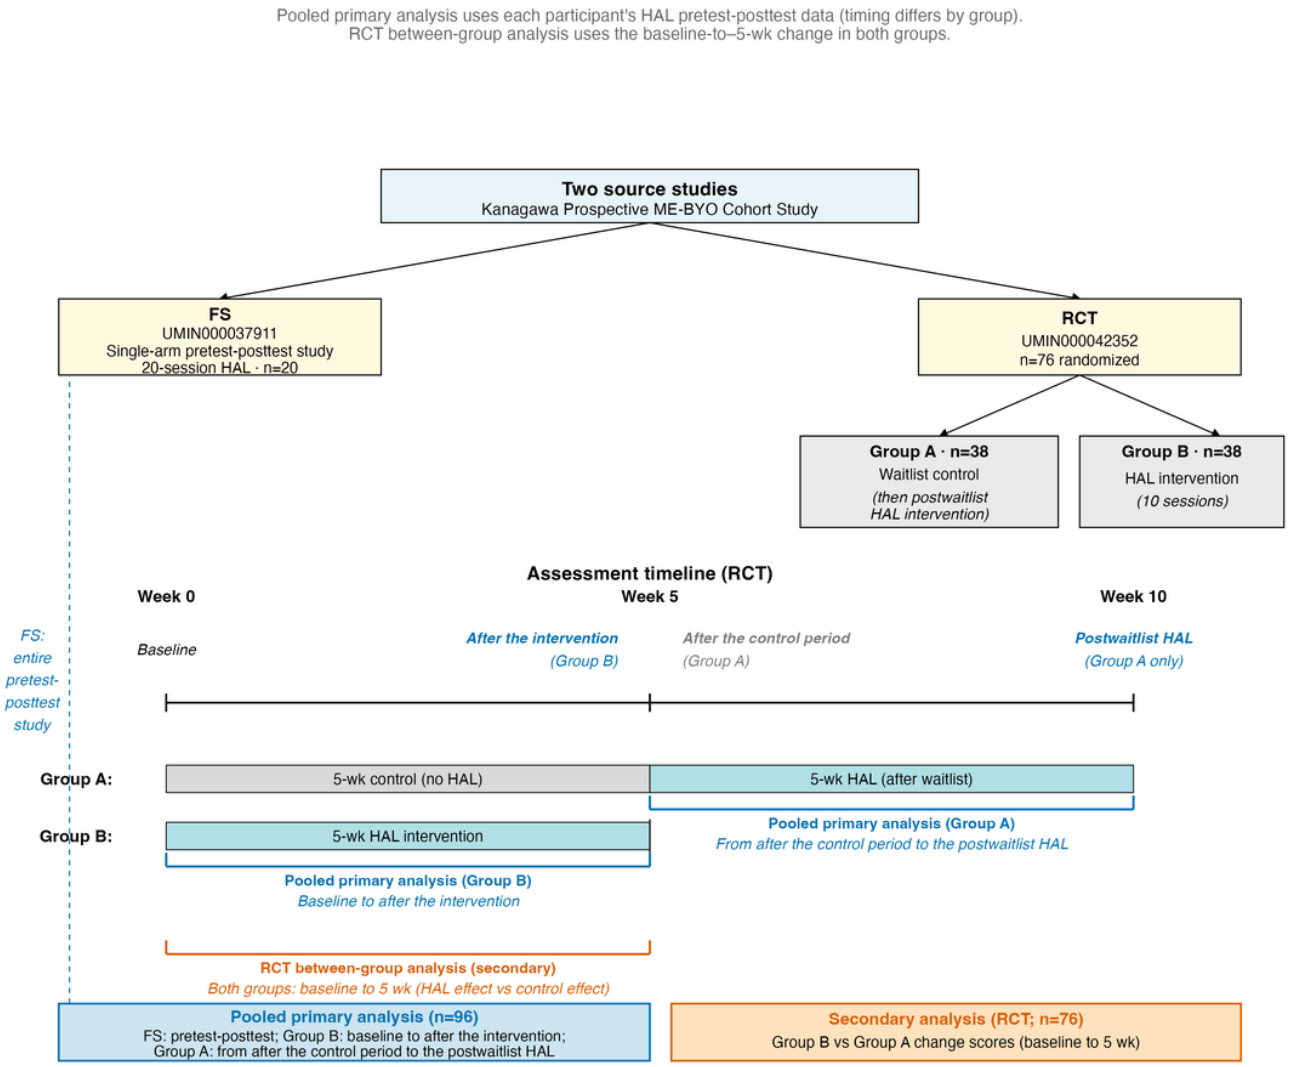
Behavioral readiness for exercise, as defined by the transtheoretical model (TTM) of behavior change, is a key determinant of intervention responsiveness [8]. Older adults in precontemplation (stage 1)—who have no intention of initiating exercise—are typically difficult to engage in conventional exercise programs and rarely accumulate mastery experiences. Although exercise interventions can improve physical function and frailty status in older adults [9], systematic reviews of TTM-based interventions report limited and inconsistent evidence for promoting PA in this population [10]. Therefore, how intervention responsiveness varies by baseline behavioral readiness remains poorly understood.

Lumbar-Type Hybrid Assistive Limb and Mastery Experience

The Hybrid Assistive Limb (HAL; Cyberdyne Inc) is a wearable cyborg that supports movement in response to voluntary intent [11,12]. It uses skin-mounted sensors to detect bioelectric signals associated with movement intention and converts these signals into motor torque assistance. Unlike conventional exoskeletons that rely primarily on preprogrammed motion patterns, the HAL generates assistance directly in response to the wearer's voluntary activity [13]. Clinical studies have shown that a lower limb–type HAL improves walking ability in patients with stroke and spinal cord injury [13-17]. The lumbar-type HAL consists of an exoskeleton frame and a power unit comprising angle sensors and actuators for both hip joints. It assists hip extension during transitions from flexion to extension, supporting standing and lifting movements. Compared with the lower limb type, it is lighter and more compact, enabling its use in settings such as home-based training and group exercise programs in long-term care. Previous studies in frail populations have reported improvements in walking speed and stride length [18], although evidence in older adults with frailty remains limited. By providing consistent, scaffolded assistance, the lumbar-type HAL may facilitate mastery experiences—particularly in individuals with low baseline self-efficacy—thereby enhancing ESE. However, its effect on ESE has not yet been examined.

Study Aim and Hypotheses

This study aimed to evaluate the effects of a lumbar-type HAL exercise program on ESE in older adults with frailty: (1) lumbar-type HAL training was hypothesized to improve ESE in this population, and (2) the magnitude of improvement was hypothesized to vary by baseline TTM stage, with the greatest gains expected among participants who had not yet established a regular exercise habit (stages 1 - 4) compared with those in the maintenance stage (stage 5).



Methods

Study Design and Data Source

This study used a retrospective secondary analysis of pooled outcome data derived from 2 prospective studies of a lumbar-type HAL–based care prevention program (see Figure 1 for the participant flow). The source studies were a feasibility study (FS; UMIN000037911) and a randomized controlled trial (RCT; UMIN000042352) based on the Kanagawa Prospective ME-BYO Cohort Study entitled "Research on the development of a nursing care prevention program using healthcare robots" [19]. Data from both the FS and the RCT were pooled to evaluate the effect of a lumbar-type HAL exercise program on ESE.

XSL•FO
RenderX

Figure 1. Participant flow and analytic use of assessment time points. FS: feasibility study; HAL: Hybrid Assistive Limb; RCT: randomized controlled trial.

The FS aimed to evaluate the feasibility and effectiveness of a care prevention program using the lumbar-type HAL. The primary end point comprised program completion rate. Participants aged below 85 years who met at least one of the frailty criteria based on the Japanese version of the Cardiovascular Health Study, including weight loss, fatigue, reduced PA level, decreased grip strength, and slow walking speed, were included in the analysis. The intervention consisted of lumbar-type HAL training delivered twice weekly for 90 minutes per session over 20 sessions. Ultimately, 20 participants completed the program.

The RCT evaluated the effectiveness of lumbar-type HAL training for care prevention, with normal walking speed as the primary end point. A randomized, single-blind, parallel-group design was used, with participants randomly assigned to either the intervention group or a waitlist control group. Individuals aged 65 to 85 years with a score of 6 or higher on the 5-question Geriatric Locomotive Function Scale, a normal walking speed of less than 1.0 m/s (eligibility based on either the Geriatric Locomotive Function Scale or walking speed criteria), and no certification for long-term care were analyzed. The intervention group received lumbar-type HAL training twice weekly for 90 minutes per session over 10 sessions, whereas the waitlist control group received no intervention during the 5-week period [19]. Ultimately, 77 participants completed the study.

Intervention: Exercise Program Using Lumbar-Type HAL

In both the FS and the RCT, lumbar-type HAL training was conducted primarily in cybernic voluntary control mode, in which assistive torque supporting hip extension during standing and lifting tasks was generated in response to bioelectric signals detected by skin surface sensors placed over the erector spinae muscles. Assistance levels were individually adjusted according to each participant's functional capability to ensure appropriate support during training. The program included repetitive exercises such as sit-to-stand movements and squats.

Assessment Measures

Assessment measures included ESE, the 10-m walk test (10MWT), the timed up and go (TUG) test, amount of PA, TTM stage of behavior change [8], and a self-administered questionnaire. ESE was assessed using a 4-item questionnaire developed by Oka [4] evaluating confidence in exercising when slightly tired, unmotivated, busy, or under unfavorable weather conditions. Responses were rated on a 5-point Likert scale (1=not at all confident; 5=very confident), with higher scores

XSL•FO
RenderX

indicating greater ESE. In the 10MWT, participants walked at a usual pace along a 10-m walkway, and walking speed (m/s) was calculated using stopwatch timing. The TUG test measured the time required to rise from a chair, walk 3 m, turn, return, and sit. PA was assessed using 2 items: weekly exercise frequency (5 - 7 days, 3 - 4 days, 1 - 2 days, or none) and daily exercise duration. Average daily duration was estimated by multiplying frequency (coded as 6, 3.5, 1.5, and 0 days per week) by duration per day and dividing by 7 [20]. TTM stage was rated on a 5-point scale: stage 1 (precontemplation: no intention to perform PA), stage 2 (contemplation: planning to start soon), stage 3 (preparation: performing activity once a week), stage 4 (action: regular activity for <6 months), and stage 5 (maintenance: regular activity for ≥6 months). Regular PA was defined as engaging in PA for 60 minutes per day or more (≥40 minutes for individuals aged ≥65 years) even at low intensity. The self-administered questionnaire was structured as an interview to capture participants' subjective perceptions of changes after program completion. Data from both studies were pooled for analysis, with ESE as the primary end point and the 10MWT, the TUG test, PA, and questionnaire responses as secondary end points.

Sample Size Calculation

Sample size calculation was based on ESE data from the FS (mean change 1.25, SD 2.88 points; paired Cohen *d*=0.43) [21]. For the primary pooled within-person analysis, 44 participants were required to achieve 80% power with a 2-sided α of .05; the achieved sample size (n=96) exceeded this requirement. For the secondary RCT between-group comparison, 172 participants (86 per group) were required; the achieved sample size (n=76) was below this threshold, resulting in limited statistical power (post hoc: 30% - 34% at a 2-sided α=.05).

Statistical Analysis

Overview

Descriptive data were expressed as means and SDs for continuous variables and numbers and percentages for categorical variables. The 95% CIs were reported for all primary effect estimates. All statistical tests were 2 sided, with a significance threshold of .05. Statistical analyses were performed using the R software (version 4.2.2; R Foundation for Statistical Computing). One participant with incomplete primary outcome data was excluded from the analysis.

Primary Analysis

The primary analysis comprised a within-person pretest-posttest comparison of ESE among all lumbar-type HAL recipients (n=96) pooled from the FS and the RCT (the RCT intervention group plus the waitlist control group after completion of the lumbar-type HAL exercise program) using a paired *t* test. In the RCT, ESE was assessed at baseline (week 0), after the intervention (week 5), and—for the waitlist control group only—after the subsequent 5-week lumbar-type HAL program (postwaitlist HAL; week 10). For the pooled primary analysis, each participant contributed a pretest-posttest comparison corresponding to lumbar-type HAL exposure: from baseline to week 5 for the intervention group (group B) and from after the control period to after the intervention for the waitlist group (group A; Figure 1). The waitlist group received lumbar-type HAL training after the control period for ethical reasons in accordance with the registered protocol (UMIN000042352) [19]. This pooled pretest-posttest comparison constituted the primary inferential analysis specified in the study design, which was powered to detect changes in ESE, an outcome not individually powered in either source study. Paired *t* tests were also applied to the 10MWT, TUG, and PA outcomes.

Subgroup Analyses

An a priori dichotomous subgroup comparison was specified prior to pooled data analysis based on TTM theory [8] and findings from the FS. The comparison contrasted stages 1 to 4 (precontemplation, contemplation, preparation, and action; no established exercise habit) vs stage 5 (maintenance; regular exercise for ≥6 months). This contrast was not included in the original University Hospital Medical Information Network Clinical Trials Registry protocols (UMIN000037911 and UMIN000042352) as those preceded the development of the pooled analysis plan; however, specification occurred prior to data integration from the 2 source studies. The empirical rationale was derived from the FS, in which participants in lower-readiness stages (n=10) demonstrated a mean ESE increase of 2.5 points compared with 0 points in higher-readiness participants (n=10; *P*=.052) [21]. The theoretical basis aligns with the social cognitive theory by Bandura [5], which predicts stronger mastery-related effects among individuals with lower baseline self-efficacy, and with the TTM framework, in which stage 5 reflects a maintenance phase associated with attenuated intervention effects due to ceiling effects. Within-stratum changes in the pooled dataset were analyzed using paired *t* tests, and between-stratum differences in change scores were assessed using the Welch *t* test. ESE changes were also described across all 5 TTM stages; given the small sample sizes within some stages, these analyses were considered exploratory.

Secondary Analysis (RCT; Between Groups)

The randomized design of the RCT (n=76) was used as a secondary analysis to compare ESE change over the same 5-week period between the lumbar-type HAL group (n=38) and the waitlist control group (n=38). Between-group differences in change scores were assessed using the Welch *t* test. Results were further confirmed using analysis of covariance, with postintervention ESE as the dependent variable, group as the fixed factor, and baseline ESE as a covariate. The Cohen *d* was calculated as a standardized effect size. The prespecified TTM dichotomy was also examined within this between-group framework.

Sensitivity Analyses for the Pooled Estimate

Robustness of the pooled estimate was evaluated against potential heterogeneity between the source studies (FS: 20 sessions, single arm; RCT: 10 sessions with a waitlist control group) using three prespecified sensitivity analyses within a fixed-effects framework: (1) source-stratified paired *t* tests performed separately within each study, (2) source-adjusted linear regression including a binary study indicator (FS=1; RCT=0), and (3) a between-study heterogeneity assessment

XSL•FO
RenderX

using the Welch *t* test on change scores comparing FS and RCT participants.

Ethical Considerations

Both source studies were approved by the Research Ethics Review Committee of the Graduate School of Health Innovation, Kanagawa University of Human Services (FS: approval number 20019-36-004; RCT: approval number Hodai 30-008). Written informed consent was obtained from all participants, including permission for secondary analyses of deidentified data. The present pooled analysis was reviewed by the same committee and deemed exempt from full ethics review (review notification number SHI 62) as it used existing deidentified data. This study was conducted in accordance with the Declaration of Helsinki.

Results

Participant Characteristics

ESE data were available for 99% (96/97) of the participants who completed either the FS or RCT programs. Participants' age ranged from 50 to 84 years. Baseline characteristics of these participants are shown in Table 1.

Table . Participant characteristics (n=96)[a].

Characteristics	Participants, n (%)
Age (y)	
50 - 59	4 (4.2)
60 - 69	10 (10.4)
70 - 79	66 (68.8)
80 - 84	16 (16.7)
Sex (n=95)	
Male	28 (29.5)
Female	67 (70.5)
Source study	
FS[b]	20 (20.8)
RCT[c]	76 (79.2)
Stage of TTM[d] (n=94)	
Stage 1 (precontemplation)	6 (6.4)
Stage 2 (contemplation)	28 (29.8)
Stage 3 (preparation)	13 (13.8)
Stage 4 (action)	9 (9.6)
Stage 5 (maintenance)	38 (40.4)

[a]Sex was not available for 1% (1/96) of the participants. Transtheoretical model stage data were missing for 2.1% (2/96) of the participants (1 in the postwaitlist group A and 1 in the randomized controlled trial lumbar-type Hybrid Assistive Limb group).

[b]FS: feasibility study.

[c]RCT: randomized controlled trial.

[d]TTM: transtheoretical model.

Pooled Pretest-Posttest Analysis (Primary Analysis)

In the primary pooled within-person analysis of all lumbar-type HAL recipients (n=96), ESE increased significantly by 1.05 points (95% CI 0.41-1.69; *P*=.002) from a baseline mean of 11.94 (SD 3.05) points to 12.99 (SD 3.21) points after the intervention (Table 2). Secondary outcomes also showed significant improvement: 10MWT walking speed increased by 0.37 m/s (95% CI 0.33-0.40; *P*<.001), TUG time decreased by 1.68 seconds (95% CI −2.01 to −1.35; *P*<.001), and PA increased by 18.28 minutes per day (95% CI 12.95-23.62; *P*<.001; Table 2).

XSL•FO
RenderX

Table . Effect of lumbar-type Hybrid Assistive Limb training on primary and secondary outcomes (pooled paired analysis; n=96)[a].

Outcome	Participants, n	Baseline, mean (SD)	After the intervention, mean (SD)	Change, mean (95% CI)	*P* value	Cohen *d*
ESE[b] total score (range 4 - 20)	96	11.94 (3.05)	12.99 (3.21)	+1.05 (+0.41 to +1.69)	.002	0.33
10MWT[c] speed (m/s)	96	0.99 (0.28)	1.36 (0.37)	+0.37 (+0.33 to +0.40)	<.001	—[d]
TUG[e] time (s)	96	10.12 (8.47)	8.45 (7.64)	–1.68 (–2.01 to –1.35)	<.001	—
PA[f] (min per d)	96	30.47 (29.27)	48.75 (33.99)	+18.28 (+12.95 to +23.62)	<.001	—

[a]Exercise self-efficacy is the primary outcome; 10-m walk test speed, timed up and go time, and physical activity are secondary outcomes. Pooled paired analysis (n=96): paired *t* test, 2-sided α=.05. The 10-m walk test speed (m/s) was calculated as 10 m divided by walking time.

[b]ESE: exercise self-efficacy.

[c]10MWT: 10-m walk test.

[d]Cohen *d* is reported only for the primary outcome (ESE).

[e]TUG: timed up and go test.

[f]PA: physical activity.

Sensitivity analyses supported the robustness of the pooled estimate to source-related heterogeneity (Table 3). Source-stratified analyses demonstrated similar improvements (FS: Δ=+1.25 points, *P*=.07, and n=20; RCT lumbar-type HAL group: Δ=+1.00 point, *P*=.009, and n=76). The between-source heterogeneity test was nonsignificant (*P*=.74), and source-adjusted regression produced a comparable estimate (+1.00 point) with a nonsignificant source effect (*P*=.76).

Table . Sensitivity analyses for the pooled estimate of exercise self-efficacy change[a].

Analysis	Participants, n	Point estimate (95% CI)	*P* value
Primary pooled paired analysis	96	+1.05 (+0.41 to +1.69)	.002
Source stratified			
FS[b] only	20	+1.25 (−0.10 to +2.60)	.07
RCT[c] lumbar-type HAL[d] recipients	76	+1.00 (+0.26 to +1.74)	.009
Between-source heterogeneity[e]			
FS − RCT difference	96	+0.25 (−1.26 to +1.76)	.74
Source-adjusted regression[f]			
Pooled estimate (RCT reference)	96	+1.00 (+0.28 to +1.72)	.007
Source coefficient (FS vs RCT)	—[g]	+0.25 (−1.33 to +1.83)	.76

[a]Prespecified sensitivity analyses for the pooled primary estimate. A fixed-effects framework was applied as the 2 source studies represent sequential phases of a single research program.

[b]FS: feasibility study.

[c]RCT: randomized controlled trial.

[d]HAL: Hybrid Assistive Limb.

[e]Between-source heterogeneity test: Welch *t* test comparing change scores between FS and RCT participants.

[f]Source-adjusted regression: linear regression of exercise self-efficacy change on a source-study indicator (FS=1; RCT=0). The intercept estimate represents the pooled mean change, with RCT as the reference. The source coefficient tests for between-source difference.

[g]Not applicable (the source coefficient tests the between-source difference within the regression model including all 96 participants and does not correspond to a separate participant subgroup).

Pooled TTM Subgroup Analysis

Subgroup analyses stratified by baseline TTM stage were conducted to characterize changes in ESE (Table 4). Participants in the precontemplation stage showed a mean increase of 3.50 (SD 3.08) points following lumbar-type HAL training. The mean ESE increases were 1.14 (SD 3.27), 1.46 (SD 2.79), and 2.78 (SD 3.56) points in the contemplation (n=28), preparation (n=13), and action (n=9) stages, respectively. In contrast, the maintenance stage (n=38) showed a minimal change of 0.05 (SD 2.86) points. The prespecified between-stratum comparison was significant. Stages 1 to 4 combined (n=56) demonstrated

XSL•FO
RenderX

a mean ESE increase of 1.73 points (95% CI 0.87-2.60; *P*<.001) compared with 0.05 points in stage 5 (n=38; 95% CI −0.90 to 1.01; *P*=.91), yielding a between-stratum difference of +1.68 points (95% CI 0.41-2.95; *P*=.01; Table 4).

Table . Change in exercise self-efficacy by baseline transtheoretical model stage (pooled analysis; n=94)[a].

	Participants, n	Baseline score (4-20), mean (SD)	Postintervention score (4-20), mean (SD)	Change (points), mean (95% CI)	*P* value
Stage 1 (precontemplation)	6	8.00 (3.16)	11.50 (4.18)	+3.50 (+0.27 to +6.73)	.04
Stage 2 (contemplation)	28	11.46 (3.17)	12.61 (3.65)	+1.14 (−0.13 to +2.41)	.08
Stage 3 (preparation)	13	12.00 (2.58)	13.46 (2.67)	+1.46 (−0.22 to +3.15)	.08
Stage 4 (action)	9	12.22 (2.28)	15.00 (3.32)	+2.78 (+0.04 to +5.52)	.047
Stage 5 (maintenance)	38	12.76 (2.89)	12.82 (2.81)	+0.05 (−0.90 to +1.01)	.91
Stage 1 - 4 (combined)	56	11.34 (3.08)	13.07 (3.51)	+1.73 (+0.87 to +2.60)	<.001
Difference (stages 1 - 4 vs 5)	—[b]	—	—	+1.68 (+0.41 to +2.95)	.01

[a]Paired *t* tests within each subgroup; between-stratum comparisons were performed using the Welch *t* test on change scores. Two-sided α=.05. Per-stage analyses are exploratory and hypothesis generating due to the small sample sizes within several stages.

[b]Baseline and postintervention values are not applicable for the between-stratum difference row as it reflects a contrast between groups rather than a within-group estimate.

RCT Between-Group Comparison (Secondary Analysis)

The secondary analysis used the randomized design of the RCT to support causal inference (Table 5 and Figure 2). The lumbar-type HAL group (n=38) showed a mean ESE change of +1.16 (SD 3.67) points compared with −0.05 (SD 3.05) points in the waitlist control group (n=38). The between-group difference in change was 1.21 points (95% CI −0.33 to 2.75; *P*=.12; Cohen *d*=0.36). Analysis of covariance adjusting for baseline ESE yielded a similar adjusted between-group difference of 1.08 points (95% CI −0.28 to 2.44; *P*=.12). Limited statistical power was present for this between-group comparison (post hoc: 30% - 34% at α=.05), and interpretation relied on consistency with the pooled primary estimate. Within the prespecified TTM dichotomy, the between-group difference was 2.10 points among participants in stages 1 to 4 (lumbar-type HAL: n=21; control: n=21; 95% CI −0.16 to 4.35; *P*=.07; Cohen *d*=0.58) and 0.02 points among participants in stage 5 (lumbar-type HAL: n=16; control: n=17; 95% CI −2.21 to 2.24; *P*=.99; Cohen *d*=0.01; Table 5 and Figure 2). Stage-specific descriptive results are provided in Multimedia Appendix 1.

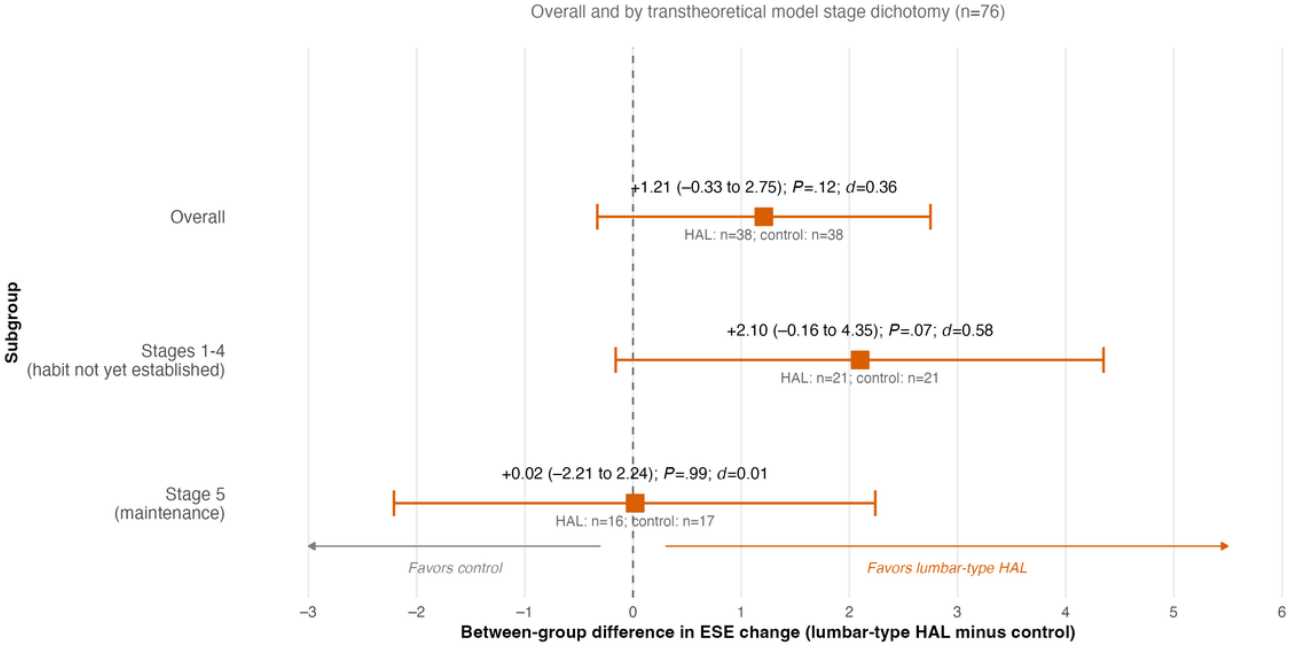
Table . Effect of lumbar-type Hybrid Assistive Limb (HAL) training on exercise self-efficacy in the randomized controlled trial: between-group comparison overall and by transtheoretical model stage dichotomy[a].



Group and subgroup	Participants, n	Baseline score (4-20), mean (SD)	Postintervention score (4-20), mean (SD)	Change (points), mean (SD)	Difference (95% CI)	*P* value	Cohen *d*
Overall					+1.21 (−0.33 to +2.75)	.12	0.36
Lumbar-type HAL	38	11.63 (2.84)	12.79 (3.31)	1.16 (3.67)			
Waitlist control	38	11.87 (3.19)	11.82 (3.21)	−0.05 (3.05)			
Stage 1-4[b]					+2.10 (−0.16 to +4.35)	.07	0.58
Lumbar-type HAL	21	10.57 (2.64)	12.33 (3.65)	1.76 (3.81)			
Waitlist control	21	11.67 (3.15)	11.33 (3.06)	−0.33 (3.41)			
Stage 5[c]					+0.02 (−2.21 to +2.24)	.99	0.01
Lumbar-type HAL	16	12.88 (2.66)	13.19 (2.86)	0.31 (3.53)			
Waitlist control	17	12.12 (3.31)	12.41 (3.39)	0.29 (2.59)			

[a]Between-group difference (lumbar-type HAL minus waitlist control) was calculated using the Welch *t* test on change scores. Analysis of covariance adjusting for baseline exercise self-efficacy yielded similar results: +1.08 points (95% CI −0.28 to +2.44; *P*=.12).

[b]Stages 1-4: precontemplation, contemplation, preparation, and action stages (regular exercise habit not yet established).

[c]Stage 5: maintenance stage (regular exercise habit established for ≥6 months).

Figure 2. Randomized controlled trial between-group comparison of exercise self-efficacy (ESE) change. HAL: Hybrid Assistive Limb.

Subjective Feedback

Responses to the self-administered questionnaire included individual statements such as the following:

My motivation to exercise has increased.

I want to continue exercising in the future.

It has become easier to move. Standing up takes less effort now.

I can stand up without having to hold on.

I felt that my back was more comfortable after using the HAL for the first time. My sitting posture has improved.

Discussion

Principal Findings

This retrospective pooled analysis combining an FS and an RCT of lumbar-type HAL training in older adults with frailty demonstrated a significant improvement in ESE of 1.05 points (95% CI 0.41-1.69; *P*=.002) among 96 recipients with lumbar-type HAL. Improvements in ESE were accompanied by significant gains in physical function (10MWT and TUG test) and PA, indicating concurrent enhancement of physical and psychological readiness for exercise. Improvements in physical function likely reinforced mastery experiences, thereby contributing to increased ESE [5-7]. By providing consistent, scaffolded assistance, the lumbar-type HAL enables successful completion of functional tasks such as sit-to-stand movements and squats that may otherwise exceed baseline capacity, thereby strengthening confidence in performing exercise under everyday conditions.

Subgroup analyses demonstrated differential effects across baseline TTM stages. The prespecified between-stratum contrast (stages 1‐4 vs stage 5) was significant (between-stratum difference of +1.68 points, 95% CI 0.41-2.95; *P*=.01), indicating that responsiveness varied by behavioral readiness. The largest effect was observed in precontemplation (stage 1), where 4 of 6 participants improved (none deteriorated; mean change +3.50, SD 3.08 points; Cohen *d*=1.14; Figure 3). This exploratory finding (n=6) is of interest given that precontemplators are typically difficult to engage in conventional exercise programs and have limited opportunities for mastery experiences [6,10]. In contrast, participants in stage 5 (maintenance) showed minimal change (+0.05 points; *P*=.91). Although baseline ESE in this subgroup did not approach the scale maximum, it was already relatively high for this population, leaving little room for further improvement; in addition, the intervention tasks (sit-to-stand exercises and squats) may have provided limited additional challenge for individuals with established exercise habits [22]. Sensitivity analyses supported the validity of pooling FS and RCT data (between-source heterogeneity: *P*=.74; source-adjusted regression: *P*=.76; RCT-only results were directionally consistent), suggesting minimal influence of methodological differences between studies. The secondary RCT between-group analysis was not significant (between-group difference of +1.21 points; *P*=.12; Cohen *d*=0.36), likely reflecting limited statistical power (post hoc: 30% ‐ 34%; required n=172 for 80% power). However, the effect estimate aligned closely with the pooled primary result (+1.21 vs +1.05 points), and the TTM pattern was consistent (Cohen *d*=0.58 for stages 1 ‐ 4 vs Cohen *d*=0.01 for stage 5); thus, the direction of the effect estimates was consistent across analyses rather than contradictory. However, confirmation through a sufficiently powered, dedicated RCT is required before causal inference can be established.

Figure 3. Stage 1 (precontemplation) detailed analysis. ESE: exercise self-efficacy.

Comparison With Previous Studies

These findings extend those of previous studies on the lumbar-type HAL by demonstrating effects on a psychological outcome (ESE) in addition to previously reported physical function [18]. To our knowledge, this study is the first to examine lumbar-type HAL responsiveness according to TTM stage and describe an exploratory finding among precontemplators. The observed effect size in this subgroup (Cohen *d*=1.14) aligns with the theory by Bandura [5] that mastery experience interventions yield the largest gains among individuals with low baseline self-efficacy. The minimal change observed in the maintenance stage is consistent with prior exercise intervention studies in older adults with established activity habits, in which ceiling effects on self-efficacy measures are commonly reported [22]. A recent systematic review reported limited and inconsistent evidence on TTM-based interventions for PA in older adults [10], highlighting the scarcity of evidence on stage-tailored exercise strategies. The present findings provide preliminary evidence that lumbar-type HAL training may serve as a stage-appropriate entry strategy for previously disengaged individuals. Notably, a recent study of a wearable walking assistance robot in community-dwelling older adults [23] reported feasibility and acceptability without

XSL•FO
RenderX

examining ESE; the present study extends this line of research by linking robot-assisted exercise to a psychological readiness outcome.

Limitations

This study has some limitations. First, the FS and RCT differed in the structure and delivery of the lumbar-type HAL–based exercise programs. The FS implemented an individualized program, whereas the RCT combined individual and group-based training. Group-based settings provide opportunities for social encouragement and observational learning (vicarious experiences), both of which enhance self-efficacy [5]. Accordingly, participants in the RCT may have had greater exposure to self-efficacy–enhancing mechanisms than those in the FS. Moreover, the number of lumbar-type HAL training sessions differed between studies (20 in the FS vs 10 in the RCT), which may have influenced the magnitude of ESE improvement. These heterogeneities were addressed through prespecified sensitivity analyses (source stratified, source-adjusted regression, and between-source heterogeneity testing), all of which supported the robustness of the pooled estimate. Second, the secondary RCT between-group analysis was underpowered: the achieved sample size (n=76; 38 per group) was below the required 172 to detect a medium effect (Cohen *d*=0.43) at a 2-sided α of .05 with 80% power, corresponding to a post hoc power of 30% to 34%. The directionally consistent effects observed in the pooled primary analysis (significant; +1.05 points; *P*=.002) and the secondary RCT analysis (nonsignificant; +1.21 points; *P*=.12) suggest a potentially meaningful intervention effect; however, a larger adequately powered RCT is required for definitive between-group inference. Third, subgroup analyses by TTM stage were limited by small sample sizes within some strata (eg, stage 1: n=6 in the pooled analysis; n=2 in the lumbar-type HAL group and n=4 in the control group of the RCT). Consequently, stage-specific findings should be considered exploratory and hypothesis generating. The prespecified dichotomous comparison between stages 1 to 4 vs stage 5 (*P*=.01) therefore served as the primary stratified analysis. Although no participant in stage 1 showed a decline in ESE, confirmation in studies adequately powered to assess effects within individual TTM stages remains necessary. Fourth, open recruitment may have preferentially attracted participants with greater health awareness, potentially limiting the generalizability of the findings.

Future Directions

Future research should recruit larger numbers of participants in the precontemplation stage (stage 1) to confirm the large effect estimate observed in this exploratory analysis (n=6; Cohen *d*=1.14). A purposive sampling strategy targeting disengaged older adults—who are often underrepresented in exercise research—would enable rigorous evaluation of whether the pronounced ESE gains observed in precontemplators can be replicated. Adequately powered studies stratified by baseline TTM stage are needed to determine whether lumbar-type HAL training reliably benefits older adults with low readiness for exercise. The differential effects observed across TTM stages also support a stratified intervention approach whereby lumbar-type HAL training may be appropriately targeted to lower-readiness individuals (stages 1 - 4), whereas alternative strategies may better serve those in the maintenance stage.

Conclusions

In this retrospective pooled analysis, a lumbar-type HAL exercise program demonstrated a significant within-person improvement in ESE in older adults with frailty, with the greatest improvement observed among individuals without established exercise habits. Evidence from the RCT indicated a favorable but inconclusive between-group effect, and adequately powered confirmatory RCTs remain necessary.

The exploratory response in precontemplators—a group traditionally difficult to engage in exercise interventions—suggests that HAL-supported mastery experiences may provide a novel entry point to PA for disengaged older adults at high risk of frailty. Future studies should specifically target participants in stage 1 using purposive sampling, confirm the differential effects in adequately powered stratified designs, and examine whether improvements in ESE translate into sustained PA over time.

Abstract

Background: The UGO lower limb exoskeleton rehabilitation robot is designed for patients with lower limb motor dysfunction, and it can be used to assess the peak torque of hip and knee flexors and extensors.

Objective: The primary aim of this study was to establish the concurrent validity of peak isokinetic torque using the UGO exoskeleton and Humac Norm dynamometers in healthy young adults.

Methods: Twenty healthy young adults were enrolled in this study. All participants underwent isokinetic muscle strength tests using both the UGO exoskeleton and the Humac Norm dynamometers. Peak torque (Nm) of the hip and knee flexors and extensors was measured. The Pearson correlation coefficient was used to determine concurrent validity. Bland-Altman analysis was used to assess the agreement between the 2 devices.

Results: At the knee, peak torque of the extensors measured by the UGO exoskeleton correlated strongly with that measured by the Humac Norm dynamometer (right: r=0.662; P=.001; left: r=0.768; P<.001), with 95% limits of agreement (LoA) ranging from −22.89 to 82.21 Nm and from −24.60 to 75.65 Nm, respectively; the right knee flexors showed a moderate correlation (r=0.547; P=.01), with 95% LoA ranging from −26.27 to 36.01 Nm, whereas the left knee flexors showed no significant association (r=0.347; P=.12), with 95% LoA ranging from −2.40 to 75.02 Nm. At the hip, peak torque of the flexors correlated strongly on the right (r=0.615; P=.003) and moderately on the left (r=0.443; P=.04), with 95% LoA ranging from −15.52 to 86.57 Nm and from −12.53 to 98.50 Nm, respectively, whereas the bilateral hip extensors showed no significant association (right: r=0.337; P=.14; left: r=0.391; P=.20), with 95% LoA ranging from −51.57 to 76.80 Nm and from −28.19 to 79.59 Nm, respectively.

Conclusions: In healthy young adults, the UGO exoskeleton demonstrated moderate to strong concurrent validity for peak torque of the bilateral knee extensors and hip flexors, but not for the nondominant knee flexors or bilateral hip extensors. The device may serve as a convenient torque assessment tool for selected muscle actions, but systematic overestimation and posture-related differences must be considered, and validation in the intended clinical population of patients with neurological conditions is required in further studies.

Introduction

Lower limb motor dysfunction is a significant complication associated with normal aging or nervous system diseases that may result in a considerable decline in quality of life [1-3], impose a heavy health burden, and lead to substantial economic losses to society [4]. Lower limb muscle strength is an important factor in maintaining balance and gait [5,6]. Among lower limb muscles, knee extensors and flexors play a critical role in weight bearing, propulsion [7], and stability during ambulation [8], making their accurate assessment essential for rehabilitation planning and outcome evaluation. Traditional muscle strength testing methods, such as manual muscle testing, are widely used in clinical settings due to their simplicity and low cost. However, these methods suffer from well-documented limitations, including subjective interpretation, assessor strength bias, and poor reliability [9], particularly when testing stronger muscle groups such as the knee extensors in individuals who are healthy or moderately impaired. Therefore, the ability to assess muscle strength efficiently and with high precision has become a clinical imperative. Isokinetic dynamometers are known as the gold standard for muscle strength testing because of their high accuracy. However, their clinical utility is limited by their cumbersome design, stationary nature, and high cost [10].

Recently, exoskeleton-based rehabilitation robotics has emerged as a cutting-edge intervention for restoring function in patients with neurological sequelae [11-13]. A hallmark of these systems is the capacity to autonomously deliver highly repeatable, standard rehabilitation exercises, dramatically reducing the physical load on therapists [14]. Exoskeleton rehabilitation robots have emerged as a promising intervention for neurological recovery. Current hot topics include upper limb goal-directed training, lower limb motion control strategies, and exoskeleton rehabilitation robot power [15]. A pilot randomized controlled trial of the REX robotic exoskeleton (REX Bionics PLC), a self-stabilizing lower limb device that supports patients in a hands-free upright standing position without crutches or walking frames, included 3 supplementary training programs—standing balance activities (pushing a Bobath ball and multidirectional reaching), thera-band elastic band resistance training following an upper limb PNF diagonal spiral pattern, and lower limb function training (single-leg weight bearing, lateral and repeated strides, squatting, and alternating strides)—to promote balance and lower limb motor recovery in patients with subacute stroke [16]. The integration of series elastic actuators in lower limb exoskeletons has significantly advanced robotic rehabilitation, particularly for enhancing human-robot interaction safety and motion control [17]. Prasad et al [11] proposed 4 conceptual configurations for cable-driven exoskeletons, which address key power-related challenges inherent in traditional actuation systems.

Exoskeleton rehabilitation robots overcome some limitations of traditional clinical assessment by providing more objective, sensitive, reliable, and efficient measurements [18]. Several groups have proposed using robotic devices to assess proprioception and motor function [18-20], such as gait and joint position sense; the Lokomat, for example, has been used to assess lower limb joint position sense [19], and the bilateral Harmony upper limb exoskeleton can measure joint angles across the shoulder, forearm, and wrist [21]. An intelligent assessment study using a lower limb exoskeleton for patients with stroke reported predictive accuracies of 85% for the 6-minute walk distance and 93% for the Fugl-Meyer assessment lower extremity score, outperforming traditional manual measurement in efficiency and objectivity [22]. Although these studies establish that exoskeleton and robotic platforms can quantify kinematic and functional variables, the agreement of an exoskeleton's isokinetic torque output with a criterion standard dynamometer has, to our knowledge, not been reported. The UGO rehabilitation exoskeleton is seeing growing adoption in clinical practice for treating patients with lower limb motor dysfunction resulting from stroke, spinal cord injury, or peripheral nerve injury [23]. Designed to provide high-frequency, repetitive, standardized gait training, the device additionally features isokinetic muscle strength testing as a key diagnostic function. Unlike conventional isokinetic dynamometers, it is equipped with force sensors at both the hip and knee joints on each side, so that bilateral testing does not require positional changes—a design that theoretically makes testing more convenient and efficient. Although the UGO exoskeleton is widely used and has recognized theoretical benefits, the measurement properties of its strength assessment capability remain to be established. These properties are conventionally established in 2 distinct steps. In a previous study, we examined the intratester and intertester reliability of the device (an internal, device-only property—whether it produces reproducible values) [24]. The present study addresses the separate and complementary question of concurrent validity (an external property—whether the device agrees with an accepted reference standard). Reliability is a prerequisite for, but is conceptually and statistically independent of, validity: a device may be reliable yet invalid. The 2 studies drew on an overlapping healthy participant pool but used entirely different analyses and report no duplicate results; the present work provides the first agreement-based, reference standard comparison of the UGO's isokinetic torque function.

The aim of this study was to determine the concurrent validity of isokinetic hip and knee peak torque measurements obtained with the UGO rehabilitation exoskeleton against those obtained with the Humac Norm dynamometer in healthy young adults, using both agreement and association analyses. We hypothesized that peak torque measured by the 2 devices would show at least moderate, statistically significant correlations and clinically moderate to strong agreement for the major muscle actions.

Methods

Study Setting

This study was carried out in the Biomechanical Rehabilitation Engineering Laboratory of the Department of Rehabilitation Medicine at the First Affiliated Hospital of Sun Yat-sen University. Participants were randomly recruited from interns within the department. Measurements were taken by the same physical therapist, who had >5 years of clinical experience and was proficient in operating both pieces of equipment, using the 2 isokinetic dynamometers. This tester had previously undergone

XSL•FO
RenderX

training and passed evaluations related to the operation of isokinetic muscle strength testing equipment for both devices.

Sample Size Calculation

According to a previous study [25] that investigated the correlation between a Biodex isokinetic dynamometer (Evome Medical Technologies Inc) and a hand-held dynamometer in male football players (r=0.322-0.617), a sample of 17 participants provides approximately 80% power to detect a correlation of r=0.60 at α=.05 (2-tailed) in this study, as calculated using G*Power. To draw a stronger conclusion, the sample size was finally determined to be 20.

Recruitment

This study recruited participants via 2 approaches. First, a recruitment announcement was posted in the WeChat (Tencent Holdings) group for interns within the department, followed by on-site screening to identify eligible candidates. Baseline information such as age, sex, height, weight, BMI, and the dominant lower limb were collected for each participant. Researchers contacted potential participants who satisfied the testing equipment requirements (height between 150 cm and 190 cm, weight not exceeding 100 kg) to confirm their willingness to participate [23].

Inclusion Criteria

The inclusion criteria were as follows: (1) aged 20 to 30 years, (2) absence of any history of cardiovascular or respiratory diseases, (3) lack of a history of lower limb musculoskeletal conditions (eg, hip or knee joint surgery, ligament injury, or muscle strain or sprain) that would affect the test, and (4) absence of high-intensity physical activities during the past week.

Ethical Considerations

The study was approved by the medical ethics committee of the First Affiliated Hospital of Sun Yat-sen University in Guangzhou, China ({2020}430) and conducted according to the Declaration of Helsinki. This was a safe and noninvasive experiment. Prior to the commencement of the experiment, a member of the research team elucidated the experimental procedures to all participants and obtained their informed consent. Furthermore, throughout the experiment, the participants had the option to withdraw from the experiment at any time without providing any reason.

Instrument

Two isokinetic dynamometers were used in this study: the UGO rehabilitation exoskeleton (Chengtian) and the Humac Norm (CSMi Solutions) (Figure 1). The UGO lower limb exoskeleton robot is widely used as a research and clinical platform for validating gait planning algorithms. Notably, its capacity for isokinetic concentric torque testing at the hip and knee joints constitutes one of its most important evaluation functions, providing reliable and functionally relevant measurements in a natural upright posture. Many studies have confirmed that the Humac Norm is a highly reliable and accurate isokinetic dynamometer [10,26-28]. Identical angular velocity (60°/s) and joint range-of-motion settings were configured on both dynamometers; body posture, however, differed between the devices by design (UGO: upright; Humac Norm: seated for the knee, supine for the hip).

Parameter

This study primarily focused on collecting peak torque data for the knee and hip flexor and extensor muscle groups during concentric contractions using the 2 isokinetic dynamometers. The isokinetic dynamometers measure muscle strength by collecting mechanical signals within the range of motion through sensors and calculating the measurements using their respective analysis software. The parameter that was recorded was absolute peak torque (in Newton-meters). Peak torque has been defined as the maximum force produced by a muscle during voluntary contraction within the range of motion under a given set of conditions [29,30].

Procedure

To minimize the potential influence of biological rhythms on the results, the 2 tests were conducted at the same time on 2 consecutive days. Participants were instructed to abstain from strenuous physical activity and refrain from consuming any nutritional supplements or functional beverages that could enhance physical performance, starting 48 hours before the tests and continuing until their completion. They were permitted to maintain their usual daily activities and diet. Prior to the formal test, participants performed 3 minutes of lower limb muscle stretching, followed by 10 knee and hip flexion and extension repetitions at a submaximal voluntary contraction level to familiarize themselves with the testing procedure. After the warm-up, each participant rested for 5 minutes to prevent fatigue. The testing sequence involved assessing the dominant side first, followed by the nondominant side after a 2-minute rest, and the knee and hip tests were performed 5 minutes apart.

To ensure consistency and comparability, in the knee test, both devices used the lateral femoral condyle as the axis of motion, with a movement speed of 60°/s and a range of 0° to 70° (0°: the fully extended position of the knee joint) for knee testing. For the UGO device, thigh and calf lengths of participants were adjusted so that the axis of movement was aligned with the lateral femoral condyle in a seated posture, and their trunk, distal femur, proximal tibia, and foot were securely fixed to avoid compensatory forces. Testing was performed in an upright position, with the external frame fixed first, and the muscle strength test of the flexion muscle group was started from the extension position of the knee joint. Each movement was followed by a cue tone, followed by movement in the opposite direction. Verbal instruction for peak torque was provided as “flexion and extension as hard and as fast as you can” to ensure maximal effort during each action.

The greater trochanter of the femur was used as the axis of motion, with a movement speed of 60°/s and a range of −10° to 60° (0° being the neutral position of the hip) in hip testing. The position was the same as that for knee testing and started from the extension position. During the UGO isokinetic muscle strength test, repositioning was not required when switching between test sides or joint angles, which saved therapists both time and operational steps. The bilateral test took 5 minutes to complete for each joint, during which 5 consecutive flexion and extension movements were executed, and peak torque values were recorded after each movement.

In accordance with the standardized testing protocol of Humac Norm, participants were seated on the isokinetic dynamometer with their hip joints flexed at 85°. The tension sensor’s rotation angle was set at 40°, and its height was adjusted to 8 cm. The rotational axis of the knee was placed in line with the dynamometer axis of rotation, and 0° was determined as 0° knee extension. The resistance arm pad was secured just proximally to the medial malleolus, so that movement of the ankle was not constricted. To minimize compensatory trunk movements, straps were used to secure the participant’s trunk, distal femur, and distal tibia. During the test, participants were required to cross their arms in front of their chest to prevent compensatory force generation by gripping the seat. The hip test was performed in the supine position; the tension sensor’s rotation angle was set at 0° and its height was set at 9 cm. The resistance arm pad was secured just distal to the femur, and a fixation band was used to fix the pelvis. Upon program initiation, 5 consecutive flexion and extension movements were completed.

Statistical Analysis

Descriptive statistics were used to analyze the demographic characteristics of the participants in this study. A 1-sample Kolmogorov-Smirnov test was used to test whether the data were normally distributed. The Pearson correlation coefficient (r) or Spearman rank correlation coefficient (ρ) was used to determine concurrent validity. Here, r or ρ values between 0.00 and 0.19, between 0.20 and 0.39, between 0.40 and 0.59, between 0.60 and 0.79, and ≥0.80 represented very weak, weak, moderate, strong, and very strong correlations, respectively [31]. A scatter diagram was constructed to evaluate agreement between the UGO and HUMAC measurements and to identify any systematic bias [10]. A Bland-Altman plot was used to compare the mean difference and the 95% limits of agreement (LoA) between the 2 devices. The upper and lower 95% LoA were calculated as the mean difference±1.96×SD. All statistical analyses were performed using SPSS (version 20.0; IBM Corp), with a significance level set at $P<.05$.

Results

Overview

Twenty healthy young adults were recruited for this study. All participants cooperated well during the tests, and each participant exerted maximal effort. The demographic characteristics of the participants are provided in Table 1. Of the 20 participants, 9 (45%) were male, 11 (55%) were female, and all 20 (100%) were right-lower-limb dominant.

Concurrent Validity of Isokinetic Knee Strength Measurements

On the dominant (right) side, the correlation coefficients for peak torque of knee extension and flexion were 0.662 (P=.001) and 0.547 (P=.01), respectively, with 95% LoA ranging from −22.89 to 82.21 Nm and from −26.27 to 36.01 Nm, respectively. Specifically, there was a strong correlation for peak torque during knee extension and a moderate correlation for peak torque during knee flexion. On the nondominant (left) side, the correlation coefficients for peak torque of knee extension and flexion were 0.768 (P<.001) and 0.347 (P=.12), respectively, with 95% LoA ranging from −24.60 to 75.65 Nm and from −2.40 to 75.02 Nm, respectively. The peak torque of knee extension exhibited a strong correlation, while that of knee flexion showed a weak correlation. These results are demonstrated in the scatter plot (Figure 2) and the Bland-Altman plot assessing agreement between the 2 devices (Figure 3). Detailed results of the concurrent validity analysis of isokinetic knee strength measurements are shown in Table 2.

Concurrent Validity of Isokinetic Hip Strength Measurements

The correlation coefficients for peak torque of hip extension were 0.337 (*P*=.14) and 0.391 (*P*=.20) on the right and left sides, respectively, with 95% LoA ranging from −51.57 to 76.80 Nm and from −28.19 to 79.59 Nm, respectively, and showed no significant correlation. The correlation coefficients for peak torque of hip flexion were 0.615 (*P*=.003) and 0.443 (*P*=.04), on the right and left sides, respectively, with 95% LoA ranging from −15.52 to 86.57 Nm and from −12.53 to 98.50 Nm, respectively. The peak torque of right hip flexion exhibited a strong correlation, while that of left hip flexion showed a moderate correlation. These results are demonstrated in the scatter plot (Figure 4) and the Bland-Altman plot assessing agreement between the 2 devices (Figure 5). Detailed results of the concurrent validity analysis of isokinetic hip strength measurements are shown in Table 3.

Discussion

Principal Findings

To the best of our knowledge, this study represents the first attempt to investigate the concurrent validity of isokinetic muscle strength testing in the context of lower limb exoskeleton rehabilitation robots. In this cross-sectional validation study, the UGO exoskeleton showed moderate to strong concurrent validity—with significant correlations of at least moderate strength and Bland-Altman agreement—for the bilateral knee extensors and the hip flexors, but not for the left knee flexors or bilateral hip extensors, which showed nonsignificant associations and greater systematic bias. Across all muscle actions, the UGO systematically overestimated peak torque relative to the Humac Norm.

Previous studies comparing torque measurements obtained with hand-held dynamometers and isokinetic dynamometers have found that tests of the knee extensor and flexor muscles show moderate to strong correlations [32], while tests of internal and external rotation of the shoulder joint show weak correlations

XSL•FO
RenderX

[33]. O'Neill et al [10] found that the C-station (Fysiometer) appeared to provide valid measurements compared with an isokinetic dynamometer for plantar flexor isometric strength. However, these studies only compared devices with an isokinetic dynamometer during isometric contraction tests. Our study compared 2 devices during isokinetic knee and hip strength testing. We found that the UGO showed strong correlations for both knee extensor torque measurements, a moderate correlation for right knee flexor torque, and a nonsignificant correlation for left knee flexor torque compared to the reference standard, the Humac Norm. In hip testing, the correlation of the flexor torque values was stronger than that of the extensor torque values on both sides. The underlying reasons for these differences included 4 factors. First, the test positions differed. During the UGO isokinetic strength test, the knee and hip flexion and extension muscles were tested in the upright position. In contrast, during the Humac Norm isokinetic strength test, the knee was positioned in the seated posture, while the hip was placed in the supine position. Diverse test positions can influence force production, thereby leading to varying torque values. During the upright position test, participants consistently reported that exerting force for hip flexion combined with knee extension required less effort than hip extension combined with knee flexion. Second, the torque signal acquisition and calculation formulas differed between the 2 devices. Despite the sampling rate of both torque sensors being 100 Hz [23,34], the torque sensor of the UGO exoskeleton has a measurement range of 150 Nm, a resolution of 0.05 Nm, and a force-sensing accuracy of 0.3% [23]. The resolution and accuracy of the Humac Norm isokinetic dynamometer force sensor have not been reported in the existing literature, but Habets et al [35] reported that the Humac Norm dynamometer showed good to excellent reliability in strength tests of the knee and shoulder joints. The disparities in the mechanical structure and software of the 2 devices may likewise affect the calculation of the lever arm and the torque value of the generated force [27]. As torque is obtained by multiplying the measured force by the perpendicular lever-arm length ($\tau=F\times d\perp$), such device-related discrepancies have been shown to produce systematic torque differences of around 8 Nm between hand-held and isokinetic dynamometers [36]. Third, the number of torque sensors differed between the 2 devices. The UGO dynamometer has 4 torque sensors, and the Humac Norm has only 1 sensor. We hypothesize that the presence of numerous force sensors may increase the potential for error associated with torque calculation [37]. Finally, factors related to the patient's maximum voluntary force contraction may have contributed to the differences. In knee testing, the correlation coefficient for peak hamstring torque appeared to be lower than that for peak quadriceps torque [25]. This finding may be partly explained by the characteristically lower test-retest reliability of hamstring strength measurements relative to those of the quadriceps [38].

In hip testing, the complexity and standardization of hip joint testing present additional challenges. Hip movements are more difficult to isolate and standardize than knee tasks because of greater degrees of freedom, pelvic tilt variability, and compensatory trunk or lumbar involvement. The UGO, as a functional exoskeleton, may capture more multijoint, closed-chain dynamics, while Humac Norm emphasizes open-chain, single-plane isokinetic testing, leading to divergent torque profiles. Hip extension involves strong gluteal or hamstring recruitment with potential antagonist cocontraction (eg, flexors and abdominals), which exoskeletons may detect differently from laboratory dynamometers. Participants may unconsciously alter their movement strategies (eg, trunk leaning) on the UGO, inflating or deflating measured torque relative to Humac Norm. Interestingly, we found that the measurement of peak torque exhibited significantly higher correlation coefficients for the anterior muscle group than the posterior muscle group.

For patients, a significant inconvenience arises from standard isokinetic muscle strength testing, which requires repositioning the body when assessing multiple joints in the lower limbs. Although the UGO's isokinetic muscle strength test results **e**xhibit certain discrepancies compared to those of the Humac Norm reference standard, it offers superior clinical convenience. In particular, the isokinetic muscle strength testing function of the UGO device enables therapists to quantitatively assess changes in patients' lower limb function during clinical treatment and across treatment courses (preintervention and postintervention). The exoskeleton robot establishes a closed-loop rehabilitation training protocol for patients, allowing the rehabilitation therapist to adjust the training program based on the results of muscle strength testing.

Overall, the UGO's isokinetic muscle strength test is more convenient and maneuverable than traditional isokinetic dynamometers. This device not only reduces the operational requirements of therapist-operated devices and saves time, but it also alleviates patient discomfort by minimizing repositioning—especially for those with mobility difficulties. Therefore, the isokinetic muscle strength assessment capability of the UGO device enables therapists to evaluate lower limb motor function and implement targeted treatment strategies more effectively in clinical rehabilitation settings.

Limitations

This study has several limitations. First, the inherent hardware differences between the devices inevitably lead to discrepancies in test posture and lever-arm length. Second, device-specific error sources for the UGO include reliance on estimated segment lengths for lever-arm or torque computation, the distributed 4-sensor architecture, and a proprietary, nontransparent torque calculation algorithm; for the reference device, fatigue status before Humac Norm testing was assessed only subjectively, which may partly explain the relatively lower recorded torques. Third, the relatively small sample size in this study may limit the statistical power of the analyses and preclude definitive conclusions. Fourth, only healthy young adults were studied; findings cannot be extrapolated to patients with neurological impairment, in whom spasticity, weakness, altered tone, impaired trunk control, and reduced range of motion may alter both torque magnitude and device-reference agreement. Finally, as the device testing order was fixed, potential order effects （learning or fatigue）cannot be fully excluded, although the 24-hour interdevice interval and activity restriction were intended to mitigate them.

XSL•FO
RenderX

Conclusions

In healthy young adults, the UGO exoskeleton demonstrated moderate to strong concurrent validity for peak torque of the bilateral knee extensors and the hip flexors, but not for the nondominant knee flexors and bilateral hip extensors, and it systematically overestimated peak torque relative to the Humac Norm. The device may serve as a convenient torque assessment tool for selected muscle actions; however, its use for the knee flexors and hip extensors is not yet supported, and validation in the intended clinical population is required in future studies.

Abstract

Background: Digital assessment technologies, such as optical motion capture and inertial measurement units, enable detailed kinematic analysis and continuous monitoring of upper limb activity in persons with neurological conditions. While such *digital metrics of functioning* are increasingly recognized in research, their uptake in clinical neurorehabilitation is limited. It remains unclear which *digital metrics of functioning* clinicians perceive as most meaningful and how these are integrated into patient-centered care. Understanding clinicians' information needs and reasoning processes is a prerequisite for implementing digital assessment technology.

Objective: This study aims to characterize how rehabilitation professionals perceive, prioritize, and integrate *digital metrics of functioning* into clinical reasoning and to identify features that would support their routine use.

Methods: Three 90-minute focus groups were conducted in 3 Swiss neurorehabilitation centers, involving 11 clinicians with diverse professional backgrounds (5 physiotherapists, 4 occupational therapists, 1 movement scientist, and 1 medical practitioner). Participants discussed essential parameter domains and individually rated the relevance and meaningfulness of 17 kinematic metrics for the well-studied drinking task and 10 established arm use performance metrics. Verbatim transcripts were analyzed using reflexive thematic analysis, and rating data were summarized descriptively.

Results: Five main themes were identified. (1) *Functional requirements to interpret movement quality and performance* (active/passive range of motion, strength, selective muscle control, and grasp) form the basis for interpreting movement. (2) *Essential aspects of movement quality* (smoothness, efficiency, and compensatory movement) are valued when aligned with observable task execution. (3) *Added value of real-world performance* (hourly activity profiles, arm-use symmetry, and functional workspace) represents the reference for patient-centered reasoning. (4) *Individualizing what matters*, including diagnosis-specific preferences, shapes assessment selection. (5) *Blending clinical eye and reference data* reflects clinicians' reliance on visual judgment complemented by normative values. Intuitive metrics such as task duration, number of movement units, and range of motion were favored, whereas confidence was lower in more complex metrics (eg, jerk and interjoint coordination).

Conclusions: Clinicians value intuitive *digital metrics of functioning* when they are clearly linked to patient-centered outcomes and supported by normative references. The findings highlight the need for targeted educational strategies and digital competency training that help clinicians interpret digital metrics and integrate them with contextual information and clinical reasoning.

Introduction

Upper limb dysfunction is among the most disabling consequences of neurological conditions such as stroke and spinal cord injury (SCI). Loss of dexterity and limited arm use reduce independence in activities of daily living (ADL) and restrict participation in social and professional roles [1,2]. The International Classification of Functioning, Disability and Health (ICF) captures these interactions under the umbrella term "functioning," which encompasses body functions, activities, and participation [3]. Assessment of upper limb functioning is therefore central to motor rehabilitation, informing both patient-centered goal setting [4] and comprehensive recovery monitoring [5,6].

Guidelines for clinical assessments after stroke emphasize the routine application of established core sets to ensure that clinically relevant and meaningful domains of functioning are systematically evaluated [7-9]. In conventional clinical assessments, clinicians evaluate the patient's maximal voluntary capacity, relying on observation and standardized rating scales to assess constructs such as active range of motion (ROM) and patient-reported ADL performance. These methods are often integrated into the decision-making process known as clinical reasoning, which clinicians use to interpret information and guide treatment. However, these assessments are limited in their ability to adequately and reliably capture movement quality and detect subtle changes [10,11]. Additionally, upper limb capacity assessments often fail to align with the actual performance in real-world settings. Multiple studies show a capacity-performance mismatch [12,13] and indicate that gains on standardized tests do not always translate into increased arm use [14,15].

To address these limitations, technology-based assessments have been developed to reliably quantify upper limb movements with high temporal resolution. In analogy to the ICF framework, we introduce a technology-based counterpart: *digital metrics of functioning*. These metrics are derived from technologies such as optical motion capture, computer vision, and wearable sensors, which enable the quantification of fine-grained movement execution and real-world activity. *Digital metrics of functioning* can be grouped into 2 complementary domains. In our framework, movement quality is the overarching construct that characterizes how a movement is executed. It can be evaluated through observational movement analysis (clinician-rated) or instrumented kinematic analysis, the latter yielding kinematic metrics that quantify aspects of movement quality such as smoothness, movement time, and compensatory movements during both standardized and habitual tasks. In standardized tasks, these metrics reflect what an individual can perform under controlled conditions, that is, upper limb capacity.

In contrast, *real-world performance metrics* reflect arm use behavior in daily life, for example, through average acceleration or arm use symmetry, thereby capturing arm use in people with neurological conditions in a habitual environment.

Although related, *kinematic* and *real-world performance metrics* represent distinct constructs. Improvements in task-based kinematic metrics, that is, movement quality or upper limb capacity, do not necessarily translate into arm use behavior in a habitual environment. Moreover, real-world performance may be influenced by contextual, motivational, and behavioral factors beyond the assessed movement quality and capacity under controlled conditions [15,16]. By integrating these different domains into clinical practice, digital measures could provide information beyond observer-based ratings [17,18] and enable clinicians to identify meaningful patterns, such as a potential mismatch between increased capacity and reduced real-world arm use performance [15,19]. For instance, by capturing both *digital metrics of functioning* (ie, *kinematic* and *real-world performance metrics*) and clinical assessments, individuals requiring special attention can be identified, including those who show a mismatch between increased functional capacity and declining real-world performance. These people may benefit from personalized rehabilitation that includes monitoring arm use performance, feedback, and targeted interventions [20]. This underscores the value of multidomain assessments in detecting such discrepancies and guiding intervention planning.

Among *kinematic metrics*, those quantifying the movement quality of reach-to-grasp movements have been validated most extensively [21]. The reach-to-grasp function is critical for independence in daily life [22,23] and provides insights into recovery mechanisms [11,16]. The drinking task, a standardized and meaningful ADL, has been recommended by international expert consensus for assessing upper limb movement quality in both research and clinical contexts [11]. A set of validated *kinematic metrics* exists for individuals with stroke or SCI, as well as healthy populations [24-26].

Real-world performance metrics are particularly valuable for monitoring arm use behavior in uncontrolled, ecologically valid environments [27]. Established *real-world performance metrics* include measures of arm use duration and intensity [28,29], which are widely used in research but rarely in clinical settings [30]. Novel metrics, such as real-world reach-to-grasp quantification [31] or mapping functional reaching space [32], provide task-specific insights into the real-world performance of the upper limbs.

Both kinematic and real-world performance metrics are modulated by contextual and task-related constraints, such as health status, environmental factors, and personal factors, which influence movement execution [33,34] and everyday arm use [35] beyond underlying motor capacity. When operating in an ICF-based framework, clinicians need complementary information on health-related goals, environments, and individual behavior to integrate *digital metrics of functioning* into clinical reasoning.

Despite these advances, it remains insufficiently understood how established *digital metrics of functioning* are interpreted and integrated into everyday clinical reasoning by frontline clinicians. While international expert consensus initiatives have defined key metrics and assessment paradigms [8,9,11], less is known about how practicing rehabilitation professionals make sense of these metrics in relation to their clinical expertise and decision-making processes. To support user-centered adoption of digital assessment technologies, evidence is needed on how established *digital metrics of functioning* can be harmonized

XSL•FO
RenderX

with clinicians' empirical knowledge and contextual judgment. The objective of this study was to explore rehabilitation professionals' perspectives on the use of *digital metrics of functioning* when assessing the upper limb in neurological conditions. In this context, relevant *digital metrics of functioning* are understood as those that convey actionable meaning for clinical understanding, decision-making, and communication in practice. By examining how clinicians interpret and integrate such metrics into clinical reasoning, this perspective complements existing consensus and validation work by adding the dimension of clinician-perceived interpretability and clinical utility. Specifically, we addressed the following research questions:

1. Which measurement constructs do clinicians consider essential when interpreting *digital metrics of functioning* of the upper limb (ie, *kinematic* and *real-world performance metrics*) in neurological rehabilitation?
2. Which specific *kinematic* and *real-world performance metrics* are regarded as relevant and intuitive for daily clinical practice?
3. Which complementary information is deemed important to facilitate the integration of *kinematic* and *real-world performance metrics* into clinical reasoning?

Methods

Study Design

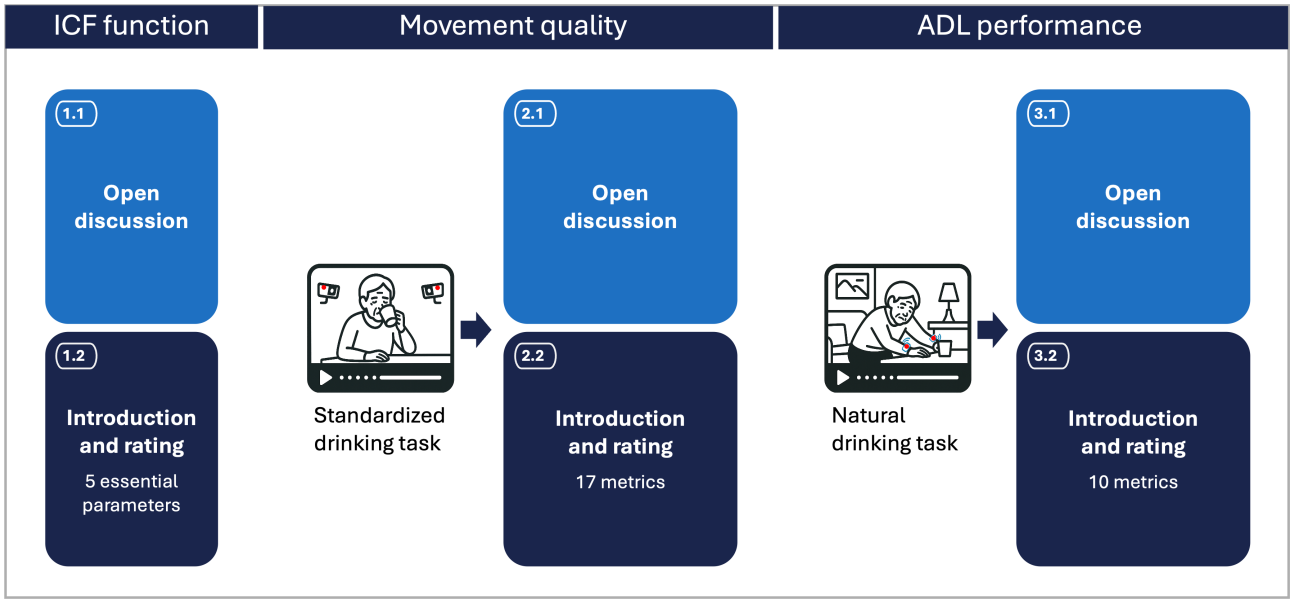
We conducted a focus group study using reflexive thematic analysis (realist orientation) to explore opinions on metrics for functioning in the Swiss neurorehabilitation landscape. Focus groups were held between December 2023 and July 2024. All participants received verbal and written information about the study and provided written informed consent prior to participation. Participants also consented to the audio and video recording of the focus group discussions for research purposes. Data were anonymized during transcription, and any potentially identifiable details were removed before analysis and reporting.

Ethical Considerations

According to the Swiss Federal Act on Research involving Human Beings (HRA), the study did not require formal ethical approval because it involved health care professionals only and did not collect health-related personal data. A formal determination of competence (Req-2025-009-30) was obtained after data collection, serving as administrative confirmation that the project was outside the scope of the HRA.

Participants and Recruitment

Invitations were distributed via email, along with a recruitment flyer addressed to therapy leads and medical directors at 8 neurorehabilitation clinics. Clinics were asked to nominate at least 3 clinicians who treated neurological patients with upper limb impairments and had at least 3 years of clinical experience. Prior experience with technology-based assessment was described as beneficial but not required. Nonparticipation was mainly due to organizational constraints (ie, allocating staff for a 90-minute time commitment). Out of 8 invited clinics, 3 agreed to participate in a focus group discussion (one per site).



Procedures

Focus groups, each lasting 90 minutes, were held in quiet meeting rooms at the participating clinics and guided by a moderator (JP, a physiotherapist with 10 years of experience in mixed clinical and research settings), who had no prior supervisory relationship with the participants. A co-moderator (LM, a physiotherapist) managed audio recordings, field notes, and whiteboard visualizations. Focus groups consisted of 3 to 4 participants. Smaller focus groups (3 - 5 participants) are considered appropriate in health research when participants share specific expertise, as they allow more time per participant and facilitate open, more in-depth discussion [36,37].

Participants were familiarized with the principles of focus group discussions and the ICF as the conceptual framework for health assessments. The focus group discussions were conducted according to an interview guideline (Multimedia Appendix 1), which included key questions and practical patient examples, and were structured into 3 parts (Figure 1). Each part began with a discussion of parameters that are relevant and meaningful for quantifying the respective ICF domain, followed by participants indicating the importance of each parameter on individual handouts. Throughout this paper, the term "rating" denotes an indication of importance (yes/no selection) for each parameter.

XSL•FO
RenderX

Figure 1. Structure of focus group discussions, including joined components of discussions before ratings. ADL: activities of daily living; ICF: International Classification of Functioning, Disability and Health.

The first part of the session focused on identifying key metrics within the ICF body function domain (32 items, including ROM, muscle strength, and somatosensory function; Table S1 in Multimedia Appendix 2). This section served as a warm-up to familiarize participants with the domain-specific reasoning process. To stimulate discussion on prioritization and underlying reasoning at the beginning, participants were limited to selecting a maximum of 5 metrics they considered most important in their clinical routines. As this exercise was intended to stimulate reasoning rather than generate interpretable quantitative rankings, the individual votes were not analyzed as outcomes. For transparency, the full table of items is provided in Table S1 in Multimedia Appendix 2.

The second part, focusing on kinematic metrics that quantify aspects of movement quality, began with a video clip showing a patient with moderate one-sided paresis performing the standardized drinking task from both frontal and sagittal perspectives. The drinking task was designed as a representative reach-to-grasp activity to provide a shared, standardized reference for discussing movement quality constructs; however, participants were encouraged to reflect on upper limb movement more broadly, beyond this specific task. Participants then discussed important movement characteristics, clinically relevant features, and requirements for clinical reasoning. The concept of "relevance" was intentionally not predefined or operationalized using explicit criteria. Instead, participants were invited to discuss *digital metrics of functioning* within clinical scenarios, allowing perceptions of relevance to be implied through how metrics were contextualized, interpreted, and integrated into clinical reasoning. In practice, participants appeared to associate relevance with aspects such as clinical interpretability, usefulness for decision-making, familiarity, feasibility in clinical workflows, and perceived patient-centered value.

Thereafter, participants indicated the perceived importance of a list of kinematic metrics for the drinking task [24,25], which are commonly categorized into the following domains: *velocity and movement time*, *movement smoothness and coordination*, *movement strategy*, and *ROM* (Table S2 in Multimedia Appendix 2).

The third part included key discussion points on upper limb performance during ADLs, prompted by video clips of the same patient performing the drinking task in a daily-life context. Metric importance was assessed across 10 performance metrics in the domains of *arm use duration*, *arm use intensity*, and *reaching count and space*. Metrics quantifying the duration and intensity of arm use have shown good measurement properties [29] and explain real-world performance well [28] (Table S3 in Multimedia Appendix 2). Despite the limited evidence base for validity, the metrics for reaching count and movement space were included based on previous reports of clinical professionals' preferences [38].

Data Analysis

The participants' opinions were analyzed using a mixed methods analysis. In qualitative evaluations, reflexive thematic analysis was applied to transcriptions, while ratings were evaluated quantitatively by calculating, for each metric, the proportion of participants who selected it. In the ICF-function section, quantitative evaluations of ratings were excluded due to differences in rating logic.

The reflexive thematic analysis framework [39] enables an interpretative, flexible, and researcher-reflexive engagement with participants' perspectives, making it particularly well suited to capturing how clinical experts construct clinical reasoning, decision-making, and value-based evaluation of upper limb functioning. Transcripts were imported into the text annotation software Taguette (v1.4.1) [40] and coded by 2 coders (JP and LM) from a realist perspective, assuming that the participants' words represented their actual experiences and opinions. Codes were generated by adopting an inductive-deductive approach, combining data-driven coding with concepts from existing frameworks (Table 1). Both coders discussed the essential aspects, interpretations, and underlying theories of code labels

XSL•FO
RenderX

in regular meetings. Codes were then structured into clusters, forming subthemes and superordinate themes, by 2 researchers (JP and LM), who collated coherent clusters. The meaning, reflexivity, and coherence of themes were then discussed between both researchers. Differences in coding or theme boundaries were addressed through deeper analysis of the coded data. The researchers explored how different interpretations reflected different aspects of participants' opinions. Where divergent interpretations arose, both perspectives were discussed and revised as the analysis progressed.

Finally, verbatim German quotations and their English translations, together with contextual descriptions of the respective subthemes, were sent to participants for review. All participants confirmed that the translations accurately reflected the original meaning and context. This study was conducted and reported in accordance with the Standards for Reporting Qualitative Research (SRQR) [41]. The completed SRQR checklist, indicating where each item is addressed in the paper, is provided in Checklist 1.

Table . Coding process.

Step	Action
1. Inductive coding	Independent coding (JP and LM) capturing semantic meaning line-by-line. No fixed codebook or a priori agreement threshold was imposed.
	Discussion, merging, or retaining code labels whose semantics were judged "functionally identical." Differences in coding were resolved with deeper analysis of the code and discussions of divergent interpretations until consensus was reached.
2. Deductive mapping	Code mapping of agreed labels to ICF[a] and existing measurement taxonomies.
3. Theme construction	Code-clustering into preliminary themes (JP and LM) upon agreement for coherence, divergences, and reflexive commentary.
4. Integration of quantitative priorities	Alignment of priority ratings with qualitative themes in a joint display, where illustrative quotes explain *why* specific metrics were prioritized or deprioritized.

[a]ICF: International Classification of Functioning, Disability and Health.

Results

Study Sample and Focus Group Characteristics

Out of the 8 invited clinics, 3 participated in the focus group study, including a total of 11 participants across 3 focus groups (one conducted in each clinic). Participants presented a range of professional backgrounds, including physiotherapy, occupational therapy, movement science, and medical practice, and varied in clinical roles and experience levels (Table 2). Clinical experience ranged from 4 to 26 years, and research experience ranged from 0 to 20 years. Average durations of focus group discussions were 33 (SD 9.6) minutes for ICF functions, 25 (SD 1.5) minutes for kinematic metrics, and 15 (SD 3.5) minutes for real-world performance, respectively.

Five themes were identified in the analysis: (1) functional requirements to interpret movement quality and performance, (2) essential aspects of movement quality, (3) added value of real-world performance, (4) individualizing what matters, and (5) blending clinical eye and reference data. Each theme comprises between 2 and 4 subthemes, as shown in Figure 2. Illustrative quotations are referenced in the text using an identifier (eg, Q1). The corresponding quotations, including participant IDs and full wording, are provided in Tables S1-S5 in Multimedia Appendix 3. Quantitative ratings of *kinematic* and *real-world performance metrics* are presented in Figure 3 and are reported convergently within respective themes.

XSL•FO

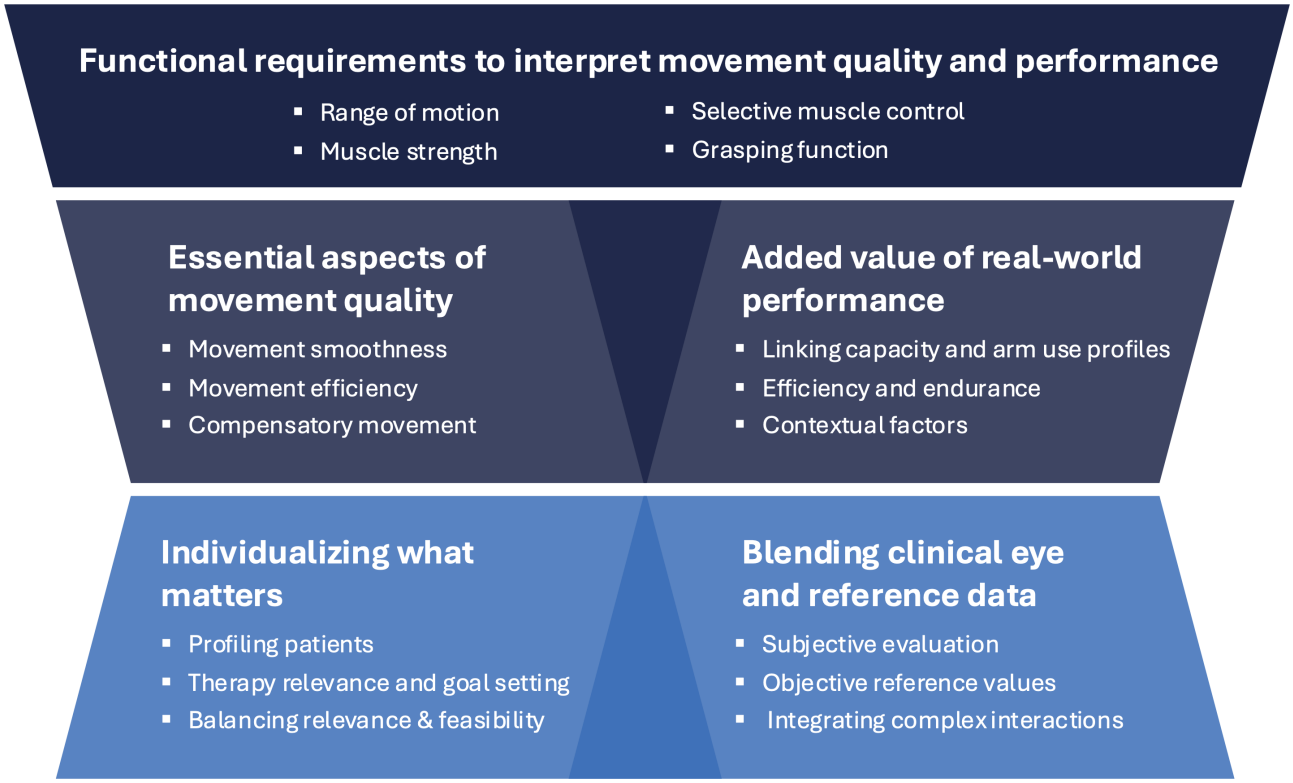
Figure 2. Themes and subthemes from the clinician focus group analysis illustrating the key dimensions guiding the interpretation and integration of *digital metrics of functioning*.



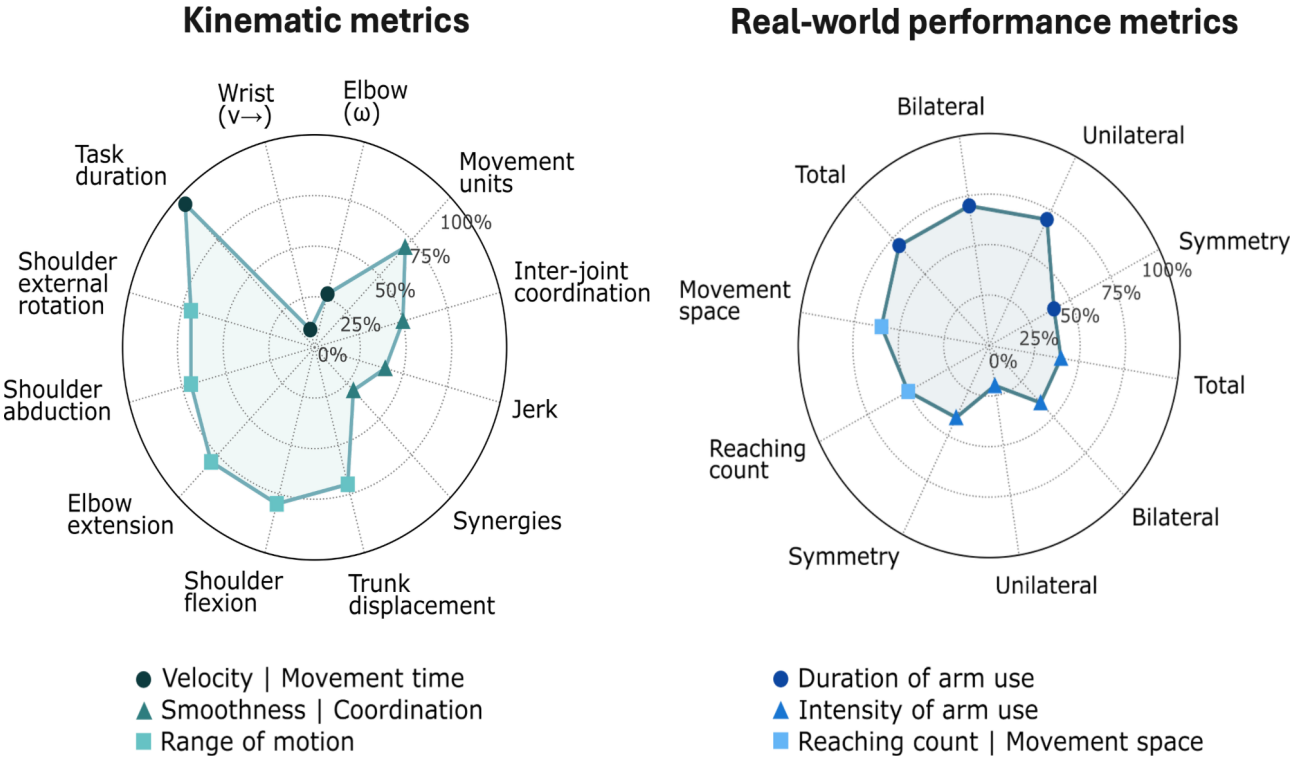


Figure 3. Radar plots representing the proportion of participants who rated each metric as meaningful and relevant for clinical practice. Kinematic metrics and real-world performance metrics, color-coded by metric domains. In the real-world performance panel, metrics with identical names (eg, symmetry) are distinguished by their domain (intensity vs duration), as indicated in the legend. Percentages represent the proportion of participants who rated each metric (0% at the center indicates no rating; 100% at the outer ring indicates all participants rated). The movement strategy domain was excluded from the *kinematic metrics* because no participant identified it as important. *v*→: velocity; ω: angular velocity. Detailed metric definitions and units are provided in Tables S2 and S3 in Multimedia Appendix 2.

XSL•FO
RenderX

Theme 1: Functional Requirements to Interpret Movement Quality and Performance

This theme outlines the functional requirements that clinicians considered essential for meaningful interpretation of movement quality, whether assessed through observational movement analysis or instrumented kinematic analysis. These prerequisites, typically assessed through standard clinical evaluations, provide the baseline context needed to interpret technology-based metrics. Participants highlighted 4 key aspects as particularly decisive for understanding upper limb performance: range of motion, muscle strength, selective muscle control, and grasping function (Table S1 in Multimedia Appendix 3).

Range of Motion

Participants consistently emphasized that both active and passive ROM must be known to interpret movement quality and determine whether upper limb ADL can be attempted. For instance, elevation above 90° was highlighted as necessary for tasks such as combing hair or reaching overhead [Q1]. Importantly, clinicians considered functional joint interaction, such as shoulder, elbow, and spinal mobility, as a whole rather than in isolation.

Muscle Strength

Assessing strength was considered an important complement to active ROM, as it provides information on stability and control during functional movements such as grasping or lifting objects. Rather than isolated maximal testing, participants preferred strength assessment in task contexts, as this better reflects real-world performance. One clinician noted that strength “is always somewhere in relation to mobility” [Q2].

Selective Muscle Control

The ability to activate muscles selectively, such as flexing the elbow while relaxing the extensors, was described as crucial for coordinated movement. Impaired selectivity, often linked with sensory-motor deficits, could lead to compensatory strategies or coexist with abnormal muscle tone [Q3, Q4]. Clinicians highlighted that such neuromuscular control issues strongly influence how movement quality should be interpreted.

Grasping Function

Finally, hand opening and grip strength were identified as the most practical tests of functional capacity. Grasping integrates ROM, strength, and selectivity into a single action and was considered indispensable for ADL tasks involving objects, such as drinking from a glass [Q5].

Taken together, these 4 requirements provide a functional foundation for interpreting movement analysis in clinical contexts. Without them, technology-driven assessments risk misrepresenting patients’ true abilities. Participants also noted that this information helps them *reason about the causes of impaired movement quality*, for example, whether limitations in ROM, strength, selectivity, or grasping contribute to observed difficulties.

Theme 2: Essential Aspects of Movement Quality

This theme highlights movement smoothness, efficiency, and compensatory movements as the 3 key attributes that clinicians use to judge movement quality in relation to the drinking task (Table S2 in Multimedia Appendix 3). These aspects capture how well movements are performed, how effortful they are, and whether patients rely on compensatory patterns.

Movement Smoothness

Participants referred to fluent versus jerky movement as meaningful indicators of movement quality [Q6.2]. Participants with research experience favored jerk as an intuitive single-value measure, whereas therapists were less familiar with such metrics. Although the concept of smoothness appeared familiar to therapists, they were not familiar with jerk or interjoint coordination, as reflected in ratings ranging from 4 (40%) to 5 (50%) across 10 participants (Figure 3). The *kinematic metrics* of the movement strategy domain for the drinking task were considered irrelevant or unintuitive and were not selected by any participant.

Movement Efficiency

Efficiency was understood as completing a task within a reasonable time and without visible strain. For instance, clinicians looked for speed and absence of effort cues, such as facial tension [Q7.1]. The metric *task duration* was indicated as important by all participants. The time required to complete a task was found to be an interesting factor in determining whether the task would be adopted into daily movement behavior. Quantitative prioritization echoed this emphasis: *task duration* received the highest mean rating among *kinematic metrics* (Figure 3).

Compensatory Movement

Compensatory movement, especially excessive trunk flexion or shoulder elevation, was considered a marker for adaptation to motor impairment [Q8.1]. Thus, clinicians were particularly interested in distinguishing between compensatory and physiologically correct movement. Participants found the analysis of compensatory movements challenging due to the dynamic interactions among multiple joints. Participants expected certain compensatory movement patterns involving the shoulder and torso [Q8.2, Q8.3], based on functional deficits highlighted in theme 1.

Theme 3: Added Value of Real-World Performance

Clinicians emphasized that *what patients do outside the therapy room* ultimately determines functional recovery. Three interrelated aspects of real-world performance framed this discussion: the amount and patterns of arm use, efficiency and endurance, and contextual factors influencing ADL behavior (Table S3 in Multimedia Appendix 3).

Linking Capacity and Arm Use Profiles

Participants valued continuous activity profiles across the day, with timing information to link activities to mealtimes or therapy sessions. Altered patterns, such as asymmetrical arm use, were flagged as essential indicators of disability and the need for intervention [Q9.1-Q9.3]. The ability to track both the amount and timing of use was seen as highly relevant for follow-up. Quantification of the functional workspace, as reflected in terms such as “volume” or “radius” of purposeful movement, was

XSL•FO
RenderX

considered highly relevant for capturing real-world performance [Q10] relative to instantaneous ROM and muscle strength [Q11].

Efficiency and Endurance

Clinicians emphasized that performance in everyday tasks depends not only on speed but also on the sustained capacity to repeat movements without excessive strain [Q10.1, Q10.2]. They noted that the effortless execution of a straightforward standardized task indicated a likely transfer into ADLs, whereas repeatedly eating or drinking at mealtimes required substantially more endurance due to the effortful nature of the movements [Q10.3]. This distinction between instantaneous efficiency and sustained endurance was considered central to judging functional outcomes.

Contextual Factors

Clinicians considered individual motivation, fatigue tolerance, and frustration levels, along with environmental influences such as assistive devices, to be crucial for real-world performance [Q11.1]. Wheelchair use was mentioned as particularly important, as it fundamentally shapes the range and types of upper limb movement available [Q11.2]. Such contextual modifiers were consistently described as necessary to interpret measures of arm-use volume and endurance in relation to each patient's capacities and circumstances.

Taken together, clinicians considered real-world performance metrics most clinically meaningful when they combined patterns of arm use with endurance and contextual information.

Theme 4: Individualizing What Matters

This theme underscores the importance of individualized selection of assessments, as standardized protocols often fail to capture patient-specific differences. Clinicians highlighted tailoring measures to priority ADLs, balancing functional relevance with feasibility, and adapting to diagnosis-specific challenges (Table S4 in Multimedia Appendix 3).

Profiling Patients

Patients with the same diagnosis often require different selective assessments depending on residual function, spasticity, or use of assistive devices. For example, transfers in paraplegic patients demand highly adaptive assessments of wheelchair transitions: One participant stated, "In our patient clientele, I would say that this is more in the direction of highly individualized functions rather than a one-size-fits-all model" [Q12.1]. As confirmed by another clinician, severely affected patients, in particular, require a problem-specific assessment in addition to standardized measurements [Q12.2]. Standardized protocols were mentioned as often not suitable, for instance, in patients with SCI, where residual function and spasms can be highly variable. Clinicians agreed that tailoring was especially important for patients with severe conditions and high support needs.

Therapy Relevance and Goal Setting

Goal setting and intervention, informed by individualized assessment, were other key components that emerged from expert discussions [Q13.1]. For example, *real-world performance metrics* were individually screened for patients prone to compensation or learned nonuse, and consequently, effective intervention programs, such as constraint-induced movement therapy or an individual tele-rehabilitation program [Q13.2], were selected. Participants would identify metrics indicating limitations in performing ADLs and evaluate potential changes in their real-world performance profile following the intervention. Therapy goals focus on enhancing specific functions that directly support meaningful activity improvements, with assessments tailored to measurable parameters and joints for active therapeutic intervention. Function alone is not considered a sufficient outcome measure if it is not translated into daily life activity [Q13.4].

Balancing Relevance and Feasibility

Active ROM and muscle strength were prioritized as the most relevant metrics, yet clinicians considered their feasibility and level of detail needed: "You also have to think about the clinic […] what can be measured in everyday clinical practice, or what is realistic here in a laboratory?" [Q14.1]. Basic information, such as whether the upper limb could be moved through full ROM against gravity, was sufficient to judge the patient's capability. Some questioned the value of standardized impairment measures, noting that "What we measure [in] muscle status does not mean that a patient can really use it in the activity" [Q14.2]. Real-world arm use was therefore considered more informative, though more challenging to capture feasibly in daily practice.

Theme 5: Blending Clinical Eye and Reference Data

This theme described how clinicians combine subjective observation, objective reference values, and reasoning across interacting constructs when interpreting movement analysis (Table S5 in Multimedia Appendix 3).

Subjective Evaluation

Clinicians agreed on the importance of visual movement analysis for primarily assessing functional impairment. Clinicians argued to "simply look" and identify how a problematic movement task begins, proceeds, and ends without formal quantification [Q15.1]. Thus, visual observation is an integral part of the therapeutic setting and a straightforward way to identify a motor problem. When exploring potential causes for abnormal movement characteristics (compensatory or jerky movement), taking a closer look at movement units and interpreting *kinematic metrics* became more interesting [Q15.4]. Despite the interest in movement quality, we identified generally cautious opinions on whether *kinematic metrics* would confirm visually flagged deficiencies or support interpretation [Q15.4].

Objective Reference Values

Reference values and normative data played important roles in interpretation and clinical implications. Participants expressed the need for reference values to compare patients with healthy individuals and to assess the meaningfulness of changes registered by *digital metrics of functioning*. Normative data from healthy individuals were consistently mentioned for interpreting movement smoothness metrics (eg, jerk or multijoint coordination). The comparison between the left and right upper limbs was considered a practical norm for patients with unilateral impairments such as stroke [Q16.1]. For bilateral

XSL•FO
RenderX

conditions like SCI, however, clinicians emphasized that reference to healthy controls was crucial [Q16.5]. Yet even when normative data were available, interpreting *kinematic metrics* remained challenging. Because daily movement behaviors are highly variable, applying and comparing such benchmarks to real-world performance was approached with caution [Q16.6].

Integrating Complex Interactions

Clinicians acknowledged the difficulty of disentangling the interrelationships among strength, ROM, coordination, and sensation, which often jointly shape real-world performance. Deviations in smoothness or interjoint coordination were seen as cues to probe underlying impairments, such as force deficits, motor control issues, or sensory loss [Q17.1-Q17.7]. They also emphasized that movement quality (*kinematic metrics*) and *real-world performance metrics* are closely interrelated and that only empirical experience with these measures in practice will build the expertise needed to interpret them reliably [Q17.7]. While movement quality and real-world performance were considered central to clinical reasoning, clinicians acknowledged limited experience applying these metrics and anticipated that their value might shift as they are used more widely in clinical contexts.

Discussion

This study examined clinicians' views on the constructs that underpin functional health, identified which *digital metrics of functioning* were considered clinically meaningful, and outlined what is needed for intuitive integration into clinical systems. Clinicians reasoned across *functional requirements*, *kinematic* and *real-world performance metrics*, while tailoring judgments to the individual and anchoring observations to reference information. Together, these themes demonstrate how *digital metrics of functioning* can become clinically interpretable when integrated into patient-specific reasoning and contextualized within conventional assessment frameworks.

Functional Requirements as the Foundation

With respect to objective 1, clinicians emphasized that ROM, strength, selective muscle control, and grasping function form the foundation for functional health and for the interpretation of movement analysis. Testing functional requirements (eg, passive ROM) is recommended as critical before conducting standardized observation-based assessments, such as the Fugl-Meyer Assessment for Upper Extremity (FMA-UE) [42] and the Action Research Arm Test (ARAT) [43]. The FMA-UE and ARAT are core assessments for stroke [8,11]. They also serve as a reference for identifying benchmark *kinematic* [21,44] and *real-world performance metrics* [29,45] in individuals with neurologic conditions. Notably, impairment measures and *digital metrics of functioning* are not only highly correlated but also exhibit similar recovery trajectories [46,47]. These relationships are robust yet not interchangeable: task instructions (eg, maximal speed vs comfortable speed) and compensatory movements can alter kinematic profiles without corresponding changes in impairment. The reliance on basic impairment and capacity assessment reflects long-standing rehabilitation research. Our findings reinforce that *digital metrics of functioning* should complement rather than replace these clinical assessments.

Digital Metrics of Functioning: Relevance and Meaning

Considering objective 2, the clinicians prioritized *digital metrics of functioning* that are simple, familiar, and intuitively interpretable. In our study, the drinking task duration, number of movement units, trunk displacement, and dynamic motion trajectories of the elbow and shoulder joints were the metrics consistently selected across professions. These metrics have previously shown good reliability [48] and responsiveness (ie, sensitivity to change over time) [47] in stroke populations, and also inform observation-based assessment of drinking tasks [49]. While these metrics were evaluated in the context of the drinking task, the underlying constructs they represent, such as movement efficiency, smoothness, and compensatory strategies, are relevant across a range of functional upper limb activities. Quantifying upper limb movement quality has been found to be critical for assessing and preventing compensatory movements [38], particularly abnormal interactions among shoulder, elbow, and trunk motion trajectories [25,49,50]. Clinicians in our sample found quantification of compensatory movements or movement intermittency/jerk particularly important, as these metrics could help explain a person's limited real-world arm use outside the therapy setting.

Performance Outside Therapy

Revealing patients' activity performance outside inpatient therapy sessions, or even in habitual environments, is considered highly relevant by clinicians in this and other cohorts [51-54]. This insight into real-world arm use behavior enables goal setting and evaluation. This performance-centered clinical decision-making may be enhanced when therapists are provided with sensor-based measures [51,53,55], whereas therapists showed a preference for activity capacity measures [56].

Advances in measurement technology and data processing enable differentiation of activity types, such as walking [57,58], distinguishing functional from nonfunctional upper limb movements [59,60], and even movement primitives, such as reaching or object transportation [61,62]. About half of the therapists in this study selected more specific metrics, such as reaching count and movement space, which were also reported in other studies on clinicians' preferences [38,63]. Therapists in our study emphasized daily arm use behavior, which is effectively captured by arm-use duration metrics, including symmetry, both of which are recognized as key indicators in stroke rehabilitation research [28,29,64]. Performance duration metrics are intuitive and straightforward because they directly measure time, making them easy to understand without additional context. Notably, therapists working in rehabilitation after SCI did not consider symmetry metrics important, which lowered the overall percentage of symmetry metrics. Consistent with theme 4 (individualizing what matters), this suggests that metric relevance is shaped by diagnosis-specific reasoning: in unilateral conditions such as stroke, between-limb symmetry is a meaningful comparison, whereas in bilateral conditions such as SCI, it loses interpretive value. Selection of real-world performance metrics should therefore be aligned with the clinical population rather than applied uniformly.

XSL•FO
RenderX

Reference and Context for Interpretation

Revealing the meaning behind naked numbers can be challenging and requires complementary information, especially for clinicians who lack experience and knowledge about metrics and their psychometric properties. With respect to objective 3, clinicians expressed a need for visual references and normative data to interpret *kinematic metrics*, as well as contextual information and normative data for *real-world performance metrics*. Daily arm use performance can be highly variable, influenced by numerous factors, including health status, activity limitations, functional impairment, personal, and environmental factors [35]. To support interpretation and informed decision-making, clinicians in this study expressed a need for population-specific reference data, alongside cutoff values (eg, percentiles, visual benchmarks, or expected recovery trajectories), to determine whether observed changes are clinically meaningful. In clinical settings, aligning data with daytime and therapy schedules is a practical way to contextualize performance metrics to activity type [51,65]. For goal setting and evaluating therapy effectiveness, the minimal detectable change (MDC) and minimal important change (MIC) are important references for within-person change. Consequently, the successful integration of *digital metrics of functioning* into clinical reasoning depends on their linkage to patient-specific contexts, diagnostic-specific expectations, and usable normative data to inform treatment planning and progression. Benchmarking schemes for upper limb *kinematic* and *real-world performance metrics* [66], together with patient-centered benchmarking approaches [67], offer concrete frameworks that translate changes in *digital metrics of functioning* into actionable targets for neurorehabilitation practice.

Future Directions

Electronic health records are the backbone of information collection and sharing among clinical professionals. An integration of continuous monitoring of *digital metrics of functioning* could enable personalized rehabilitation, provide richer representations of a patient's health status, and enable timely detection of recovery plateaus or declines in real-world performance. To ensure clinical interpretability across heterogeneous neurorehabilitation populations, robust reference datasets are needed that include healthy controls and relevant patient groups, stratified by diagnosis, age, hand dominance, and impairment level. For *kinematic metrics*, task-specific benchmarks for validated tasks, such as the drinking tasks [25,48,68], could provide z-scores or percentiles alongside MDC/MIC thresholds. For *real-world performance metrics*, normative data and MIC thresholds exist but remain limited to stroke populations [29].

Future research should explore the optimal convergent set of meaningful, intuitive information that is accessible through graphical illustration. Nearly a decade ago, Ploderer et al [69] proposed dashboard designs that bring together ROM, kinematic analyses, hourly activity patterns, and 3D functional workspace visualizations. The need for integrated, actionable displays remains, but infrastructural and implementation barriers continue to slow adoption [70,71]. Currently, measurement technologies that capture upper limb *digital metrics of functioning*, such as 3D trajectory analysis and ADL movement space and task detection, remain largely impractical for routine clinical settings. Advances in scalable sensor- or computer vision-based systems are therefore crucial for facilitating precise, clinically relevant visualizations of *kinematic metrics* and functional reaching space during ADL.

Building on the identified clinical reasoning priorities, Weikert et al [72] developed a learning health system embedded in clinical neurorehabilitation practice. This integrated learning health system enables an end-to-end evaluation of multimodal patient data capture and clinical data presentation. These systems aim to integrate kinematics [73], performance data, cognitive/mental status, patient-reported outcomes, speech, sleep, nutrition, and contextual information (including therapy schedules and temporal patterns) [72]. A key principle for clinical embedding is that clinician-facing outcomes must provide meaningful information to ensure adherence and acceptance.

Such systems directly address two priorities raised by our participants: blending objective metrics with contextual reference information (theme 5) and combining task-based capacity with real-world performance profiles (theme 3). Realizing this potential, however, requires systematic evaluation of the system components, the clinical utility [74], usability [75,76], and the real-world effectiveness of new digital outcome domains. Ultimately, a multipronged approach comprising clinical value systems [77], educational programs, and user-friendly data capture is needed to introduce precision neurorehabilitation at scale [78-80].

Training programs should align with recognized digital-health competency frameworks [81,82] to ensure clinicians acquire the knowledge, skills, and attitudes needed to interpret and act upon *digital metrics of functioning*. As demonstrated in electronic health record–based educational initiatives, targeted modules on dashboard use and metric literacy can improve clinician proficiency in real-world data-driven workflows [83]. In the present context, educational efforts should therefore focus on foundational metric interpretation and practical integration of *digital metrics of functioning* into routine decision-making. Such programs could serve as an educational scaffold for translating digital metric evidence into individualized, data-informed rehabilitation planning.

Limitations

This study was conducted in 3 Swiss rehabilitation clinics, which may limit transferability to other health care systems, settings (inpatient vs. outpatient), and languages/cultures. The low participation rate (3/8 clinics, 38%) was primarily due to organizational constraints in releasing multiple clinicians simultaneously for a 90-minute focus group discussion. Recruitment through clinic nomination may have favored clinicians who are more open to digital assessments, potentially more optimistic in their perspectives, although skeptical views also emerged during the focus groups.

The small number of focus groups and the limited number of participants per group may have influenced group interaction dynamics and the breadth of perspectives discussed. Given the

XSL•FO
RenderX

limited number and size of focus groups, thematic saturation cannot be assumed. Furthermore, the small group sizes and site-specific sampling limit the transferability of the findings to clinics with a broader mix of patient populations. Consistent with the exploratory qualitative design, we aimed to provide information-rich insights rather than comprehensive coverage. Accordingly, our findings should be interpreted as exploratory and context-dependent rather than representative or generalizable.

The concept of "relevance" was not operationalized using predefined criteria during the focus group discussions. This approach was chosen to allow clinicians to articulate their own interpretations and reasoning processes. However, participants may have interpreted the term differently, for example, in terms of clinical usefulness, familiarity, feasibility, or patient-centeredness. Such variability may introduce construct ambiguity or response-process bias. While the qualitative analysis allowed us to capture these perspectives through thematic interpretation, future studies could benefit from more explicit operationalization or structured rating criteria.

In addition, the variation in clinicians' prior experience with *digital metrics of functioning* may have influenced interpretations. Future research should examine how perspectives differ across professional roles, experience levels, and clinical contexts and assess the impact of targeted training and exposure on the interpretation of *digital metrics of functioning* in clinical routine.

Moreover, participants were shown an example of a patient performing a drinking task and were evaluated using kinematic metrics validated in this context to provide a tangible, standardized reference and ensure a common frame of reference. While this approach supported understanding of abstract kinematic concepts, presenting a specific task and task-validated metrics may have introduced contextual bias and may limit the full generalizability of the findings.

Both moderator and co-moderator were clinician-researchers, introducing potential social desirability bias despite reflexive views. To mitigate this risk, analytic decisions and theme development were documented through saved versions of code structures, cluster maps, and theme definitions, allowing us to track the evolution of codes and themes.

Finally, we focused on the clinical significance of *digital metrics of functioning* while intentionally setting aside practical constraints. The feasibility, usability, and data-quality requirements of instrumented assessments (eg, sensor setup and maintenance, nonwear detection, calibration procedures, processing resources, and data privacy demands) warrant dedicated evaluation before routine deployment.

Conclusions

This exploratory study mapped how clinicians in Swiss neurorehabilitation interpret and prioritize digital metrics of functioning of the upper limb. Participants valued *kinematic* and *real-world performance* metrics when they were embedded in patient-specific reasoning and paired with contextual information. They consistently favored intuitive metrics, such as task duration, number of movement units, and ROM, over more complex measures whose interpretation requires specialized knowledge. Across the five themes, three priorities emerged for translating digital metrics of functioning into routine practice: (1) stratified normative and reference datasets and meaningful change thresholds, integrated into co-designed dashboards that link task-based kinematic metrics to daily activity profiles; (2) targeted training that builds metric literacy and supports interpretation alongside conventional clinical reasoning; and (3) scalable measurement technologies that integrate seamlessly into clinical workflows, evaluated pragmatically for decision impact, usability, and adoption. These findings should be interpreted as context-dependent rather than generalizable, given the small number of focus groups and the specific clinical and organizational settings sampled. Perspectives are likely to vary across health care systems, professional backgrounds, and levels of experience with digital assessments. Nonetheless, the convergence across professions and clinics on the need for interpretability, contextualization, and clinical embedding offers a clear direction for future work. Centering on clinician and patient preferences will be essential for meaningful integration of *digital metrics of functioning* into clinical practice and for narrowing the evidence-practice gap.

Acknowledgments

The authors would like to thank André Boeni for his valuable support in developing the interview guidelines and conducting the pilot focus groups, and Selina Tanner for administrative support during the first focus group session. We would also like to thank all the volunteers who participated in the study, as well as Sandra Stadelmann for assistance with transcriptions and data administration.

Funding

This work was funded by the P&K Puhringer Foundation.

Data Availability

Due to the qualitative nature of the data and the inclusion of potentially identifiable video and audio material, the raw focus group data (recordings and transcripts) cannot be publicly shared. Deidentified extracts supporting the study findings are included in Multimedia Appendices 2 and 3. Additional anonymized excerpts or coding summaries may be shared by the corresponding author upon reasonable request, subject to ethical and institutional data protection requirements.

Authors' Contributions

JP conceived and led the study, including conceptualization, methodology design, and overall supervision. JP moderated the focus groups with LM as co-moderator and revised the interview transcriptions for correctness. JP and LM conducted data labeling and thematic analysis. JP created all visualizations and drafted the manuscript, with LM contributing complementary sections and revisions. CEA and OL provided critical review, interpretation of findings, and editorial feedback on the final manuscript.

Conflicts of Interest

Some authors (JP, CA) were involved in early pilot work related to the described learning health system; however, this work was conducted in a noncommercial research context and does not constitute a conflict of interest.

Abstract

Background: Persisting symptoms affect about one-third of youth following concussion. Mental health history, distress, and coping style are key predictors of prolonged recovery. Early and scalable psychological interventions, such as mindfulness-based intervention (MBI) delivered via smartphones, may improve patients' ability to regulate their emotions and neurophysiologically recover, reducing overall symptom burden. However, no digital therapeutic (DTx) trials in adolescents experiencing concussion exist.

Objective: This study primarily aimed to assess the feasibility of conducting a larger randomized controlled trial (RCT) evaluating the effectiveness of a DTx-MBI in adolescents with a concussion compared with an attention-matched sham intervention.

Methods: This was a Health Canada-regulated, parallel-group, blinded, single-crossover feasibility RCT. Adolescents aged 12 to <18 years presenting to a Pediatric Emergency Department or interdisciplinary concussion clinic within 7 days of a physician-diagnosed concussion were approached for participation from November 2022 to June 2024. After providing consent, participants were randomized (1:1), stratified by sex, to either the experimental group (DTx-MBI) or the control group (sham, attention-matched math puzzle game). The DTx-MBI was delivered via the AmDTx platform (Mobio Interactive Pte Ltd, Singapore) as a custom-designed 4-to-8-week program of 8 standardized modules for adolescents with concussion, including audio-recorded guided mindfulness exercises, goal setting, journaling, and psychoeducation. The control intervention, delivered through the same interface, excluded mindfulness content and instead featured the open-source game "2048". Participants in both groups were encouraged to engage with the app for at least 10 minutes/day, at least 4 days/week. Feasibility criteria to support progression to a full-scale RCT included: eligibility rate >40% of those screened; recruitment rate >50% of eligible participants randomized; intervention credibility >70% scoring above the midpoint on the credibility and expectancy questionnaire (CEQ) at 1 week; retention >75% of randomized participants completing 4-week outcomes; and adherence >70% completing 10 minutes of intervention on at least 4 days/week for 4 weeks.

Results: A total of 124 out of 195 (63.6%) screened youth met eligibility criteria. Of these, 99/124 (79.8%) consented and were randomized to either the DTx-MBI group (n=49, median [IQR] age=15.28 [13.66 - 16.19] years, 30 [61.2%] female) or the Sham group (n=50, median [IQR] age=14.92 [13.32 - 16.71] years, 30 [60.0%] female). Credibility was high, with 62/83 (74.7%) of participants scoring above the credibility midpoint (DTx-MBI: 75.0%; Sham: 74.4%). Retention was strong, with 89/99 (89.9%) of participants completing the 4-week outcomes (DTx-MBI: 89.8%; control: 90.0%). Overall adherence was moderate (54/99

XSL•FO
RenderX

[54.5%]; DTx-MBI: 59.2%; control: 50.0%), and a little higher among outcome assessment completers (53/89 [59.6%]; DTx-MBI: 63.6%; Sham: 55.6%). Feasibility indicators were similar between groups.

Conclusions: This feasibility trial supports the implementation of a larger RCT, with modifications to enhance adherence, to rigorously evaluate the clinical efficacy of the DTx-MBI. By targeting modifiable psychological risk factors through a scalable digital platform, DTx-MBI could be a low-burden, cost-effective adjunct to pediatric concussion care.

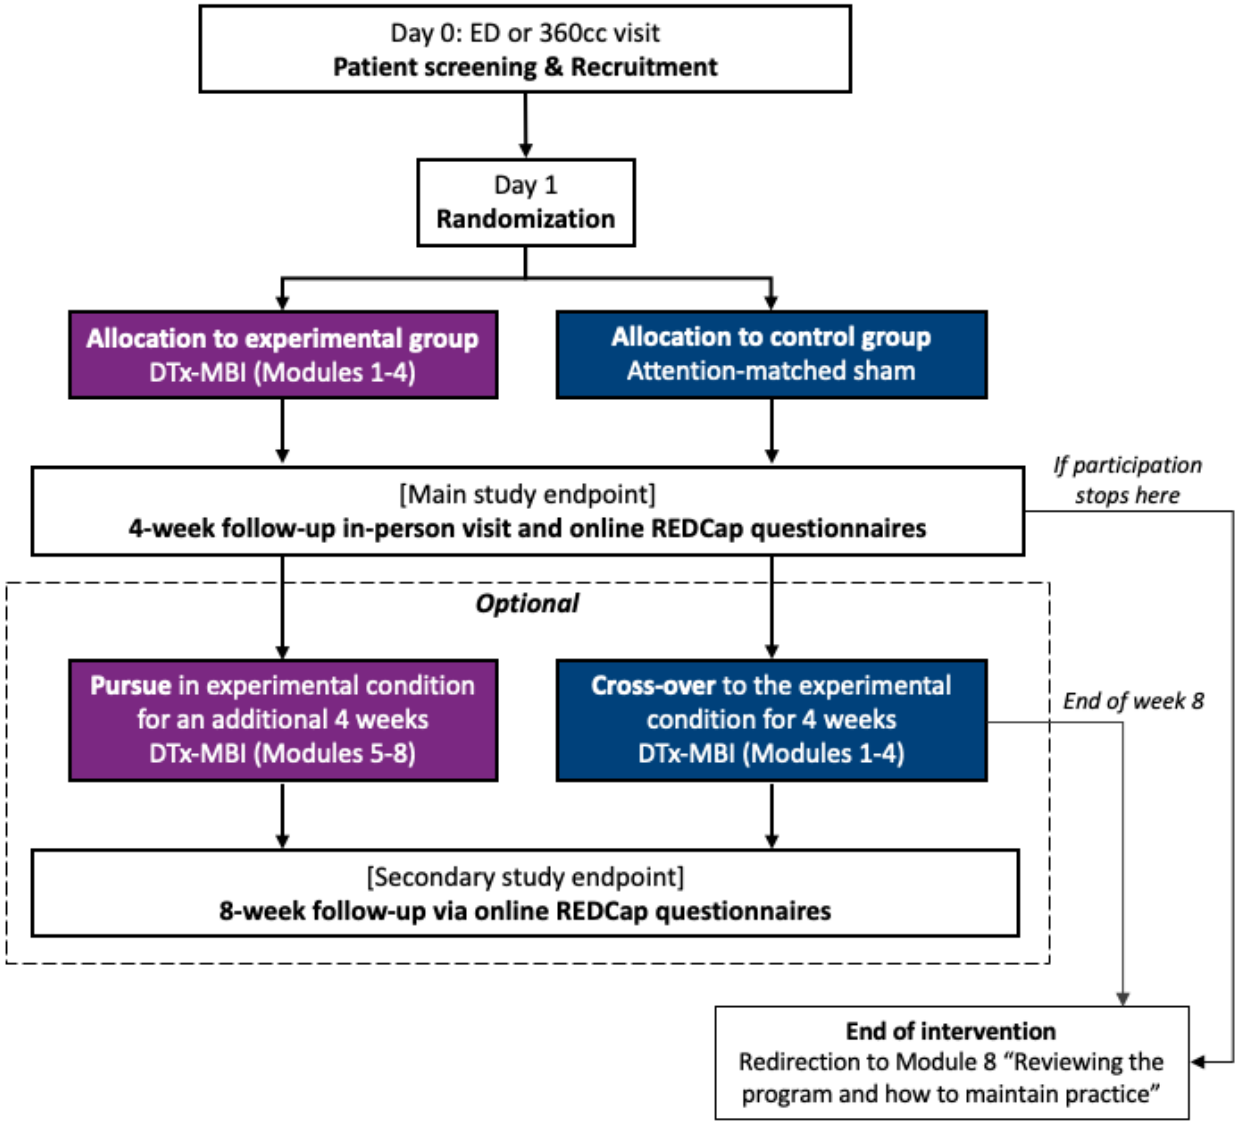
Introduction

Approximately one-in-three children sustaining a concussion develop persisting symptoms after concussion (PSAC), defined as ongoing physical, cognitive, emotional, and sleep symptoms that persist beyond 4 weeks postinjury [1], and may persist for months [2,3]. PSAC can disrupt academic performance, reduce social engagement, and increase susceptibility to substance use, depression, anxiety, and suicidal ideation [4-7]. Youth recovering from a concussion face an elevated risk of mental health challenges, including a 40% increased likelihood of developing psychiatric disorders, a 47% higher risk of hospitalization for psychiatric conditions, and a 49% increased risk of self-harm behaviors compared with age- and sex-matched youth with an orthopedic injury [4]. Both injury-related and non-injury-related factors contribute to PSAC [3,8,9]; however, the influence of injury-specific factors tends to diminish over time. In contrast, premorbid factors, such as somatic symptoms [10], migraines [3], cognitive difficulties [11], attention and mood disorders [12], anxiety [13], and maladaptive coping strategies [13], remain strong predictors of prolonged recovery [10,14]. Early interventions that bolster psychological resilience and emotional regulation may be critical in mitigating symptom burden and preventing chronicity [11,14].

Mindfulness-based interventions (MBIs) offer a promising approach by promoting present-focused practices that cultivate nonjudgmental awareness of thoughts and emotions, thereby improving affect regulation and reducing psychological distress [15]. MBIs have been shown to enhance attention, cognitive flexibility, emotional well-being, and academic performance in children, while reducing anxiety, depressive symptoms, affective reactivity, and fear [16]. In addition, MBIs have been shown to reduce default mode network (DMN) hyperactivity across clinical and pediatric populations [17-22], and since concussion similarly involves DMN disruptions [23-27], MBIs may confer neurophysiological benefits postconcussion. MBIs may target several known preinjury risk factors for PSAC, including mood disorders [28-30], somatization [28,31,32], headache disorders [33], and chronic pain [34]. MBIs may improve fatigue, depression, self-efficacy, and quality of life in individuals of different ages with persistent symptoms following mild-to-moderate traumatic brain injuries, including concussions [35-38]. However, these in-person programs are often costly, time-intensive, and not always accessible [35-38]. Digital therapeutics (DTx) have emerged as scalable tools for delivering psychological interventions. Evidence supports the effectiveness of brief web-based MBIs in reducing anxiety, perceived stress, and negative mood across different populations [39-43]. Moreover, a recent meta-analysis found that app-based MBIs show small to moderate effectiveness in improving stress, mood, and quality of life among users without a recent concussion [44]. However, the use of short, app-based DTx-MBIs in pediatric concussion remains unexplored.

This study aimed to assess the feasibility of conducting a larger randomized controlled trial (RCT) evaluating the effectiveness of DTx-MBI to reduce symptom burden and reduce risk of PSAC in youth with a concussion compared with an attention-matched sham intervention by examining recruitment efficiency, intervention credibility, intervention adherence, and participant retention rates at week 4 postenrollment. The secondary research objectives included the following. (1) Determine the participants' treatment expectations and satisfaction with both interventions. (2) Explore potential efficacy signals across clinical outcomes (ie, concussion symptoms, quality of life, fatigue, anxiety, depression, resiliency, self-efficacy, mindfulness, and cognitive function) to inform future sample size calculations. (3) Examine safety by comparing adverse events between interventions. (4) Assess the feasibility of incorporating a neuroimaging component into the larger trial by examining recruitment and retention for the neuroimaging subset, as well as intervention credibility and intervention adherence among participants who completed neuroimaging (Multimedia Appendix 1 [26,45]). (5) Explore differences in baseline characteristics, adherence, and attrition rates between the experimental group and control group. Experimental group: participants who decided to complete the study at 4 weeks and participants who continued for an additional 4 weeks of MBI for weeks 5 - 8; Control group: participants who decided to complete the study at 4 weeks and who crossed over to the experimental intervention for weeks 5 - 8 (Multimedia Appendix 1 [26,45]).

Methods



Study Design

This Health Canada-regulated feasibility RCT (ClinicalTrials.gov: NCT05105802) used a parallel-group (1:1), blinded, single-crossover design. Participants in the control

XSL•FO
RenderX

group who completed the initial 4-week study and wished to pursue the experimental intervention crossed over (modules 1 - 4) during weeks 5 - 8, while those in the experimental group could extend their MBI training for an additional 4 weeks (modules 5 - 8; Figure 1). To maintain focus on the primary endpoints, only the 4-week outcomes are presented in the main text; week-8 outcomes are reported in Multimedia Appendix 1 [26,45]. Methods and results of the feasibility of the magnetic resonance imaging (MRI) component are presented in Multimedia Appendix 1 [26,45].

Ethical Considerations

This study was approved by the Research Ethics Board (protocol #20/720X) of the Children's Hospital of Eastern Ontario (CHEO) Research Institute in August 2020. Authorization from Health Canada was granted in July 2022. The study was carried out according to the principles outlined in the Declaration of Helsinki and Good Clinical Practices, and within the laws and regulations of the Tri-Council Policy Statement.

Before consent was sought, the study was introduced, and its purpose was explained verbally. The consent form also presented the purpose of the research, the procedures, potential risks and benefits, and the use and security of the data. Informed written consent was obtained from the parents, and participants were deemed capable of consenting. Informed assent was obtained from the participants deemed by the research assistant (RA) to be cognitively unable to provide informed consent.

The participants were remunerated with a CAD $20 (US $15) gift certificate (eg, Tango) for completing surveys. Participants received an additional CAD $20 (US $15) gift certificate for completing the MRIs. The gift certificate was sent electronically to their email address. They also received a parking voucher or vouchers for in-person meetings and a letter attesting that they have completed 20 hours of volunteer work (5 hours per week completing the intervention).

Participant information was coded using study identification numbers. Research personnel took all appropriate and customary

XSL•FO
RenderX

steps to ensure that data remain secure and that patient privacy and confidentiality are maintained.

Procedures

The full protocol was published previously [46]. Briefly, participants were recruited from the CHEO emergency department (ED) and the 360 Concussion Care (360cc) clinic, an interdisciplinary tertiary health clinic in Ottawa, from October 2022 to June 2024. Families of adolescents with a concussion were approached by an RA to discuss the research study. Interested families completed a screening form on a tablet with the RA, and if eligible (concussion confirmed by a physician) and enrolled, filled out electronic questionnaires via Research Electronic Data Capture (REDCap) [4748] to collect patient demographics, diagnostic history, injury characteristics, and a concussion symptoms checklist.

The day after the ED or 360cc visit, an RA called participants to randomize them into either the experimental or control group. They provided instructions for installing AmDTx on the participant's mobile device of their choice. Participants completed Day 1 surveys by phone or via REDCap and began the intervention that same day. At the 4-week mark, participants attended an in-person appointment to complete the cognitive testing at either the CHEO Research Institute or the Royal Ottawa Hospital (for those enrolled in the neuroimaging component; see below). After this visit, participants in the experimental group were offered 4 additional weeks of psychoeducation modules and mindfulness practices. Control group participants were given the option to cross over and begin the DTx-MBI. Follow-up questionnaires were completed on REDCap at 1, 2, 4, and 8 weeks. A subset from each group was prospectively approached and enrolled for a neuroimaging (Multimedia Appendix 1 [26,45]).

Randomization, allocation concealment, and blinding

Participants were randomly assigned to one of 2 groups using a 1:1 allocation ratio stratified by sex. (1) Experimental group: DTx-MBI program, or (2) control group: sham digital attention-matched puzzle game. The CHEO Clinical Research Unit provided data management services for this study and retained randomization codes. A statistician who was not involved in the study created and maintained the master list.

Only the RAs responsible for randomization and app setup were unblinded to participants' group assignments, as this was necessary for intervention setup and delivery. These RAs were blinded to the randomization sequence until the point of group assignment and were not involved in outcome assessment or data analysis.

During the consent process and follow-up, we gave controlled information to participants about both interventions, while keeping them unaware of the hypothesis, design, and treatment assignment (experimental or control). The study hypothesis and the distinction between experimental and control conditions were disclosed only at the 4-week follow-up, at which point DTx-MBI participants could choose to extend their intervention and the Sham participants could cross over to the experimental condition.

Participants

Adolescents presenting to the ED or 360cc within 7 days of sustaining a direct or indirect traumatic brain injury were eligible to participate if they: (1) were aged 12 to <18 years; (2) had a diagnosed concussion (by a physician); (3) had 1 highest level of certainty symptom (eg, loss of consciousness, posttraumatic amnesia) or 2 higher level of certainty symptoms (eg, nausea/vomiting, headache) immediately or within 1 hour of injury from the adapted version of the Centers for Disease Control and Prevention tiered framework [49]; (4) had a score of >4 on the Predicting and Preventing Postconcussive Problems in Pediatrics clinical risk score, a validated prediction score to identify those at risk of poorer outcomes at 4 weeks postinjury [3]; (5) were proficient in English.

Patients were excluded if they presented with traumatic brain injuries with any of the following: (1) Glasgow Coma Scale score of ≤13; (2) trauma-related abnormality on standard neuroimaging studies (if performed) [50]; (3) neurosurgical operative intervention, intubation, or intensive care required; (4) multisystem injuries with the treatment requiring hospital admission, operating room, or procedural sedation in ED; (5) severe neurological developmental delay resulting in communication difficulties; (6) intoxication to alcohol or drugs at the time of ED/360cc presentation as per clinician judgment; (7) no clear history of head trauma as the primary event to the concussion (eg, seizure and migraine attack); (8) prior psychiatric hospitalization; (9) inability to obtain written informed consent or assent; (10) legal guardian not present (certain forms needed to be completed by parents or legal guardians); (11) no internet and mobile or tablet access; and (12) was in psychological therapy at enrollment.

Intervention

Experimental Group: DTx-MBI

The DTx-MBI program was delivered via the AmDTx platform and consisted of a 4-to-8-week, custom-made program (containing 8 psychoeducation modules) for adolescents with concussions, including goal setting, check-ins on mood and stress, audio-recorded psychoeducation, guided meditations, and journaling. Each standardized module was unlocked as the participant progressed through the program. Participants were encouraged to participate in the DTx-MBI activities for at least 10 minutes every day, for a minimum of 4 days/week over the study period. Those who chose to end their participation at the end of week 4 were immediately directed to module 8, "Reviewing the program and how to maintain practice," while those who decided to continue moved on to modules 5 through 8. The DTx had previously undergone pilot testing demonstrating acceptability, credibility, and usability [51].

Control Group: Attention-Matched Sham Comparator

The sham digital math puzzle was delivered on the same main interface within AmDTx, including the Snapshot (see below); however, these participants did not have access to any of the MBI training or psychoeducational content. The sham DTx was the open-source math game called "2048", developed by Gabriele Cirulli [52]. The game required participants to slide numbered tiles on a grid and combine matching numbers, aiming

XSL•FO
RenderX

to reach 2048 by creating larger numbers through merges. Each move adds a new tile, and the game ends when the grid is full with no possible merges. The game is programmed to only be accessible for 10 minutes per session. The selected control task has precedent as a digital comparator and has shown no effects on stress, psychological well-being, or symptoms in prior studies [42,53].

Snapshot

AmDTx includes 4 simple tools for tracking patient well-being over time, collectively called the Snapshot, in which participants in both groups were prompted to complete before and after each session:(1) 30-second "selfie" video analyzed via photoplethysmography [54] and a deep neural network to quantify psychological stress from heart rate [55] (2) a digital emotion mapping board (circumplex) to capture emotional stress levels; (3) a subjective stress slider, benchmarked against standard psychological surveys [42]; and (4) an open-text personal notes field. The snapshot feature qualified as meaningful engagement; however, completing the snapshot alone did not fulfill the requirement.

Standard of Care

All participants received standard-of-care [56] instruction pamphlets provided by RAs in the ED or at 360cc. The pamphlet includes advice to refrain from physical and cognitive exertion for the first 24 to 48 hours after injury. After the initial rest period, low-to-moderate levels of physical and mental activity can be started, including screen time, provided that the activities do not cause a recurrence or exacerbation of symptoms. It further advises that adolescents avoid activities with an increased risk of reinjury until fully asymptomatic and cleared by their primary care or other medical providers. The study intervention was therefore intended as a supplement to usual care rather than a replacement for standard concussion management.

Measures and Outcomes

Primary Outcomes

The prespecified feasibility targets for progressing to a definitive trial were informed by established benchmarks from previous feasibility trials [57,58] and our experience recruiting pediatric concussion patients from the ED [59]. We used a traffic light system to assess the feasibility of proceeding to a full-scale trial [60]. Progression is classified as feasible without modifications (green), feasible with adjustments (amber), or infeasible due to unresolvable issues (red). Advancement to a full-scale trial is determined by the criterion with the least favorable performance. The 5 prespecified targets are outlined in Table 1. Credibility was assessed using the CEQ (questions 1 - 3) at week 1 postenrollment [61], and retention was defined as completing the health behavior inventory at the 4-week follow-up [62].

Table . Feasibility benchmarks and performance.

Feasibility outcomes	Prespecified benchmark		
	Green zone (go)	Amber zone (amend)	Red zone (stop)
Eligibility	>40% of patients screened are eligible	20% - 40% of patients screened are eligible	<20% of patients screened are eligible
Recruitment	>50% of eligible patients are randomized	30% - 50% of eligible patients are randomized	<30% of eligible patients are randomized
Credibility	>70% of participants score above the scale mid-point[a]	50% - 70% of participants score above the scale mid-point[a]	<50% of participants score above the scale mid-point[a]
Retention	>75% of participants complete the follow-up assessment at 4-week[b]	50% - 75% of participants complete the follow-up assessment at 4-week[b]	<50% of participants complete the follow-up assessment at 4-week[b]
Adherence	>70% of participants complete the minimal requirement (ie, 10 minutes of activity, 4 times/week)	50% - 70% of participants complete the minimal requirement, that is, approximately (ie, 10 minutes of activity, 4 times /week)	<50% of participants who completed the outcomes complete the minimal requirement (ie, 10 minutes of activity, 4 times/week)

[a]Credibility and expectancy questionnaire questions 1 to 3.

[b]Health behavior inventory.

Secondary Outcomes

Treatment expectancy was assessed with the CEQ (questions 4 to 6) at week 1 after enrollment [61]. Expectancy was considered good if >70% participants scored above the midpoint.

Intervention satisfaction was assessed with the modified version (to align with the digital nature of the intervention) of the Client Satisfaction Questionnaire at 4 weeks [63]. The intervention was deemed satisfactory if >70% of participants scored above the midpoint on the questionnaire.

Safety of the MBI was determined by capturing and monitoring the worsening of symptoms and adverse events associated with the app or intervention. Adverse events were defined as any unscheduled visits to the ED or primary medical providers because of exacerbation of symptoms during the study participation. Events were considered intervention-related if they involved symptom provocation during or within 30 minutes of DTx use. The determination of whether an adverse event was related to the intervention was made by the Qualified Investigator, based on predefined criteria established by the Data and Safety Monitoring Board and reviewed by the institutional quality assurance and regulatory compliance personnel. Participants were asked about possible adverse events at the 1-, 2-, 4-, and 8-week follow-ups.

XSL•FO
RenderX

Other outcome measures were collected at baseline (in the ED or on day 1 for 360cc) and at 4- and 8-week follow-ups, unless otherwise specified:

- Symptom burden: Health behavior inventory, assessed retrospectively for preinjury and acute postinjury symptoms, with additional assessment at 1 and 2 weeks follow-ups [62];
- Quality of life: Pediatric Quality of Life Inventory (PedsQL, version 4.0) [64,65];
- Fatigue: PedsQL Multidimensional Fatigue Scale (PedsQL-MFS, version 4.0) [66,67];
- Depression symptoms: Center for Epidemiologic Studies Depression Scale for Children [68];
- Anxiety: Generalized Anxiety Disorder 7-item scale [69];
- Resilience: Connor-Davidson Resilience Scale-10 [70];
- Mindfulness: Child and Adolescent Mindfulness Measure [71,72];
- Self-efficacy: Self-Efficacy Questionnaire for Children [73];
- Cognition: National Institutes of Health Toolbox (NIH Toolbox) [74,75] assessed fluid cognition on week 4 only: Fluid Cognition composite score, and Picture Sequence Memory, List Sorting Working Memory, Flanker Inhibitory Control and Attention, Dimensional Change Card Sorting, and Pattern Comparison Processing Speed tests [76].

Adherence

App adherence was quantified based on meaningful in-app activity time, defined as active engagement with core features assigned to each group. For the DTx-MBI group, this included guided meditation exercises, psychoeducational content, and snapshots. For the Sham group, the core features were the "2048" game and snapshots, which served as the control activities for engagement tracking. Any single app session lasting <3 minutes were excluded from adherence calculations, as this duration was deemed insufficient to complete meaningful activities. Weekly adherence was calculated by summing the total seconds of the qualifying app session within every 7 days over the 4-week study period.

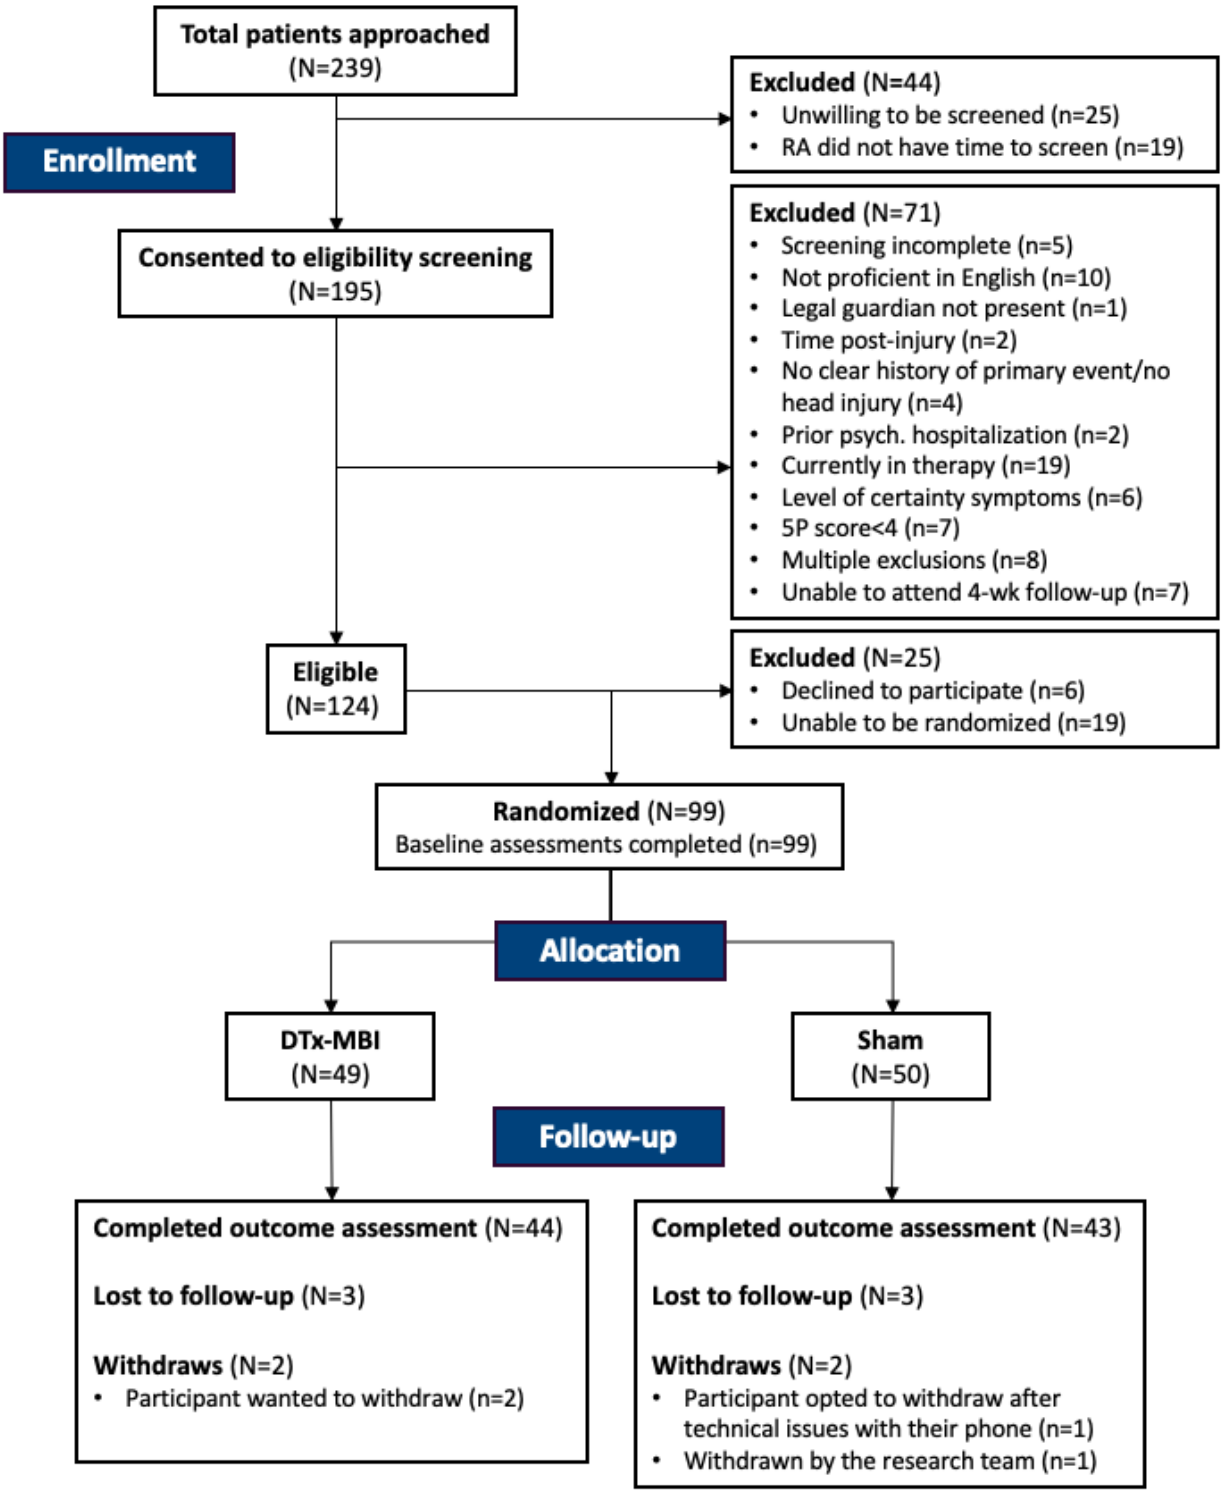
Statistical Analysis

Overview

Descriptive statistics were used to summarize participant characteristics, with medians reported for continuous variables and frequencies for categorical variables. Feasibility outcomes were reported as proportions. For outcome measures at 4 and 8 weeks, medians and IQRs were calculated for each group. In a post hoc exploratory analysis, a multiple regression was conducted to examine factors associated with app engagement (in seconds, square root transformed to address nonnormality and improve model assumptions) over the 4-week intervention period. The regression model included group allocation, age, sex, and preinjury ratings of anxiety, depression, mindfulness, and self-efficacy. All statistical analyses were conducted on R (version 4.4.1; R Core Team, 2024) [77].

Sample Size Calculation

Detailed sample size justifications can be found in the published protocol [46]. Briefly, sample size estimates were based on feasibility trial guidelines using the traffic light system [60,78]. To achieve >90% power for each of the 5 feasibility criteria, the highest requirement was adherence (n=55). Accounting for a 20% attrition, 70 participants were needed. Assuming 40% eligibility and 50% recruitment rates, ≈350 children needed to be screened.



Results

Participants

A total of 99 out of 124 eligible patients were randomized to DTx-MBI (n=49; median age [IQR]=15.28 [13.66 - 16.19] years; 30 [61%] female) or Sham groups (n=50; median age [IQR]=14.92 [13.32 - 16.71] years; 30 [60%] female) (Figure 2). A total of 65 participants were recruited from the ED and 34 from 360cc. Demographics and clinical characteristics were comparable between groups among all randomized participants and those who completed the 4-week follow-up (Table 2).

Four out of the 5 prespecified feasibility outcomes met the “green zone” benchmarks.

Eligibility

A total of 124 out of 195 (63.6%) participants were screened, exceeding the >40% eligibility criteria.

Recruitment

A total of 99 out of 124 (80%) eligible participants consented and were randomized, surpassing the 50% benchmark.

Credibility

A total of 62 out of 83 (75%) of participants scored above the scale midpoint, with similar results between the DTx-MBI (33/44, 75%) and Sham groups (29/39, 74%), exceeding the 70% target.

Retention

A total of 89 out of 99 (90%) of participants completed the 4-week follow-up assessments, with similar completion rates between the DTx-MBI (44/49, 90%) and Sham groups (45/50, 90%), meeting the 75% benchmark.

Adherence

A total of 53 out of 89 (60%) of participants completed the minimal requirement of activity, below the 70% target, falling into the amber zone. The DTx-MBI group showed slightly higher adherence (28/44, 64%) compared with the Sham group (25/45, 56%).

Secondary Analyses

Treatment Expectancy and Satisfaction

A total of 61 out of 83 (74%) participants scored above the scale mid-point on treatment expectancy (DTx-MBI: 34/44, 77%; Sham: 27/39, 69%). Moreover, intervention satisfaction was good, with 71/86 (83%) participants scoring above the scale mid-point (DTx-MBI: 37/43, 86%; Sham: 34/43, 79%).

Efficacy Signal

Given the nonnormal distribution of the outcome measures, medians and IQRs were calculated for all outcomes at baseline and week 4 (Table 3) and week 8 (Tables S1 and S2 in Multimedia Appendix 1 [26,45]). These analyses were intended to inform future sample size calculations; the study was not powered to detect statistically significant between-group differences.

Safety of the App

Two participants from the DTx-MBI group reported unscheduled medical visits during their study participation, but no visits met our predefined safety criteria for adverse events associated with the use of the application: one participant visited the ED for a second concussion in week 3, while the other visited for worsening of concussion symptoms prior to AmDTx use.

Post Hoc Exploration: Factors Associated With Activity Engagement

Given low adherence, we conducted a post hoc analysis to examine factors associated with intervention adherence. In the post hoc exploratory multiple regression, none of the demographic or preinjury factors showed statistically significant associations with activity engagement during the 4-week intervention period (Table 4).

Table . Demographic and preinjury factors associated with activity engagement (measured in seconds) over the 4-week intervention period.

Variables	Estimate	SE	Statistic	*P* value	95% CI
Intercept	59.62	121.06	0.42	.62	−181.49 to 300.73

Among participants who completed the intervention, weekly adherence rates (ie, meeting the threshold of ≥10 minutes of "meaningful" app engagement for 4 days over a 7-day week) declined from week 1 (DTx-MBI: 22/44, 50%; Sham: 31/45, 69%) to week 4 (DTx-MBI: 17/44, 39%; Sham: 17/45, 38%). Similarly, median weekly engagement time decreased from 40.9 minutes (IQR 20.2 - 89.9) to 17.1 minutes (IQR 0 - 76.8) in the DTx-MBI group and from 75.2 minutes (IQR 26.2 - 108.1) to 12.6 minutes (IQR 0 - 60.0) in the Sham group over the 4 weeks (Figure 3).

Figure 3. Weekly adherence. (A) Percentage of participants meeting the weekly 40-minute app activity engagement target across the 4 weeks of protocol within the experimental (DTx-MBI) and control (attention-matched cognitive Sham comparison; Sham) groups. Data points show exact percentages for each group at each week. (B) Distribution of weekly app activity engagement (in minutes) shown as violin plots for each group. Each violin plot shows the density of engagement duration, with a larger width indicating higher data concentration. Black dots represent median values, and vertical lines span the IQR (**Q1-Q3**). The red dashed horizontal line at 40 minutes indicates the target engagement threshold. Only participants who completed the 4-week outcomes were included in the figure. DTx-MBI: digital therapeutics mindfulness-based intervention.

Discussion

Principal Findings

This feasibility RCT indicated that a larger-scale trial evaluating the effectiveness of DTx-MBI in youth with a concussion compared with an attention-matched sham intervention is viable, with 4 out of the 5 prespecified feasibility benchmarks—eligibility, recruitment, credibility, and retention—being met or exceeded. Only adherence fell slightly below the target threshold, with engagement levels comparable to other digital health interventions in youth [28], suggesting that minor adjustments could improve adherence in the large-scale efficacy RCT.

The high eligibility rate suggests that the inclusion criteria were well aligned with the characteristics of the target population, and the high recruitment rates underscore the strong relevance and suitability of this intervention for the target population. Moreover, retention at 4 weeks approached 90% in both groups, reflecting strong participant commitment and the feasibility of our follow-up strategy. The high credibility and satisfaction across both intervention and control groups support the acceptability of the app-based interventions, regardless of their content. This reinforces findings from our earlier open-label preliminary study [51,80]. In the mixed methods evaluation (n=7), credibility, expectancy, and satisfaction ratings were even higher, although this may have been influenced by the small sample size, open-label design, and participants' awareness that they would be asked for feedback during the 4-week interview [51]. This blinded RCT strengthens the evidence for the acceptability of the DTx-MBI through a more rigorous randomized design and the inclusion of an attention-matched comparator. Although treatment expectancy was above the scale midpoint for all participants, those in the MBI-DTx reported a qualitatively higher expectancy that the treatment would be helpful, suggesting greater perceived relevance or believability of the experimental intervention. The treatment expectancy ratings in the Sham group were just below the threshold considered "good" in this study, whereas the experimental group met the benchmark. In the efficacy RCT, we will address this potential imbalance by providing participants in the Sham group with additional education about how cognitive training may promote recovery through neuroplasticity during enrollment.

Notably, in this study, no adverse events related to app use were reported, supporting the intervention's safety. Furthermore, the

XSL•FO
RenderX

optional MRI component also met the feasibility benchmarks, with high enrollment and scan completion rates, suggesting that a neuroimaging component can be successfully integrated into future trials.

Adherence, while below the 70% benchmark, remained within an acceptable range (nearly 60%), with slightly higher adherence in the DTx-MBI group across the 4 weeks. Weekly adherence declined over the 4 weeks in both groups, with median weekly engagement time decreasing substantially from week 1 to week 4 in both groups, with a more pronounced decline in the Sham group. This reduction may reflect the natural waning of novelty or motivation over time. This pattern is consistent with Eysenbach's "Law of Attrition," which posits that drop-off in usage is an expected and inherent feature of eHealth interventions, as users often disengage over time regardless of intervention quality or intent [81]. The drop-off in app engagement around weeks 2 and 3 may also coincide with the typical course of concussion recovery, a point at which participants may no longer perceive the intervention as necessary [9]. While the DTx-MBI group began with lower adherence rates than the Sham group, they sustained slightly higher engagement by week 4, potentially indicating greater long-term relevance or perceived efficacy or benefit of the mindfulness-based content. Previous studies in adolescents and adults have reported wide variability in adherence to digital MBIs, ranging from 40% to 92% [28]. In this study, we did not identify any participant characteristics associated with lower app engagement. However, prior work suggests that psychological factors such as resilience and coping style may moderate response to behavioral concussion interventions, suggesting that engagement may depend on characteristics not captured here [82]. Future efficacy trials may benefit from enhanced engagement strategies, such as personalized reminders and motivational interviewing. However, such strategies may reduce scalability and accessibility, as they require additional resources and personalization. Implementing them only when early signs of disengagement emerge (as observed in this study around week 2) may help balance these trade-offs.

It is also important to note that the engagement tracking metrics may under-report actual engagement, as the developer's system was designed to capture only completed "meaningful interactions." Sessions that were started but not completed (eg, if a participant began a meditation recording but exited before finishing) were not logged. Likewise, activities and assessments (snapshots, journaling, etc) that lasted at least 3 minutes but were not explicitly submitted by the participant once they were done, were not logged. The same goes for the sham app. Based on the developer's user testing, these incomplete sessions and unsubmitted assessments may account for roughly 10% - 20% of potential meaningful interactions. As such, the engagement data presented here represent only fully completed meaningful interactions, and actual usage may have been modestly higher than reported.

Although not powered for efficacy, both groups seemed to show reductions in symptom burden and improvements in quality of life at the 4-week assessment. The Sham group appeared to report higher sleep and school quality of life at 4 weeks, while these scores declined slightly in the DTx-MBI group. At 8 weeks, among participants who continued with the DTx-MBI, sleep and school quality of life increased, whereas they showed minimal change in the Sham participants who crossed over to the MBI intervention. Moreover, performance on the NIH Toolbox Pattern Comparison task, a measure of processing speed, was modestly higher in the DTx-MBI group compared with the Sham group, although this difference may reflect pre-existing group differences rather than a potential intervention effect since no baseline measures were available for the NIH Toolbox. These descriptive comparisons were not formally tested and are presented only to provide preliminary signals to inform future fully powered trials. Accordingly, these preliminary findings should be interpreted cautiously and warrant further investigation in a fully powered trial to determine the intervention's efficacy and clarify its impact across recovery outcomes.

Limitations

Despite overall strong feasibility metrics, this study has some limitations. First, estimates of recruitment, eligibility, adherence, and retention were based on a modest sample size, which may limit precision. Second, the control group's treatment expectancy was qualitatively lower and just below the benchmark for being considered "good," which may suggest that some participants suspected they were not receiving the genuine cognitive training intervention, indicating partial unblinding or differential perceived value, despite the use of an active sham. This may have been further compounded by the nature of the control condition, which consisted of math puzzles without concussion-specific content. However, it should be noted that all participants received standard-of-care concussion guidance regardless of group allocation, which is itself expected to support natural recovery and limits the interpretation that any observed differences reflect expectancy alone. These factors will need to be carefully addressed in the design and interpretation of the efficacy trial. Last, as expected for a feasibility study, it was not powered to detect efficacy, and outcome findings should be considered exploratory and interpreted accordingly. This is particularly relevant for weeks 5 - 8, which included only a small subset of participants who elected to continue.

Conclusions

There are a few established preventive nonpharmacological interventions for PSAC in pediatrics [83]; however, psychological approaches are increasingly explored. This feasibility trial supports the implementation of a larger RCT to rigorously evaluate the clinical efficacy of the DTx-MBI in pediatric concussion when compared with an attention-matched cognitive sham delivered on the same digital platform. With refinements to improve adherence, especially in weeks 2 to 4, we will be positioned to evaluate whether this intervention reduces symptom burden and enhances multifaceted recovery outcomes, including quality of life, mood, cognition, and neurophysiology, in youth with a concussion.

Acknowledgments

We thank the Children's Hospital of Eastern Ontario emergency room research assistant volunteers and research staff at 360 Concussion Care who initially approached participants to gauge interest in the study and completed the eligibility screening. We thank Olivier Brown, Lauren Butterfield, Zoe Ivan, and Matthew Richmond for their contribution to data collection.

This study was completed in collaboration with TRANSCENDENT Concussion Integrated Discovery Research Program.

Funding

This study was funded by a CHAMO Innovation grant (PI: AAL and RZ), a University of Ottawa Brain and Mind Research Institute team grant (Principal Investigator [PI]: AAL), a Martin Osmond Research Grant Award at Children's Hospital of Eastern Ontario Research Institute (PI: AAL), and Ontario Brain Institute NERD Program (PI: AAL). VS is supported by a Canadian Institutes of Health Research postdoctoral fellowship.

Data Availability

The datasets generated and analyzed during the current feasibility RCT are available from the corresponding author on reasonable request. Requests will be considered in accordance with institutional guidelines and applicable ethical approvals.

Authors' Contributions

VS contributed to conceptualization, methodology, data curation, formal analysis, visualization, and writing of the original draft. MC contributed to the conceptualization, methodology, and review and editing of the manuscript. RZ contributed to the conceptualization, provision of resources, and review and editing of the manuscript. NDS, GSG, NR, and AS contributed to the conceptualization and review and editing of the manuscript. BJS contributed to software development and review and editing of the manuscript. AAL contributed to the conceptualization, methodology, project administration, funding acquisition, supervision, visualization, and writing of the original draft.

Conflicts of Interest

VS is supported by a Canadian Institutes of Health Research postdoctoral fellowship and receives royalties for the publication of a book on concussion by Flammarion. MC is one of the authors of the Mindfulness-Based Intervention for Concussion protocol used in this study, but she did not receive any financial benefit. She has received competitively funded research grants from the Canadian Institutes of Health Research (CIHR) and Michael Smith Health Research BC. RZ received financial support through competitively funded research grants from the Canadian Institutes of Health Research, Ontario Neurotrauma Foundation, Physician Services Incorporated Foundation, Children's Hospital of Eastern Ontario Foundation, University of Ottawa Brain and Mind Research Institute, Ontario Brain Institute, National Football League, Ontario Ministry of Health, Public Health Agency of Canada, Health Canada, Parachute Canada, and Ontario SPOR Support Unit. RZ was supported by a Tier 1 Clinical Research Chair in Pediatric Concussion from the University of Ottawa. All grant funding goes directly to the institution. RZ sits on the board of directors for the North American Brain Injury Society, which is a volunteer (unpaid) role. RZ is a founding partner and a minority shareholder of 360 Concussion Care (a learning health system and network of interdisciplinary concussion clinics in Ontario); no proceeds have been transferred to RZ. NR holds a Canada Research Chair (Tier 2) in Pediatric Concussion and has received research funding from the Canadian Institutes of Health Research (CIHR), Social Sciences and Humanities Research Council (SSHRC), Ontario Neurotrauma Foundation (ONF), Public Health Agency of Canada (PHAC), Parachute Canada, Special Olympics Canada, Greater Toronto Hockey League, Dr. Tom Pashby Sport Safety Fund, Holland Bloorview Kids Rehabilitation Hospital and Scotiabank. NR is an Executive Board Member for the International Pediatric Brain Injury Society (IPIBS), which is an unpaid and volunteer role. All other authors declare no other conflicts of interest. BJS is the Chief Scientist and CEO of Mobio Interactive PTE LTD (Singapore), the parent company of Mobio Interactive Inc. (Toronto, Canada), and he owned approximately 22% of the company at the time of manuscript submission. BJS exclusively served as a technical liaison for the study and did not contribute to the specific study design, select the outcome measures, nor did he directly contribute to, or have influence over, data collection or analysis. AAL is one of the authors of the Mindfulness-Based Intervention for Concussion protocol used in this study, but she did not receive any financial benefit. Andrée-Anne Ledoux has received competitively funded research grants from the Canadian Institutes of Health Research (CIHR), Ontario Neurotrauma Foundation (ONF), Physician Services Incorporated (PSI) Foundation, CHEO Foundation, Ontario Brain Institute (OBI), and University of Ottawa Brain and Mind Research. AAL received funding from the Ontario Brain Institute Neurotech Early Research & Development Program for a separate component of the study. AAL has no other conflict of interest to disclose.

Abstract

Background: Visuospatial neglect (VSN) is a cognitive disorder following a stroke, where individuals fail to perceive or respond to stimuli on the contralesional side of space. Visual scanning training (VST) is the recommended treatment in clinical guidelines.

Objective: This qualitative study explored how patients (N=10) and informal caregivers (N=8) perceived the usability and potential implementation of 3 extended reality (XR)–based serious games to enhance VST—1 in virtual reality and 2 in augmented reality—as tools for VST. These technologies not only enhance patient engagement but also enable detailed data collection to monitor therapeutic progress.

Methods: The themes and feedback were compared with themes and feedback from VSN therapists from a previous study: (1) suitability for VSN rehabilitation, (2) applicability, (3) motivation, (4) guidance, (5) versatility, and (6) detailed insights in game performance.

Results: Highlights were that patients reported high engagement and enjoyment, with many expressing willingness to use the games in both clinical and home settings. Informal caregivers supported these findings and emphasized the motivational value of the games. Additionally, both groups noted the importance of accessible instructions and technical support.

Conclusions: Although XR technology offers potential in neurorehabilitation, a uniform solution may not suit all users. This study showed the importance of including diverse end-user groups in development for usability, acceptance, and implementation. Successful integration of XR in rehabilitation requires customizable features, structured support, and attention to the differing roles of caregivers. Further research is needed to evaluate the clinical effectiveness and optimize patient-tailored applications of XR in VSN treatment.

KEYWORDS

visuospatial neglect; visual scanning training; extended reality; virtual reality; augmented reality; qualitative data

Introduction

One of the fundamental cognitive skills required for daily activities, such as locating personal belongings, navigating traffic, and engaging in social interactions, is the ability to scan the environment. Unfortunately, for individuals who have experienced a stroke, this ability is often impaired due to visuospatial neglect (VSN). VSN is a common poststroke cognitive disorder characterized by a lateralized attentional deficit [1-4]. This deficit manifests in behaviors such as bumping into objects, overlooking food on one side of the plate, or grooming only one side of the body. The consequences of VSN negatively affect functional independence, activities of daily living, and societal participation [5-8]. Informal caregivers often bear a significant burden, compensating for the functional deficits caused by VSN [9]. Clinical guidelines recommend visual scanning training (VST) as a primary intervention [10]. VST is a compensatory therapy designed to train systematic eye and head movements toward the contralesional side [11-13]. The therapy dose is quite intensive, as it requires time commitment up to 40 hours over 5 weeks [11]. Moreover, patients' lack of awareness of their VSN, a condition known as anosognosia [14-16], may diminish their motivation and engagement in therapy. This is particularly problematic when the effectiveness or quality of the learned compensatory strategy is difficult to assess visually using current forms of VST. If a device could be used that not only provides individualized,

XSL•FO
RenderX

interactive training but also objectively indicates how effectively the strategy is being applied, this could significantly enhance both monitoring and therapeutic outcomes.

Advancements in extended reality (XR) technology, especially virtual reality (VR) and augmented reality (AR), offer promising new approaches to VSN rehabilitation [17-19]. VR immerses individuals in fully simulated environments via specialized headsets, whereas AR integrates digital elements into real-world settings, allowing for interaction within familiar surroundings. When combined with serious games [20], a gamified form of therapy, XR not only enhances patient engagement, enjoyment, and usability [21-23] but also enables detailed data collection to monitor therapeutic progress [24,25]. Studies further support the potential of XR for both assessing and improving visuospatial attention after stroke. Immersive and semi-immersive VR environments have been shown to elicit and measure neglect-like behavior [26-28]. Moreover, a VR-based exploration task has demonstrated positive effects on spatial attention and engagement [29], and AR tasks have been used to strengthen compensatory scanning behavior in functional contexts [30,31]. In parallel, growing evidence shows the importance of adaptability and personalization in neglect rehabilitation. For instance, an adaptive cueing protocol, in which visual cues were gradually reduced as patients improved, resulted in meaningful gains in VSN-related functional outcomes [32]. Although this paradigm was developed outside XR, it provides a strong conceptual foundation for implementing performance-dependent, adaptive task adjustments within XR-based VST.

Despite these encouraging developments, current XR interventions for VSN often do not proceed to the implementation process. A crucial step required to eventually move from the development lab toward clinical practice is to involve end users. Thorough evaluation of end-user perspectives, especially those of patients and caregivers, is required to secure the implementation of VR and AR therapy [33,34].

Building on previous therapist evaluations [35], this study incorporated patient and informal caregiver feedback into the iterative development of 3 serious games for VSN rehabilitation (1 VR-based and 2 AR-based). In this study, we collected perspectives of patients and informal caregivers and assessed to what extent they were distinct from the perspectives of therapists on the same 3 games reported by Bousché et al [35]. We aimed to assess whether these 2 end-user groups also mentioned the same 6 key findings from therapist evaluations: (1) suitability for VSN rehabilitation, (2) applicability, (3) motivation, (4) guidance, (5) versatility (ie, patient's needs), and (6) detailed insights in game performance. Variance in responses among groups will emphasize the need for inclusion of different end-user groups in the development process.

Methods

Participants

The first group of end users consisted of patients with VSN admitted to De Hoogstraat Rehabilitation Center for inpatient rehabilitation between April and October 2021. Inclusion criteria were as follows: (1) admitted to the neurology ward, (2) presence of VSN diagnosed by a neuropsychologist or screened by a therapist using the Balloons Test [36] or Catherine Bergego Scale (CBS) [37], and (3) age 18 years or older. The second group of end users consisted of informal caregivers of participating patients. Inclusion criteria were as follows: (1) age 18 years or older and (2) a familial or social relationship with the patient. Epilepsy was the sole exclusion criterion for all participants because of potential triggers for seizures in the serious games.

XR Serious Games

Three XR serious games were administered. First, the AR Virtual Museum used a Microsoft HoloLens 1 (1268×720 pixel per eye; 60 Hz; 35° FOV). This game promotes visual search by projecting virtual paintings onto real-world walls. Participants moved around the room to locate paintings, which transformed into short video clips upon discovery [30]. Second, VR HEMIRehApp employed an Oculus Rift CV1 (1080×1200 pixel per eye; 90 Hz; 110° FOV) with handheld controllers. Designed to retrain spatial attention toward the contralesional side, the game places participants in a virtual farm setting with tasks such as harvesting crops and feeding animals. It was initially developed for right-hemispheric stroke patients with intact language abilities [38, 39], and its validity and usability were confirmed in a pilot study [24]. Third, the Balloon Popping game, developed by Holomoves, used a HoloLens 2 (2048×1080 pixel per eye; 60 Hz; 52° FOV). This AR-based intervention integrates visual search training with physical movement. Virtual balloons appear around the player, who must locate and "pop" them using finger gestures. Auditory (verbal instructions) and visual (green directional arrows) cues aid the task. Participants played 3 mini games: simple balloon popping, image pairing, and word formation.

Outcome Measures: Interviews

A semistructured interview (Textbox 1) was designed by the authors, which consisted of 15 qualitative and 2 quantitative questions where the participant could rate an aspect of the XR game. The design was informed by the System Usability Scale [40], a widely used instrument for rapid quantitative assessment of usability. To obtain a deeper understanding of participants' experiences, we supplemented the scale with additional targeted questions addressing VST, user experience (eg, own performance, equipment use, cybersickness), usability (eg, playing the game autonomously, during therapy), and preference (eg, liking, improvement) of the games. The interview was recorded for analysis. Informal caregivers received a similar interview, without item 16 (practicing visual search outside therapy). Additionally, the items on practicing autonomously were rephrased for helping the patient at home or at the rehabilitation center.

XSL•FO
RenderX

Textbox 1. Interview on user experience, usability, and preference questionnaire. Participants rated difficulty and enjoyment on a scale from 0 to 10, where higher scores indicate greater difficulty or enjoyment.

User experience

1. What did you think of the game?

2a. What went well?

2b. What went less well (game-related or personal performance)?

3. How did the headset feel on your head?

4. Was there anything about the headset or controllers that you found uncomfortable?

5. How did you experience moving around in the virtual environment?

6. Some people feel warm or need time to adjust. How was this for you? How did it feel to play the game?

Usability

7a. Did you find the game difficult or easy (rate on a scale from 0=very easy to 10=very difficult)?

7b. What influenced this?

8. What could make playing the game easier or more difficult for you?

9. What did you think about the duration of the game?

10a. Can you imagine using this game on your own for extra practice?

10b. Why or why not?

11. If we were to offer a 2-week training program to practice daily with this game, would you be willing to participate?

12a. Would you recommend this game to fellow rehabilitation patients?

12b. Why or why not?

Preference

13. How enjoyable did you find the game (rate on a scale from 0=not enjoyable at all to 10=very enjoyable)?

14. What aspects made the game particularly enjoyable to play?

15. What do you think could make the game even more enjoyable?

16. Do you currently practice searching and scanning for objects outside of therapy?

17. Is there anything that would prevent you from wanting to play this game?

Procedure

Patients were first informed about the study by researchers and invited to participate. Interested patients were scheduled to play their first game within 2 weeks. Before gameplay, the researcher reviewed the information letter and study procedure with the patient. For patients with aphasia, a speech therapist facilitated communication using simplified phrasing, repetition techniques, questioning, and pictorial techniques. The AR games were played either while walking, sitting, or rolling in a wheelchair or office chair. The VR game was played while participants were seated. After the patient completed the games, their informal caregiver was invited to participate and play the games as well. Each participant played all games once during one-on-one sessions with the researcher within a period of 3 weeks in a quiet room. Researchers assisted with headset placement, provided instructions, and answered questions. Throughout gameplay, the researcher closely monitored participants for signs of discomfort, fatigue, or cybersickness, such as dizziness, nausea, or disorientation. Participants were explicitly instructed to report any discomfort at any time, and gameplay was paused or stopped if adverse effects were observed or reported. Game order was counterbalanced, with each session lasting 10 to 15 minutes, including instructions. Each game was played once. After each game, a 15-minute semistructured interview was conducted with each participant.

Patient Data

The following patient data were collected from electronic patient files: age, sex, time poststroke onset (in days), stroke type (ischemic, hemorrhagic), and lesion side (left, right, bilateral). Functional scores were also collected for strength in the upper and lower extremities using the Motricity Index (MI) [41], global cognitive function using the Montreal Cognitive Assessment [42], level of communication using the Dutch Aphasia Foundation (Stichting Afasie Nederland) [43], and independence in activities of daily living using the Barthel Index [44]. Two neuropsychological tests were used to assess VSN severity: the Balloons Test [36,45] and the CBS [37].

Analyses

To explore the user experience, applicability, and suggestions of the patients and informal caregivers, the ratings were described and the qualitative data were analyzed. Audio files of the interviews were transcribed using Microsoft Word and later adjusted by the researchers to make a coherent story. Then, a deductive coding scheme was formed based on 6 key findings from therapists' evaluations: (1) suitability for VSN

XSL•FO
RenderX

rehabilitation, (2) applicability, (3) motivation, (4) guidance, (5) versatility (ie, patient's needs), and (6) detailed insights in game performance [35], following the approach described by Boeije et al [46]. These themes served as a preliminary analytic framework, based on the assumption that variation in perspectives across stakeholder groups would show the importance of incorporating multiple end-user voices in XR development. For the present study, each of the 6 themes was further differentiated into "positive," "negative," and "neutral" subcategories to capture the valence of participants' remarks and "suggestions" to facilitate a more nuanced comparison across user groups (Multimedia Appendix 1). All interviews were coded by 1 researcher, with 2 other researchers taking samples from both groups (ie, patients and informal caregivers). The samples were then further discussed in the research team to reach consensus on the coding process. After reaching consensus, all interviews were coded again based on the agreed-upon criteria. Qualitative findings were descriptively triangulated with test observations and available clinical data (eg, neglect severity, lesion side) to support interpretation and identify converging or diverging patterns, without formal quantitative hypothesis testing.

Ethical Considerations

This study was approved by the Medical Ethics Committee of the University Medical Center Utrecht and the Ethical Committee of De Hoogstraat Rehabilitation Center (reference number: 21/706). All procedures were conducted in accordance with the Declaration of Helsinki. All participants provided written informed consent prior to participation. The data consisted of anonymized patient and interview data, which were collected and processed in a manner that ensured participant privacy and confidentiality. Participants did not receive financial or other compensation.

Results

Patient Data

A total of 12 patients with VSN were recruited and provided informed consent to participate in the study. However, 2 patients withdrew before participation due to fatigue, reduced cognitive capacity, lack of motivation, and difficulty recalling study details or scheduled sessions. Of the 10 remaining patients (age 49 - 77 y; 70% male), 3 played all games, 6 played 2 games, and 1 played 1 game. Additionally, 10 informal caregivers were recruited (age 45 - 75 y; 25% male), of whom 8 participated in this study (n=5 played all games; n=2 played 2 games; n=1 played 1 game). Interview excerpts were translated from Dutch to English to serve as examples in this publication.

Table 1 presents individual patient demographic and clinical characteristics. The majority (n=7) had experienced ischemic stroke, 2 had experienced a hemorrhagic stroke, and 1 patient had a cerebral abscess. Lesion lateralization was right hemispheric in 6 patients, left hemispheric in 3, and bilateral in 1 patient. Most (n=8) were in the subacute phase of recovery; the rest were in the acute phase (n=2). The patient group presented with VSN that was mild or not detectable using conventional paper-and-pencil tests. However, clinical observations as scored with the CBS revealed the full range of VSN severity. CBS data for 7 patients were available, indicating mild VSN for 10% (CBS<10), moderate VSN for 30% (CBS<20), and severe VSN for 30% (CBS>20). For those patients without CBS scores, 1 patient exhibited moderate neglect symptoms on the Balloons Test (Subtest B score<17; lateralization balance score<40%), and for 2 other patients, clinical observations indicated the presence of VSN. Although VSN was underrepresented on standardized assessments, the group nonetheless included patients across the entire spectrum of VSN. Cognitive screening indicated that all patients had cognitive impairment, ranging from impaired to severely impaired levels, with all scores falling below the clinical cutoff (Montreal Cognitive Assessment score<26). Motor function, using the MI, showed that patients on average had moderate motor impairment (0 - 33 severe; 34 - 66 moderate; and 67 - 99 mild/normal). In terms of functional independence, patients were generally highly dependent on others for daily care. Based on their scores on the Barthel Index, the group as a whole fell within the range corresponding to "severely dependent" (5-9), although individual scores ranged from "completely dependent" (0 - 4) to "moderately dependent" (10-14). This reflects a patient population with substantial functional needs and limited autonomy in daily living.

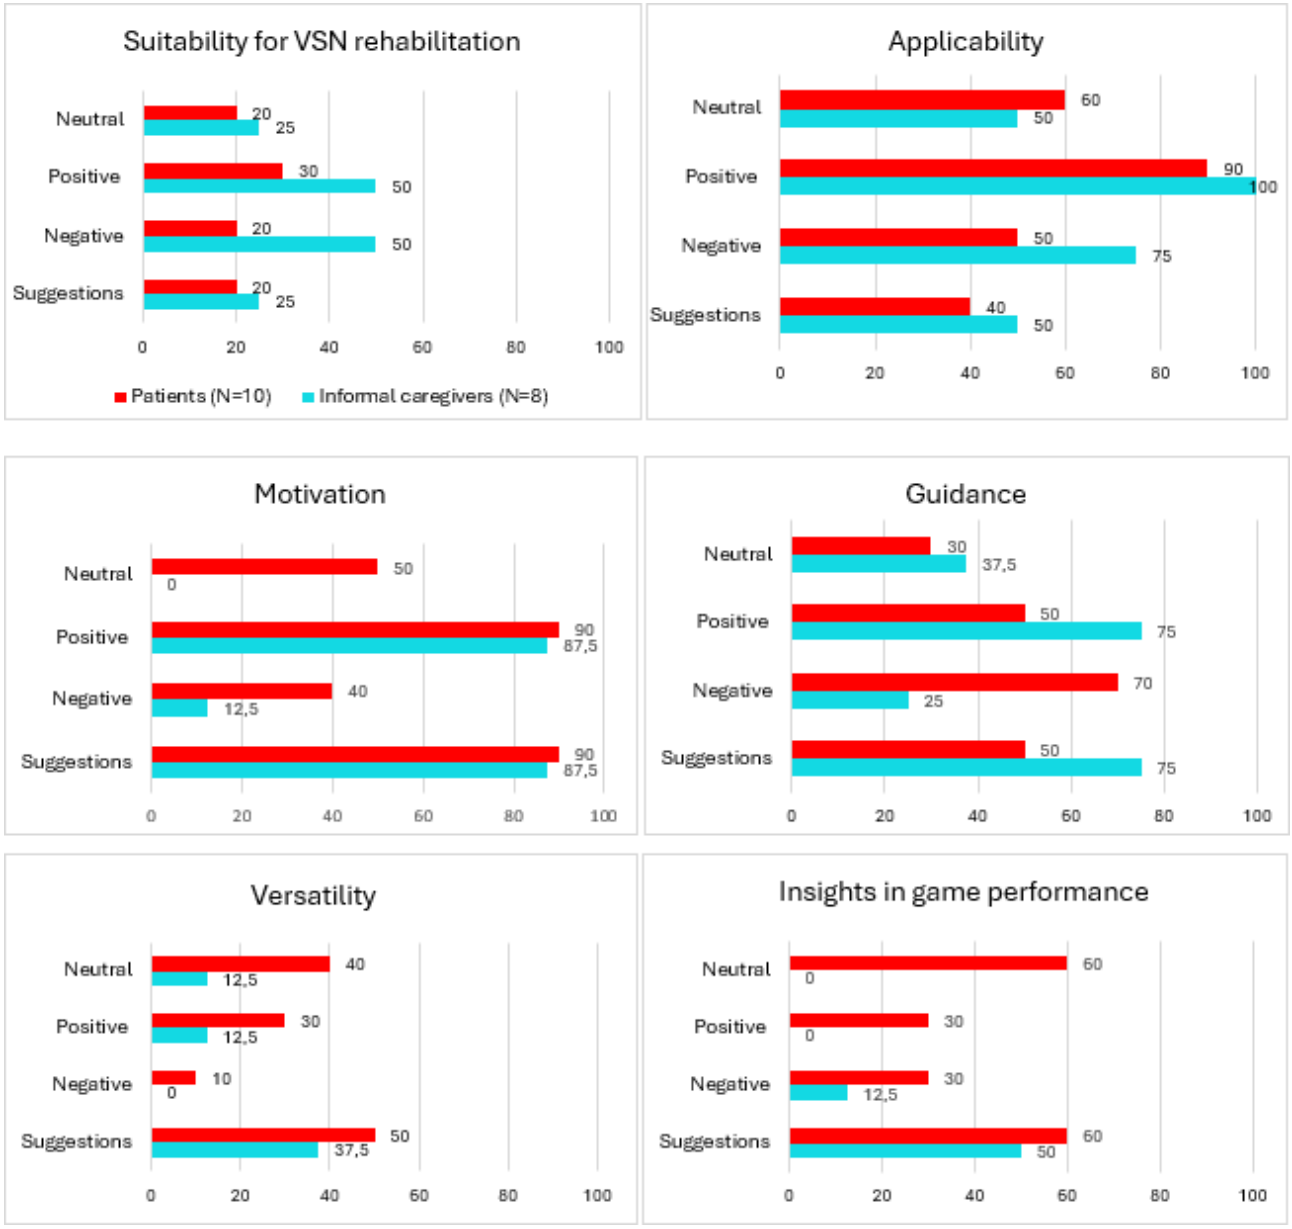
[h]Missing data.

Suitability for VSN Rehabilitation



The participants' perceptions of the games' suitability for VSN rehabilitation were varied (Figure 1). Patients provided fewer comments on this aspect compared with other categories and even fewer than their informal caregivers. Among informal caregivers, the distribution of positive and negative responses was equal. An informal caregiver mentioned that for their loved one, training would be appropriate, while it was too easy for a healthy person such as themselves. It was also suggested to improve clarity regarding the game's main objective and ensure that patients understand the added value of playing. There were also suggestions for improving the suitability of the games. For example, one informal caregiver mentioned that adjustments need to be made for suitability for neglect, because currently, the targets were only right in front of the player.

> *…I thought: now something is going to happen, but most of the targets were actually right in front of me. Those are things to which more attention is paid to: who will be playing next? Okay, this patient has left-sided neglect, then we need to place more targets*

XSL•FO
RenderX

on the left. Sometimes also behind the patient, so they really have to turn their head and search for where it is. [Informal caregiver03]

Figure 1. The coding scheme reflected in percentages of patients (N=10) and their informal caregivers (N=8) who gave neutral, positive, and negative responses and suggestions. VSN: visuospatial neglect.

Applicability

The applicability of VR and AR games to the target patient population was an important topic for both patients and their informal caregivers. Ninety percent (9/10) of patients and 100% (8/8) of informal caregivers made positive remarks about the feasibility and applicability of these games (Figure 1). Patients reported that the games were easy to play and that the duration of gameplay was sufficient. Patients also indicated feeling comfortable while playing and were able to move freely while seated in an office chair or wheelchair.

Similarly, most informal caregivers found the games intuitive and of appropriate duration when played themselves; however, some expressed concerns regarding the potential difficulty of gameplay duration for patients with VSN, thus making a distinction between their own experiences and the anticipated challenges faced by patients.

Despite overall positive responses, 50% (5/10) of patients also expressed concerns regarding the applicability of the games. One patient wondered whether older individuals would be able to engage with the games effectively.

> *I really like the idea. But I can imagine that for older people it might be quite difficult to use.* [Patient05]

Even more informal caregivers were concerned (6/8, 75%), with issues related to game content (eg, difficulty with multitasking), safety (eg, potential distraction leading to reduced awareness of surroundings), and patient-specific factors (eg, individuals with memory impairments might struggle with certain games).

XSL•FO
RenderX

> *…You get lots of information to read, so you have a lot to process. This could be hard for people who have had a stroke.…*. [Informal caregiver08]

> *No I wasn't distracted by the paintings, but the patient might bump into something.* [Informal caregiver07]

> *…But with the patient it will not be that easy. I think when making a turn, the patient might fall.* [Informal caregiver03]

> *In my case, my memory is good. But for people with a stroke, memory is often affected, right? If you make the game more difficult, I think it might become too demanding for them.* [Informal caregiver05]

Furthermore, it was observed that 1 patient encountered difficulties while engaging with AR Balloons and VR HEMIRehApp, due to the specific motor demands of these games (eg, pointing and using a controller). Conversely, AR Museum proved to be more suitable for this patient, as it only required eye fixations. Although the patient was not able to finish the games, the patient still had positive views on this type of technology.

Additionally, 40% (4/10) of the patients provided suggestions for improving applicability. Patients questioned whether it was feasible to integrate the games within the busy schedule of the rehabilitation center, proposing that a single session might be appropriate, without being specific about an exact therapy dose.

> *…But it has to be feasible alongside other therapy sessions. Well…it doesn't need to be a problem, but when you have many [therapy sessions] it could become difficult. But when you would receive it [the equipment] for a single day, it would be okay.* [Patient08]

Among informal caregivers, 50% (4/8) suggested modifications to enhance applicability, primarily focusing on safety (eg, using a large, empty space to minimize the risk of collisions) and interface adjustments (eg, a more salient cursor to keep track of one's actions in the game).

> *…I noticed quickly that you really have to poke through the balloon, but I wonder how patients will handle this, that you really need to poke through the balloon.…Maybe the game could make the cursor or pointer more salient so it's clearer what they are actually interacting with. For me it wasn't a problem, but it might be for others.* [Informal caregiver03]

Motivation

Both groups were asked about the perceived likability of the games and their motivation to continue playing or reengage with the games. Although participants expressed a range of motivation-related sentiments (neutral, positive, and negative), the content of these responses showed little variation. Overall, patients (9/10, 90%) and informal caregivers (7/8, 87.5%) reported similarly positive perceptions of the games' motivational aspects. The most frequently mentioned motivational factor was positive affect, as participants indicated that they enjoyed playing the games. For instance, 1 patient noted that, beyond the therapeutic necessity of the games, engaging with them provided a welcome distraction from routine therapy.

> *…as for the game element, I think many people would enjoy it simply because it's something different and engaging.* [Patient05]

Patients appreciated the physical engagement involved, such as making head movements, searching, and scanning, which the games facilitated.

> *I really appreciated the movements involved: searching, moving the head, and scanning. I saw many positive aspects in it.* [Patient 09]

> *Moving around was easy. You knew when the music stopped the game was finished, so you had to keep going until you found another target.* [Patient01]

Informal caregivers mentioned the appeal of the games' colors and dynamic elements, as well as their informative nature.

> *In the last game, I especially liked that the deer was moving that made it more engaging. Overall, I thought the game was well designed.* [Informal caregiver10]

> *I really enjoyed it, you receive information and things are explained, for example about a painting. I didn't necessarily recognize anything personally, but I still liked that something was being told and that you could learn from it.* [Informal caregiver08]

Negative feedback was more prevalent among patients (4/10, 40%) than among informal caregivers (1/8, 12.5%). Informal caregivers primarily mentioned the difficulty level of the games. Patients, however, reported concerns such as inadequate gamification of therapeutic elements within the game design and difficulties in locating objects.

> *At this moment I would not yet recommend it, because it is still in the research phase. First, people should practice with everyday situations, things they normally encounter and tend to neglect in daily life. That should be mastered first.* [Patient03]

> *…Yes, because I couldn't find them easily. If the targets were easier to locate, your attention would be drawn to them more, and you would probably be able to continue for longer.* [Patient04]

> *…I think it has to do with the fact that you just have to click away two things each time. Not much else happens, you know?* [Informal caregiver07]

Suggestions for enhancing motivation were largely consistent across groups, with 90% (9/10) of patients and 87% (7/8) of informal caregivers proposing modifications such as incorporating diverse themes (eg, zoo, art), increasing difficulty levels (eg, more targets, time constraints), and introducing additional objectives (eg, puzzles, object-chasing tasks).

> *Maybe there could be multiple themes, or a slightly more difficult level. For example, combining two themes in one task. That would add more challenge, because you would need to look more actively for different types of objects.* [Patient09]

XSL•FO
RenderX

> *Maybe there could be a time limit, so you know in advance that you have two or three minutes. But it has to be realistic, it should still be achievable for someone with a condition like mine.* [Patient05]

Guidance

The theme regarding guidance encompassed tutorials or support from another person, from the game itself, or from documents. Positive remarks from both patients and informal caregivers were that the instructions within the games were clear. The graphics and targets were visible, and the instructional voice was audible.

> *The instructions were explained clearly while I was seated, and everything was said out loud and shown on screen, so I didn't even have to read them. I could just start playing right away.* [Patient01]

According to the patients (7/10, 70%), negative aspects of guidance were the instructions for gameplay, controllers, or the act of selecting targets, as well as the lack of feedback on their gaming performance.

> *Maybe the next time, once you know what the intention is, it will be easier.* [Patient10]

> *What you have to remember is that with the green leaf you need to use the lower button instead of the upper one and with the orange leaf it's the other way around.* [Patient05]

Negative aspects according to informal caregivers (2/8, 25%) were, for example, that the in-game instructions were not sufficiently noticeable or understandable for patients.

> *I think that for people who have difficulties understanding due to a brain injury, a bit more guidance at the beginning would be helpful, clearly explaining what to do. After that, they would probably be able to manage.* [Informal caregiver8]

Suggestions from patients (5/10, 50%) included allowing participants to practice more to accurately remember the instructions. Another interesting suggestion was to enhance cues and feedback related to game performance.

> *I don't know if it's technically possible, but if you could see what I'm seeing, it might be helpful if you could say something like "your gaze is in the right place" or "look up" or "look down," especially since our eyes and pupils are apparently being measured.* [Patient06]

Additionally, 75% (6/8) of the informal caregivers had suggestions for improving the guidance. A recommendation was to give the instructions a more therapeutic focus, for example, by suggesting the use of a different hand to select targets.

> *…You really need to indicate "use your other hand." It's not that you will automatically use your left. If you have left-sided neglect, use your left hand. Maybe there could be text in between, indicating which finger or hand to use, to stimulate that.* [Informal caregiver09]

Versatility (ie, Patient's Needs)

Next to suitability, versatility or tailoring the games to individual patients' needs was less often mentioned, compared with other themes from the coding scheme. Versatility of the serious games was perceived positively by 30% (3/10) of patients and 12% (1/8) of informal caregivers. One negative aspect was mentioned by a single patient.

> *For me, the music could be different. I can imagine that younger people might really like this, but we are from a different generation, so I would prefer another type of music.* [Patient06]

Suggestions regarding versatility were made by half of the patients (5/10, 50%) and just over a third of the informal caregivers (3/8, 38%). Patients and informal caregivers primarily suggested adapting game themes to personal preferences, such as allowing users to choose their own virtual environment.

> *Maybe there could be multiple themes, or a slightly higher level of difficulty, for example by combining two themes in one task. That would add more challenge, because you would have to search for different types of objects.* [Patient09]

> *There should be more variation so people can choose what they want to do, for example, different environments or more animals appearing in the game.* [Informal caregiver05]

> *For example, my brother loves farm life. If the game included a video about a farm and the animals, he would probably find it much more interesting.* [Informal caregiver01]

Detailed Insights in Game Performance

A difference was found between the 2 groups in mentioning the insights derived from gameplay. Whereas patients expressed a clear desire to know how they performed in the games, informal caregivers showed less interest, with only 13% (1/8) mentioning it as a negative aspect. Suggestions for game performance insights primarily involved displaying accuracy or total score. A notable suggestion was to include an option that allows users to compare their current performance with previous results or the performance of other players.

> *Just showing the number of points or the percentage of correct answers is enough for me. Something like a graph would also work.* [Patient 03]

> *…What matters is whether you did it correctly or not.* [Patient 02]

> ***Researcher:*** *Would you like to know how well you did in the game?*

> ***Patient:*** *Yes, of course.*

> ***Researcher:*** *Would you also like to see how others performed, or just compare your own results next time?*

> ***Patient:*** *Yes actually, I'd like to see everyone's scores. That would be fun.*

> ***Researcher:*** *Then you could gradually try to catch up with the top score, like "Jan," who did better.*

XSL•FO
RenderX

Patient: *Yes, I like that.* [Patient10]

Other Findings

Other findings revealed that informal caregivers evaluated the games from both their own perspective and that of the patients. Informal caregivers often elaborated on imagining how playing the game would be for the patient.

> *Yes, I think it went well. I had no problems, but I can imagine that a patient, like the patient with left-sided neglect, would find it harder to distinguish, for instance, where a balloon is located…I can imagine that a patient might have more difficulty and would need to think constantly.* [Informal caregiver03]

> *I can imagine that if someone isn't really into games, like my brother, who doesn't like them at all, they might quickly lose interest.* [Informal caregiver01]

This dual perspective is comparable to the approach taken by therapists who primarily considered the patient's viewpoint. Interestingly, therapists leaned more toward patient-centered observations, while informal caregivers balanced their own experience with their perception of the patient's experience.

To increase the total time for dedicated training, it was explored whether patients would use the serious games at home or at the rehabilitation center, preferably with the help of an informal caregiver. Patients expressed willingness to practice at home if provided with the necessary equipment. Similarly, they were open to using the headsets at rehabilitation centers if readily available. However, reasons for not doing so included having other matters to attend to at home or preferring to spend time with friends and family at the rehabilitation center. Informal caregivers (6/8, 75%) expressed a willingness to support home practice, provided it fit within their daily schedules. However, their willingness to assist in rehabilitation centers was more divided (4/8, 50%), often dependent on practical considerations such as work commitments or the belief that therapy should primarily be managed by health care professionals.

> *It depends on the location. Not here at the Hoogstraat Rehabilitation, that would take too much time. But if he had one at home, I would be willing to do it. If I had to come here every day with him, then I think the care staff would need to do this more often.* [Informal caregiver01]

Lastly, no adverse effects were reported. The hardware and software were generally well received (7/10, 70% patients; 6/8, 75% informal caregivers). However, a few participants (2/10, 20% patients; 2/8, 25% informal caregivers) reported initial difficulty adjusting to the VR headset.

> *It took a moment to get used to it, a bit of dizziness, and then I returned and,"phew."* [Patient02]

Realistic VR scenarios, such as fish catching over a virtual lake, induced vertigo for one informal caregiver who reported fear of heights after the session.

> *I personally have a bit of a fear of heights, which may sound strange, but in that water scene it really felt as if I was above the water. When I looked down, I thought, "wow."* [Informal caregiver07]

Discussion

This study assessed the user experience of patients with VSN and their informal caregivers and compared the findings to the themes frequently mentioned by VSN therapists in a previous study by Bousché et al [35]. The participants engaged in 3 serious games, 1 VR and 2 AR games, based on VST for VSN.

Principal Findings

Participants' perceptions regarding the suitability of the games for VSN rehabilitation were varied. Patients generally made fewer comments on this aspect compared with informal caregivers, who showed an equal distribution of positive and negative feedback. Some informal caregivers noted that the training would be suitable for their loved ones but too easy for healthy individuals, and others suggested improving the clarity of game objectives and tailoring the games specifically for neglect (eg, adjusting target placement). In terms of applicability, both groups found the games feasible and user-friendly, although some expressed concerns regarding the duration and potential difficulties for patients with VSN. Suggestions for improvement included better customization for older individuals and ensuring safe use in clinical settings. It seemed to be easier for both groups to talk about applicability and feasibility than the more therapeutic properties of the games, something that is obviously not a problem for VSN therapists.

Next to the therapeutic aspects, motivational aspects were also evaluated. Incorporating gamification elements into XR rehabilitation can increase patient motivation and engagement [31,47-49]. Gamification VST was positively perceived by both patients and informal caregivers. The most frequently mentioned motivation indicator was positive affect, as participants enjoyed the gameplay and appreciated the physical engagement. However, some patients expressed concerns about insufficient gamification of therapeutic elements and difficulty locating objects. Informal caregivers suggested increasing the difficulty level to sustain interest. This is consistent with therapists' views, which were positive regarding motivational aspects but questioned whether players would pick up the game again. Suggestions for enhancing motivation were similar across groups (patients and informal caregivers), including incorporating diverse themes (eg, zoo, art), increasing difficulty levels, and introducing additional objectives (eg, puzzles).

Both groups appreciated the clear in-game instructions and the visibility of graphics that accompanied the instructions. However, more patients than informal caregivers reported challenges related to guidance, such as difficulty with controller usage and the lack of performance feedback. Morse et al [50] pointed out the importance of integrating clear guidance within XR interventions, as well as including feedback mechanisms to support user engagement. Therapists took it a step further; almost half of the therapists suggested improving the in-game tutorials, instructions for therapists, and protocols for handling the equipment.

Additionally, tailoring the games to the patient's individual needs was mentioned less frequently compared with other themes, suggesting that further adaptation may enhance the

XSL•FO
RenderX

therapeutic experience. VR interventions can be effective when the level of immersion is adapted to patient needs [28]. Tailoring by both patients and informal caregivers was targeted towards suggestions on adjusting themes to the liking of the patient, in that they could choose their own virtual environment, while therapists leaned more toward adjusting the games to different patient types and clinical requirements (eg, patient's mobility or sensitivity to sensory input).

Interestingly, we found differences between patients and informal caregivers regarding game performance insights. Patients expressed a desire to receive feedback on their gameplay, while informal caregivers showed limited interest, with one mentioning not being interested. Suggestions to improve game performance insights included displaying accuracy or total scores and incorporating a feature that allows users to compare their current performance with previous results or with others. The interest and suggestions were limited compared with the evaluations of therapists. They mentioned accuracy, temporal measures, strategy, motor measures, or combinations thereof [35].

This pattern is noteworthy in light of the fact that patients with VSN frequently present with anosognosia or reduced awareness of their deficits [14-16]. One might therefore expect limited interest in performance feedback if patients believed they were performing adequately. The opposite pattern observed in this study suggests that interactive XR-based tasks may facilitate a degree of online awareness of performance during task execution, even when more generalized or offline insight remains impaired [14]. The immediate and goal-directed nature of XR gameplay may make errors or omissions more salient to patients than conventional assessment tasks. Although this interpretation remains speculative, it aligns with theoretical accounts distinguishing between online performance monitoring and global awareness of deficits, and it points to the potential of XR environments to support self-monitoring processes without necessarily increasing cognitive burden.

Our study revealed that informal caregivers evaluated the games from both their own perspective and that of the patients. This dual perspective is different from the approach taken by therapists [35], where therapists primarily considered the patient's viewpoint. Interestingly, therapists leaned more toward patient-centered observations, while informal caregivers balanced their own experience with their perception of the patient's experience. This difference emphasizes the distinct roles and perspectives of informal caregivers compared with health care professionals. The importance of involving informal caregivers in rehabilitation is further supported by a randomized controlled trial, which found that caregiver participation in VR training improved patient outcomes in unilateral neglect [51]. They therefore recommended trained informal caregivers to provide VR guidance and supervision to patients who have unilateral neglect.

We explored whether patients could independently use the serious games at home, aiming to intensify VST by increasing the therapy dose as described by Pizzamiglio et al [11]. According to Morse et al [50], end users were positive and interested in this type of telerehabilitation for VSN. In the current study, patients expressed willingness to practice at home if provided with the necessary equipment. Similarly, they were open to using the headsets at rehabilitation centers if readily available. Since informal caregiver participation can improve therapeutic outcomes [51,52], they were asked whether they could aid the patients to play at home. Informal caregivers generally expressed a willingness to support home practice, provided it fit within their daily schedules. However, their willingness to assist in rehabilitation centers was more divided, often dependent on practical considerations such as work commitments or the belief that therapy should primarily be managed by health care professionals.

In a systematic review by Lundin et al [53], the importance of monitoring and reporting adverse effects in VR interventions was advocated. In our study, no adverse effects were reported by both patients and informal caregivers. The headsets and VR controllers were generally well received, although some participants initially struggled with headset adaptation. One informal caregiver with a fear of heights experienced mild vertigo during a realistic scenario, calling attention to the need for monitoring cybersickness in XR interventions, specifically in VR.

To conclude, consistent themes across user groups were identified. These findings demonstrate the value of involving diverse end-user groups when designing XR serious games for health care, particularly for VSN therapy. Including patients, their informal caregivers, and therapists throughout the development process [54] can enhance usability and therapeutic relevance, as supported by studies on VR-based rehabilitation [51,52,55].

Strengths and Limitations

A strength of this study is that it involved patients and their informal caregivers in the development process of different types of XR technology for VSN therapy. The aim was not only to eventually optimize the technology and tailor the games to the patient's needs but also to investigate the potential of including informal caregivers in the therapy and letting the patient work autonomously, as well as make the feedback comparable to the previous study with therapists. The diversity of end users ensures that all relevant groups were involved in the development and evaluation process. Another strength of this study is the inclusion of a representative patient sample, capturing the full range of relevant clinical impairments. The sample included patients with cognitive impairment ranging from mild to severe, VSN severity spanning from very mild to severe as measured by the CBS, and moderate motor impairments as assessed by the MI. This broad clinical spectrum enhances the ecological validity and generalizability of the findings to broader rehabilitation populations. Additionally, the sample size was somewhat larger and with a broader age range than comparable studies [30,31,50].

A potential limitation of this study concerns the assessment of VSN for participant inclusion. Conventional standardized measures were not systematically incorporated, which makes it possible that some participants were already relatively well trained or that neglect symptoms were no longer apparent during static, paper-and-pencil tests typically used in clinical practice.

XSL•FO
RenderX

Consequently, variability in neglect severity across participants may have influenced their interaction with the XR games. While no clear patterns emerged, there were indications that participants with more pronounced neglect or right-hemispheric lesions required more guidance during gameplay, which may have shaped their user experience. In addition, the presence of aphasia in some participants may have affected the depth and clarity of their verbal feedback, despite facilitation by a speech therapist. Although care was taken to support communication, responses from participants with aphasia may have differed in richness or nuance compared to those without language impairments, potentially influencing the qualitative findings. Another potential limitation is the monocenter design of the study. The rehabilitation center involved is progressive in its use of science and technology, which may have positively influenced participants' attitudes toward XR-based interventions. Furthermore, no questionnaire was administered to assess prior experience with digital technology, which limits insight into possible familiarity effects and introduces the risk of selection or contextual bias related to the study setting. Additionally, gameplay sessions were relatively short, which likely limited the occurrence of attentional fluctuations, fatigue, or more pronounced manifestations of VSN during use. As a result, the findings should be interpreted as a snapshot of user experience at a single point in time. Future research should therefore investigate patient and caregiver experiences across longer or repeated gameplay sessions to better assess sustained engagement, usability, and the potential therapeutic value of XR-based interventions over time.

Clinical Implications

This study contributed to the first steps toward implementing XR technology in rehabilitation centers. Our findings suggest that integrating XR-based therapeutic interventions into rehabilitation programs for VSN can significantly improve patient engagement and therapy adherence. Given the positive user experience reported by both patients and informal caregivers, the use of VR and AR games appears promising as a supplementary tool for VST. However, to enhance clinical applicability, it is crucial to address challenges related to guidance, customization, and motivation. Specifically, rehabilitation centers should consider integrating these technologies in a way that accommodates both patients and their informal caregivers, providing clear instructions and adaptable game settings. Furthermore, recognizing the varying levels of willingness among informal caregivers to support therapy sessions in different settings is essential for successful implementation.

Conclusion

This study reported the need for a nuanced understanding of how various end users perceive and interact with XR-based therapeutic interventions. It showed the importance of involving different end users for the development process to become more inclusive and tailored, ultimately enhancing the usability and therapeutic potential of XR applications for VSN. Future research should continue to explore the efficacy and patient-tailored approaches to optimize XR interventions in neurorehabilitation.

Acknowledgments

We thank the Knowledge Broker Neglect Study Group from De Hoogstraat Rehabilitation Center and Judy Bakker from Stichting Omring for their valuable input and assistance in recruiting participants. The members of the Knowledge Broker Neglect Study Group are as follows: Eugenie Brinkhof (Physical therapist), De Hoogstraat Rehabilitation, Utrecht, The Netherlands and Dutch Institute of Allied Health Care/Nederlands Paramedisch instituut, Amersfoort, The Netherlands; Oscar Haver (Rehabilitation physician, MD), De Hoogstraat Rehabilitation, Utrecht, The Netherlands; Marike Jansen (Occupational therapist), De Hoogstraat Rehabilitation, Utrecht, The Netherlands; Cindy van de Moosdijk (Psychologist), De Hoogstraat Rehabilitation, Utrecht, The Netherlands; Anja Timmerarends-Van Eck (Nurse specialist), De Hoogstraat Rehabilitation, Utrecht, The Netherlands.

Abstract

Background: An increasing amount of digital health data are being collected across rehabilitation settings, but their integration into routine clinical practice remains limited, despite its potential to motivate patients or inform clinical decision-making. Specifically, effective visualization and communication of assessment outcomes to both patients and health care practitioners (HCPs) represent a key gap in the neurorehabilitation practice.

Objective: This study describes the development and evaluation of RehaLink (author ND, ETH Zürich), a proof-of-concept mobile app that delivers structured, interpretable feedback from conventional and technology-based assessments to neurorehabilitation patients and HCPs.

Methods: The app was developed through a 3-step iterative co-design process involving 17 inpatients with multiple sclerosis and 15 HCPs from a single rehabilitation center. The app integrates a full battery of conventional assessments routinely conducted at the clinic, as well as digital health metrics from the Virtual Peg Insertion Test, a validated technology-based assessment of upper limb function, as a proof of concept for integrating technology-based assessment data into clinical workflows. Three structured feedback sessions were conducted, in which participants evaluated feedback types, visualization formats, and app usability using Likert-scale ratings, preference rankings, open-ended questions, and the System Usability Scale. Data were analyzed using descriptive statistics and directed content analysis.

Results: Across all 3 sessions, progress bars and color-coded indicators were consistently preferred over text-heavy or abstract formats by both patients and HCPs. A persistent set of competing demands was observed, with participants requesting both visual simplicity and access to absolute values and normative comparisons. HCPs tended to underestimate patients' preference for informative visualizations. The perceived value of structured feedback increased over the course of the study; patients' median ratings rose from 4.0 to 5.0 and HCPs' from 4.0 to 4.5 on a 5-point Likert scale. The resulting mobile app prototype demonstrated high usability, with patients achieving a mean System Usability Scale score of 93.6 (mean 6.4; best imaginable) and HCPs 80.9 (SD 8.1; good), according to established benchmarks.

Conclusions: These findings demonstrate the feasibility and value of a co-designed digital feedback tool for neurorehabilitation. By combining conventional and technology-based assessment outcomes in an accessible, user-centered format, the app has the potential to enhance patient engagement, support clinical decision-making, and advance the implementation of value-based, personalized care.

Introduction

During neurorehabilitation, both conventional and technology-based assessments are essential for diagnosing impairments, tracking progress, and tailoring treatments [1-5]. Standardized tools such as the Nine Hole Peg Test [6], the Timed Up and Go [7], and the Functional Independence Measure [8] are widely used [9]. Although they capture different domains of the International Classification of Functioning, Disability, and Health framework [10], they are subjective, time-consuming, and lack sensitivity [11-13].

Technology-based assessments address these limitations through automated data collection, improved objectivity, and greater sensitivity. Examples include (markerless) motion capture [14-16], wearable sensors [17], and robotic tools such as the Kinesiological Instrument for Normal and Altered Reaching Movement (KINARM) [18,19] or the Virtual Peg Insertion Test (VPIT) [20,21]. However, their outputs can be abstract, poorly validated, and difficult to integrate into clinical workflows [22].

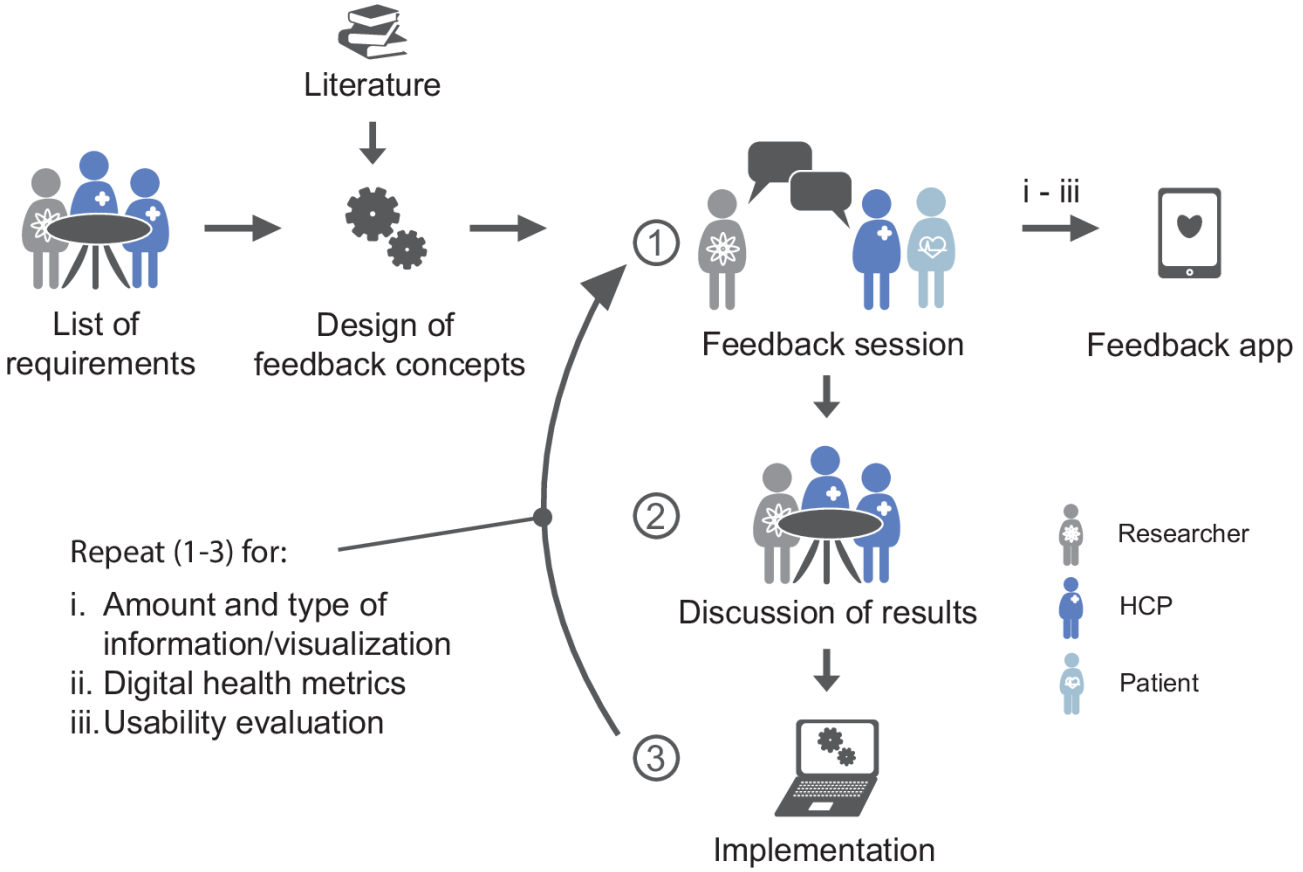
Despite their potential to support the implementation of precision medicine, integrating both conventional and digital assessments systematically into clinical routine decision-making remains challenging. In many cases, assessment outcomes are difficult to synthesize and communicate effectively during patient consultations, which can limit their ability to enhance patient motivation, satisfaction, and adherence to treatment. This limited adoption is largely driven by the high effort required to collect, summarize, and interpret the data, which can outweigh the perceived benefit in many clinical contexts. Moreover, while the level of detail offered by technology-based assessments is valuable in research [23-25], its clinical relevance remains uncertain, and there is a lack of clear guidelines for selecting or applying metrics in practice [26].

Regular and well-communicated feedback on assessment outcomes has been shown to enhance patient motivation [27,28], support engagement in shared decision-making [29], and improve rehabilitation outcomes [30,31]. Likewise, transparent and interpretable data can support clinical decisions that are often otherwise driven by prior experience and/or subjective judgment [32]. To leverage the full potential of both conventional and technology-based assessments, their results must be accessible, interpretable, and actionable for both patients and health care practitioners (HCPs). Achieving this requires a systematic and collaborative approach to identify clinically meaningful outcome measures and establish health communication strategies that enhance their practical use in clinical routine [5,33,34].

Digital apps have the potential to bridge the gap between researchers, HCPs, and patients by enabling access to individualized health data and translating complex information into intuitive, user-friendly formats. By streamlining data collection and interpretation, these tools have the potential to support more frequent assessments and promote continuous communication of outcomes throughout the rehabilitation process. In recent years, the number of released health apps in areas such as mental health [35,36], consumer health [37], and fitness [38,39] increased rapidly. While many of these apps lack sufficient validation or fail to demonstrate clear benefits, others show strong potential to increase patient motivation and adherence [35,36,38,40]. A key factor in making digital health tools effective and engaging for both patients and HCPs is the active involvement of end users in the development process [41-46]. Applying user-centered design principles helps ensure that these tools are better aligned with the real needs of all stakeholders [3-5,40,41,46-50]. However, a key limitation is that many existing digital health apps are developed primarily for the consumer market rather than for integration into clinical workflows. As a result, their design often overlooks the specific requirements of clinical environments, limiting their adoption and utility in routine care. This gap is particularly evident in neurorehabilitation, where existing digital health record systems still lack effective features for summarizing and visualizing health-related data. Consequently, both HCPs and patients may lack access to user-friendly tools to monitor and understand rehabilitation progress.

This study describes a 3-step user-centered design process for developing a digital feedback app that displays digital health metrics from conventional and technology-based assessments to patients and HCPs along the neurorehabilitation journey. As the first step, we defined the need and requirements and evaluated expectations for such feedback together with HCPs. Through iterative rounds of discussions and structured interviews with both neurological patients and HCPs, we identified an optimal type and amount of information, along with the appropriate visualizations to display health data in an intuitive and engaging way. Our evaluation focused on 3 key aspects, including informativeness, understandability, and visual appeal. Building on this, we developed RehaLink (author ND, ETH Zürich), a proof-of-concept app that visualizes typical rehabilitation data collected during clinical routine assessments, including digital health metrics from the VPIT, and evaluated its usability. This work provides insights from end users—patients and HCPs—on how to meaningfully present assessment outcomes and include digital health metrics in neurorehabilitation settings that will open new avenues for empowering patients with their health data and support HCPs in decision-making towards precision medicine.

Methods



Conceptual Approach

We used a structured co-design process to develop a digital app aimed at enhancing patient motivation and supporting clinical decision-making in neurorehabilitation. The initial requirements were identified through a multidisciplinary roundtable involving researchers from ETH Zurich and clinical staff from Kliniken Valens, including the heads of neurology, research, and therapy, as well as therapists with different backgrounds. The discussions focused on defining clinically relevant assessments, selecting the appropriate platform, and ensuring integration into routine care. The development process included three iterative feedback sessions with HCPs, designed to evaluate (1) the content and visualization of patient information, (2) the integration of digital health metrics, and (3) overall usability. Between sessions, targeted follow-up meetings with researchers and HCPs enabled

XSL•FO
RenderX

systematic incorporation of feedback into subsequent development stages (Figure 1).

Figure 1. Overview of the co-design process for a digital feedback app for patients and health care practitioners (HCPs). The illustration shows a 3-step iterative approach guided by co-design principles. HCP: health care practitioner.

To ensure clinical relevance and align with clinical practice, the app was designed to include the full battery of conventional assessments routinely conducted at admission and discharge at the Kliniken Valens. To explore integration of digital health data, we included the VPIT, a well-validated tool for assessing upper limb function. The metrics derived from the VPIT are representative of the digital health data typically obtained from wearable sensors or robotic devices used in neurorehabilitation assessments. We implemented the app as a mobile solution for iOS, with an optional future compatibility across additional operating systems. At the time of this writing, the app is intended for use on tablets, as this offers greater practicality during patient consultations compared to stationary terminals.

Participant Recruitment

Patients were recruited through purposive sampling from the inpatient neurology unit at Kliniken Valens. Although the app is intended for use across neurorehabilitation populations, patients living with multiple sclerosis (MS) were selected as the initial target group for this proof-of-concept study given the clinic's large inpatient living with MS rehabilitation program that provides a readily accessible and well-characterized patient pool for this co-design process. Recruitment targeted eligible participants advised to inpatient rehabilitation with a diagnosis of MS and sufficient cognitive and communicative capacity to participate in structured feedback sessions. Eligible patients were identified by the treating clinical team through review of the inpatient list, selecting those with an MS diagnosis and sufficient cognitive and communicative capacity as judged by the attending clinicians. Participants provided informed consent under the institutional general consent framework. No formal inclusion or exclusion criteria were predefined, consistent with the exploratory, co-design nature of this work. Interested patients were approached by clinical staff and invited to participate voluntarily. HCPs were recruited through announcements during regular team meetings within the therapy and neurology departments of the Kliniken Valens.

The number of participants per session was determined pragmatically, as the primary aim of the feedback sessions was an iterative design refinement within a co-design process, rather than achieving qualitative data saturation in the traditional sense. Session recruitment concluded when the research team judged that sufficient stakeholder input had been obtained to inform the next design iteration, consistent with descriptions of co-design as an iterative, resource-bounded process [51-53]. Session sizes were consistent with recommendations for iterative, design-oriented evaluation, in which small samples have been shown to yield sufficient feedback for informing successive design iterations [54,55]. Nonetheless, qualitative responses in later sessions showed increasing thematic overlap with earlier feedback, suggesting that the key design-relevant perspectives had been captured within the sample.

XSL•FO
RenderX

Conventional Assessments

The conventional assessments at Kliniken Valens were grouped into 6 categories, including endurance, mobility, strength, coordination, speed, and global health/function to support clearer interpretation in the app (Table S1 in Multimedia Appendix 1). These categories were based on the International Classification of Functioning, Disability, and Health framework and refined with HCP input.

VPIT

The VPIT is a technology-aided assessment of upper limb function that integrates a haptic device with a virtual environment [20]. The task involves goal-directed reaching, in which users are instructed to insert nine virtual pegs into 9 holes displayed on a board as quickly and precisely as possible. During task execution, kinetic and kinematic data are continuously recorded. From this data, 10 digital health metrics are computed to quantify various aspects of movement quality, including smoothness, efficiency, accuracy, speed, and grip force control [21]. These metrics enable sensitive and objective characterization of upper limb impairments and have been validated in diverse patient populations, including individuals with MS [56,57], stroke [58], and ataxia [59,60]. Importantly, the VPIT served as a model for integrating digital health metrics into clinical feedback systems, offering a template for incorporating validated, objective assessments into user-facing tools. As such, it offers a clinically relevant and generalizable use case for exploring how complex sensor-based outputs can be effectively visualized and communicated to both patients and HCPs. Its integration into the co-designed digital feedback app supports our broader goal of making digital health data more accessible and actionable, fostering patient engagement and shared decision-making in neurorehabilitation. In collaboration with HCPs from Kliniken Valens, the VPIT metrics were grouped into the same 5 functional categories as the conventional assessments. An overview of the 10 core VPIT metrics, including their descriptions and associated categories, is provided in Table S2 in Multimedia Appendix 1.

Structured Feedback Sessions

Overview

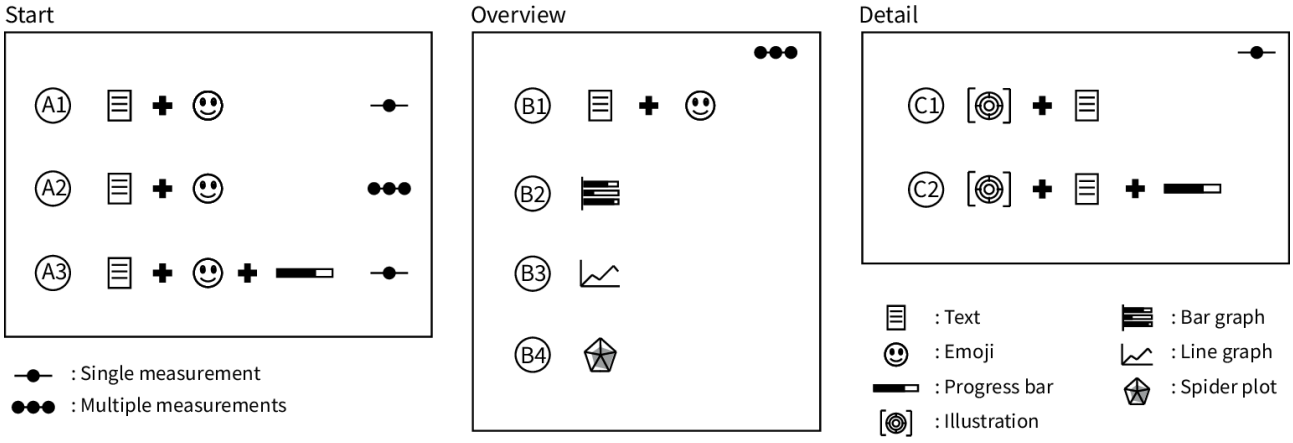
Three structured feedback sessions were conducted to iteratively evaluate key aspects of the app design, including information presentation, metric representation, and overall usability. Each session followed a standardized procedure lasting approximately 30-45 minutes, with 2 participants—either HCPs or patients—participating simultaneously. To minimize bias, all participants first received a neutral written introduction outlining the session's purpose. In sessions 2 and 3, this was supplemented by a short video and an explanation of the VPIT.

Participants were then shown a series of feedback concepts and completed the structured questionnaires in Multimedia Appendices 2-7. These included Likert-scale items (1=strongly disagree-5=strongly agree) [61], open-ended questions, and preference rankings of the concepts. Concepts were rated on motivational value, visual appeal, informativeness, and understandability. Additional items assessed the perceived usefulness of performance feedback—either for enhancing therapy motivation (patients) or supporting clinical decision-making (HCPs)—as well as attitudes toward technology-based metrics, using the VPIT as an example. Participants were encouraged to ask both technical and content-related questions throughout, ensuring a full understanding of the material.

After completing the questionnaire, participants could share additional thoughts in a brief open discussion. All reflections were manually transcribed, and quotes included in this manuscript were translated from German into English.

The feedback concepts were developed according to established user-centered design principles [41,45,48], balancing clarity and representativeness while minimizing bias during evaluation.

Feedback Session 1: Type and Amount of Information



The first structured feedback session focused on evaluating how different types and levels of information, as well as their visual presentation, influenced user perceptions of usefulness, clarity, and engagement. To reflect a realistic interaction flow, we structured the session around three conceptual screens: (1) a start screen summarizing overall therapy progress, (2) an assessment overview screen displaying all assessment outcomes, and (3) an assessment detail screen providing more in-depth information on a selected assessment outcome. The 3-level screen structure was designed to balance conciseness and depth, allowing users to quickly access key insights or explore detailed results as needed. Limiting the structure to 3 screens aimed to maintain a shallow navigation hierarchy, thereby enhancing usability in rehabilitation contexts, where cognitive and physical demands on users may be heightened [62].

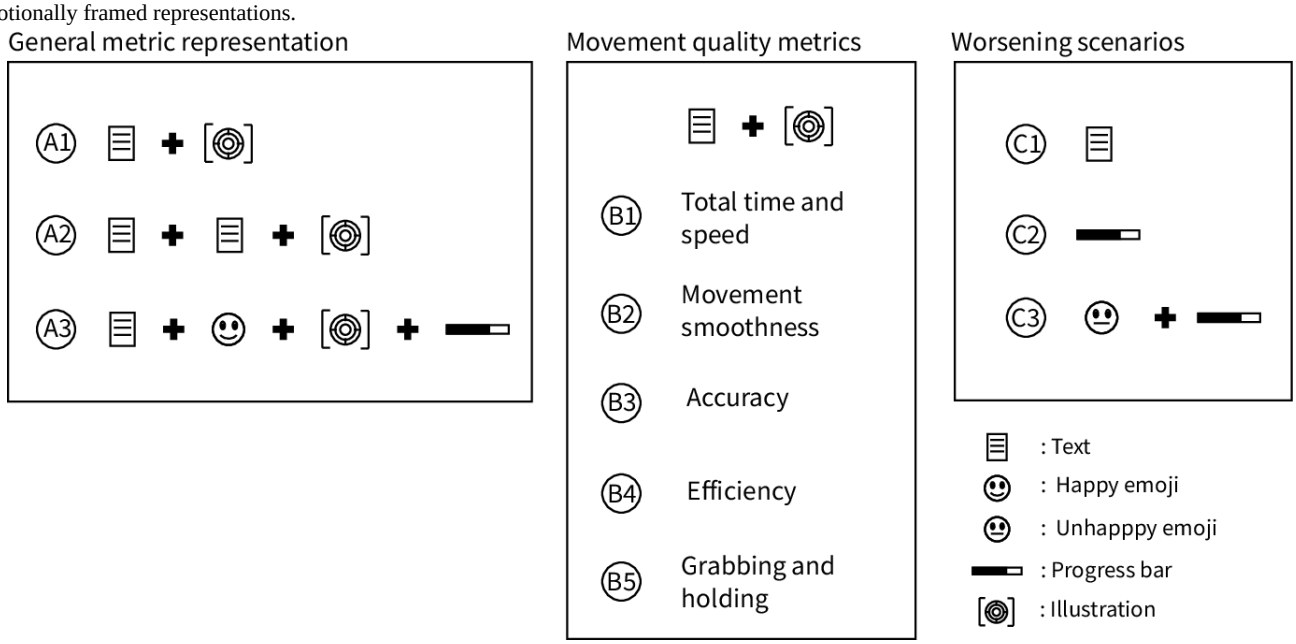
For each screen, participants were shown a set of alternative feedback concepts that varied in content complexity and visual format. These included combinations of textual summaries, color-coded timelines, bar and line charts, spider plots, emojis, and progress bars. A text- and emoji-only version was also included in the first set to serve as a low-complexity baseline. These types of visualizations were selected for their common use in digital health or consumer apps, with bar and line graphs being the most prevalent in digital health contexts [63,64].

An overview of the 3 screens and their respective feedback concepts is presented in Figure 2. This layered approach was designed to assess preferences across varying levels of information granularity and visual representation.

XSL•FO
RenderX

Figure 2. Illustration of feedback concepts shown during the first structured feedback session. The figure presents the 3 conceptual screens used to evaluate feedback design: the start screen, which provides overall performance summaries; the metric overview screen, which compares visualization types across multiple assessments; and the assessment detail screen, which presents in-depth explanations of single assessment outcomes. Each screen included multiple concepts (labeled 1-4) that varied in complexity, visual format, and content presentation.

In addition to the concept-specific ratings, patients were asked whether feedback on assessments could enhance their motivation for therapy and which types of feedback they would prefer to receive. HCPs were asked whether feedback could support clinical decision-making and help motivate patients. Further, HCPs were asked if they think that the VPIT could be helpful for them to evaluate the upper limb function of the patients. The questions of whether patients think that structured feedback could enhance their motivation and whether HCPs think that it could support decision-making were asked before providing feedback concepts and again afterward, so that we get an unbiased opinion first. Both groups were also invited to indicate the kinds of technology-based assessment feedback they considered most meaningful.



Feedback Session 2: Presentation of Digital Health Metrics

The second structured feedback session focused on how digital health metrics could be effectively communicated to patients and HCPs through intuitive, engaging visual designs. To enhance understandability, the 10 VPIT metrics (Table S2 in Multimedia Appendix 1) along with overall task completion time were grouped into 5 lay-language metrics, including total time and speed, movement smoothness, accuracy, efficiency, and grabbing and holding. These categories were derived from the original research-based classifications and were adapted in collaboration with HCPs to ensure that terminology was intuitive and meaningful for both patients and HCPs. To support aggregation of metrics with different units and easier interpretation by nonexpert users, each VPIT metric was first normalized to a 0 - 100 scale, where 0 represents the most impaired neurological subject in our database (excluding outliers), and 100 corresponds to the median performance of age-matched healthy controls. Without normalization, the raw values are too abstract and/or technical to convey meaningful feedback to patients or HCPs. The normalized metrics within each category were then averaged, without weighting, to create composite scores representing broader functional domains (eg, dimensionless log jerk and spectral arc length were combined under movement smoothness). This approach preserved metric validity while enhancing interpretability for end users. Details of the metric groupings are provided in the description column of Table S2 in Multimedia Appendix 1.

Participants were presented with three sets of feedback concepts (Figure 3), each designed to explore a different aspect of digital health metric feedback delivery.

XSL•FO
RenderX

Figure 3. Overview of feedback concepts presented in the second structured feedback session. The figure summarizes 3 sets of visual feedback concepts shown to participants: Set 1 presents different designs for a single digital health metric (movement smoothness); Set 2 shows all 5 aggregated metrics with metric names, icons, visual illustrations, and explanations; and Set 3 explores how to communicate worsening outcomes, ranging from neutral to emotionally framed representations.

Set 1 explored the general presentation of a single metric, using movement smoothness as an example. The 3 concepts varied in their level of explanation and visual complexity. Each included the metric name, an icon, and different combinations of visual elements such as color-coded bars (green for healthy and red for impaired), progress bars, emojis, and explanatory text.

Set 2 provided an overview of all 5 aggregated VPIT metrics. Each metric was shown with its name, icon, short descriptive text, and a corresponding illustration. This set aimed to assess whether the metrics were perceived as clear, useful, and engaging.

Set 3 addressed how to communicate worsening outcomes and included 3 visualizations with varying emotional tone and visual emphasis. The first concept displayed a neutral message ("No improvement") without emojis or colored bars. The second used a green progress bar to indicate decline but excluded emojis and text. The third showed worsening results with an orange progress bar and an unhappy orange emoji. Each concept included an information button linking to an HCP-validated disclaimer explaining that performance changes may reflect normal day-to-day variation and should not be interpreted as clinically significant.

Participants rated each concept based on visual appeal, informativeness, and understandability. Additional open-ended questions captured qualitative impressions. Patients and HCPs were also asked whether they found the disclaimer clear and reassuring.

Feedback Session 3: Usability Evaluation of the App Prototype

In the third feedback session, participants evaluated the usability of a high-fidelity app prototype created using Figma (Figma, Inc) [65]. The prototype featured randomly generated data and allowed participants to freely explore its interactive components, including screen navigation and button functionalities. The use of randomly generated data for prototype usability testing is consistent with standard iterative user-centered design practice [41,42], in which interface usability is established prior to clinical validation. Further, instead of just illustrations for the VPIT metrics, we included animations.

Participants were instructed to interact with the app independently. HCPs were asked to imagine they were preparing for a consultation and tasked with reviewing a patient's most recent assessment results, identifying any worsening trends, and checking the summary screen. Patients were instructed to imagine they had just completed a new assessment and were asked to explore their feedback, compare it with previous results, and interpret the meaning of their scores. Participants were encouraged to ask questions during the interaction if clarification was needed.

Following the exploration phase, all participants completed the System Usability Scale (SUS) [66] to evaluate overall usability. In addition, they responded to several targeted questions using 5-point Likert scales and open-ended questions. These assessed whether participants perceived structured feedback as valuable and if there is something to improve in the app design and implementation. Items also addressed the desire for comparative feedback (eg, performance relative to healthy individuals or other patients) and whether participants would like to celebrate personal milestones. Participants were also asked to suggest changes or propose features to add or remove.

Data Analysis

Quantitative Analysis

Likert-scale responses were collected on paper and subsequently transferred to Python (version 3.13.2; Python Software Foundation) for analysis. No data exclusion or cleaning criteria

XSL•FO
RenderX

were applied. For each item, the median and IQR were calculated separately for patients and HCPs. Median and IQR were chosen due to the ordinal nature of the data and their robustness to outliers, particularly in the context of small sample sizes. Accordingly, no inferential statistical testing was performed. Participants also ranked the feedback concepts within each concept set by assigning a unique rank to each concept, with no ties permitted. Median ranks were computed to identify overall user preferences for different content types and visual formats. Visualizations such as heatmaps and summary tables were created in Python to support interpretation.

Usability Assessment

SUS questionnaires were collected on paper and subsequently transferred to Python (version 3.13.2) for analysis. Raw SUS responses were converted into standardized scores (0 - 100) following the standard scoring procedure [66]. Group-level means and standard deviations were calculated separately for patients and HCPs. Scores were interpreted using the adjective rating scale proposed by Bangor et al [67], ranging from "worst imaginable" (<50) to "best imaginable" (>90), to contextualize the usability findings.

Qualitative Analysis

Open-ended responses from all 3 feedback sessions were analyzed using direct content analysis. All responses were collected and analyzed in German. A single coder conducted multiple passes through the data, an initial pass to assign open codes to individual responses, followed by subsequent passes to group related codes into higher-level categories and identify recurring themes. An initial codebook was developed deductively based on the predefined questionnaire dimensions (eg, visual appeal, informativeness, understandability, and motivational value). Open-ended responses were then coded iteratively, with additional codes emerging inductively from the data and grouped into higher-level categories as recurring patterns were identified across participants. Coded themes were subsequently reviewed and discussed with all co-authors to ensure their plausibility and consistency with the broader dataset. Representative quotes were selected to illustrate key findings and translated from German into English by the first author (ND) for inclusion in the manuscript.

Ethical Considerations

All participants were informed about the use of their data for scientific purposes and provided consent for further use of their data at entry to the Valens clinic. The responsibilities for this analysis were obtained by the Regional Ethics Committee of Eastern Switzerland (EKOS; EKOS 25/209). All procedures were conducted in accordance with the Declaration of Helsinki and the Swiss Human Research Act. All data collected were fully anonymized prior to analysis, and no personally identifiable information is reported in this manuscript. Participants received no financial compensation for their involvement.

Results

Participant Overview

A total of 17 neurological inpatients diagnosed with MS and 15 distinct HCPs from the Kliniken Valens participated in one of 3 structured feedback sessions. Several HCPs participated in more than one session, resulting in a total of 26 HCP participations. An overview of participant demographics and roles is provided in Table 1.

XSL•FO
RenderX

Table . Participant demographics across the 3 structured feedback sessions. The table summarizes the number of participants, their roles, and basic demographic characteristics for both patients and health care practitioners (HCPs) involved in each of the 3 structured feedback sessions.

Session and group	Participants, n	Age (years), mean (SD)	Gender (n)'	Role
Session 1				
Patients	5	40.8 (15.6)	• Female: 2 • Male: 3	—[a]
HCPs[b]	8	35.8 (10.4)	• Female: 5 • Male: 3	PT[c] (n=3), ST[d] (n=2), OT[e] (n=2), HST[f] (n=1)
Session 2				
Patients	6	56.5 (7.8)	• Female: 1 • Male: 5	—
HCPs	9	35.2 (9.3)	• Female: 3 • Male: 6	PT (n=5), ST (n=2), OT (n=2)
Session 3				
Patients	6	46.1 (14.8)	• Female: 5 • Male: 1	—

Feedback Session 1: Type and Amount of Information

Overview

The primary aim of this feedback session was to assess the preferred type and quantity of information to be presented to patients and HCPs within a digital feedback app. To reduce potential bias, participants were asked general questions about structured feedback both prior (pre) and then following their exposure to the different feedback concepts (post). The feedback concepts included various mockup screens designed to give participants an idea of how feedback might be presented; for example, through different data visualization formats such as bar charts, line graphs, spider plots, text, or even emojis. These concepts were created for a range of topics. In addition to presenting and evaluating feedback concepts, HCPs were asked whether feedback on completed assessments could aid clinical decision-making (pre: median 4.0, IQR 3.5 - 4.0; post: median 4.0, IQR 4.0 - 5.0), while patients were asked whether such feedback might increase their motivation to engage more consistently in therapy (pre: median 4.0, IQR 4.0 - 5.0; post: median 4.0, IQR 4.0 - 5.0). Median responses therefore remained consistent before and after viewing the feedback concepts. Additionally, HCPs were asked whether providing feedback to patients could enhance their motivation (median 4.5, IQR 4.0 - 5.0) and whether digital health metrics such as VPIT-derived feedback would be useful in evaluating upper limb function (median 4.0, IQR 4.0 - 5.0). Participants evaluated 9 feedback concepts across 3 screen types: the start screen, which summarized overall performance; the overview screen, which presented multiple assessment outcomes; and the detail screen, which displayed results for a single metric. All concepts were rated on visual appeal, informativeness, and understandability using Likert scales (Figure 4; Table S3 in Multimedia Appendix 1) and were ranked by preference.

XSL•FO
RenderX

Figure 4. Median Likert-scale ratings for feedback concepts in feedback session 1. Participants rated 9 feedback concepts on 3 dimensions, visual appeal (V), informativeness (I), and understandability (U), using a 5-point Likert scale. Concepts are grouped by screen: start screen, overview screen, and metric detail screen. For the start screen and the detail screen, concepts are ordered by increasing informational complexity (A1-A3; C1-C2); for the overview screen, by increasing visual complexity (B1-B4). Ratings are shown separately for patients (P) and health care practitioners (HCP). Color intensity reflects the median score (red = favorable and blue = less favorable). Numbers in bold mark ratings above 4.5. I: informativeness; HCP: health care practitioner; P: patient; U: understandability; V: visual appeal.

Start Screen

The concepts evolved from a basic emoji-based design (concept A1: text+emoji) to a timeline-enhanced version (concept A2) and finally to a version featuring a progress bar (concept A3). Both Likert scale ratings and rankings showed that concept A3 (progress bar) received the highest overall scores. Patients ranked concepts A3 and A2 (timeline) the highest (median 2.0, IQR 1.0 - 2.5 and median 2.0, IQR 2.0 - 3.0, respectively), while HCPs rated concept A3 as their top choice (median 1.0, IQR 1.0 - 1.5). Concept A3 also scored highest among both groups in terms of visual appeal, informativeness, and understandability. One patient remarked, “The progress bar makes it clear at a glance if I got better or worse,” and an HCP commented, “It is easily understandable for patients.”

Overview Screen

Concepts in this screen increased in visual complexity from text+emoji (B1) to bar plots (B2), line plots (B3), and spider plots (B4). HCPs ranked concept B3 slightly higher (median 2.0, IQR 1.0 - 2.5), while patients gave similar rankings to concepts B2 (median 2.0, IQR 2.0 - 2.0) and B3 (median 2.0, IQR 2.0 - 4.0). Both groups ranked concept B4 the lowest. Several participants commented on the need for absolute values, stating, “We want to see how much improvement or worsening there is in absolute values or percentages.”

> *If patients see norm values, they can compare what is good and where they need to improve. The same for us, we can then better compare where the patient is standing.* [A health care practitioner (HCP)]

Detail Screen

Concept C2 (illustration+ text+progress bar) was ranked highest by both patients and HCPs (median 1.0, IQR 1.0 - 1.0 and median 1.0, IQR 1.0 - 2.0, respectively). Likert scores similarly favored this concept across all 3 dimensions. Participants made several comments on workflow, such as, “During clinical routine we don’t have time to study results, we want to directly be able to extract relevant information” and “Too many screens make the system not usable, it is too much effort.”

Open Feedback Themes

Participants provided additional comments regarding feedback preferences. Several HCPs mentioned the importance of wording; for example, “The language you use is important, it can be motivating for patients or not.” Concerns were raised about potential negative feedback effects; for example, “What about if their results get worse? Then it is not motivating anymore.” Patients commented on the importance of defining goals; for example, “What is my goal? I want it defined.” HCPs also suggested linking feedback to therapeutic recommendations, such as, “Add which therapy we can do to improve the specific results.” When asked what type of feedback they would like to receive about digital health metrics (eg, VPIT), HCPs emphasized graphical visualizations and clinically relevant parameters such as endurance, time, movement precision (eg, smoothness), and daily-life applicability. Several HCPs requested simple graphical trends, such as line charts, for tracking changes. Patients primarily focused on viewing their own progress over time, especially regarding speed and differences between admission and posttherapy sessions.

Feedback Session 2: Presentation of Digital Health Metrics

Overview

The primary goal of this feedback session was to assess which digital health metrics patients and HCPs consider valuable and how these metrics could be visualized in an intuitive and engaging manner. In the second feedback session, participants evaluated 3 sets of feedback concepts, namely Set 1 focused on how to generally present digital health metrics using the example of movement smoothness; Set 2 focused on which metrics to present based on the condensed VPIT metrics; and Set 3 addressed how to communicate worsening of assessment outcomes. Each concept in Sets 1 and 2 was rated on visual appeal, informativeness, and understandability; each concept in Set 3 was rated on visual appeal and motivational aspects (Figure 5; Table S4 in Multimedia Appendix 1), while concepts in Sets 1 and 3 were additionally ranked by preference (Multimedia Appendix 1).

XSL•FO
RenderX

Figure 5. Median Likert-scale ratings for feedback on all concepts in feedback session 2. Participants rated 11 feedback concepts (A1-A3; B1-B5; C1-C3) from 3 sets: Set 1 (presentation of a single digital health metric), Set 2 (overview of all 5 grouped metrics), and Set 3 (how to present worsening results). Each concept was evaluated on visual appeal (V), each concept for Set 1 and 2 on informativeness (I), understandability (U), and on motivational (M) for Set 3 using a 5-point Likert scale. Ratings are shown separately for patients (P) and health care practitioners (HCP). Color intensity reflects the median score (red = favorable and blue = less favorable). Numbers in bold mark ratings above 4.5. I: informativeness; HCP: health care practitioner; M: motivational; P: patient; U: understandability; V: visual appeal.

Set 1: General Metric Representation

Patients assigned the highest median rank to concept A2 (extended text+illustration; median 2.0, IQR 1.5 - 2.0) and A3 (progress bar; median 2.0, IQR 1.0 - 3.0), while HCPs most frequently ranked concept A3 (progress bar) as their top choice (median 1.0, IQR 1.0 - 2.0). Among HCPs, concept A3 also received the highest Likert-scale ratings across visual appeal, informativeness, and understandability. Patients rated concepts A2 and A3 similarly on the understandability and informativeness dimensions. Qualitative feedback indicated varied preferences. One HCP described concept A2 as containing "too much information," whereas concept A3 was described as "short, concise, and to the point." Four additional HCPs commented that concept A3 was "simple, but understandable and very clear" and noted that it was "very well suited for patients." Two HCPs suggested a combination of concepts A2 and A3. One patient commented that concept B2 included "too much text," while concept A3 was "very well understandable." Two other patients similarly stated that concept A3 was "very clear."

Set 2: Digital Health Metrics

Participants evaluated 5 grouped digital health metrics, including time and speed (B1), smoothness (B2), accuracy (B3), efficiency (B4), and grabbing and holding (B5). Across all evaluated dimensions, patients generally provided higher Likert-scale ratings compared to HCPs. For visual appeal, accuracy (B3) and efficiency (B4) received the highest median ratings from both groups, with scores of 4.5 among patients and 4.0 among HCPs. In contrast, time and speed (B1) was rated lower, particularly by HCPs, with median scores of 4.0 for patients and 3.0 for HCPs. Regarding informativeness, efficiency (B4) and grabbing and holding (B5) were rated most favorably by patients, each achieving median scores of 5.0. HCPs rated all metrics slightly lower, with median scores around 4.0 and a lower rating for grabbing and holding (approximately 3.5). In terms of understandability, time and speed (B1), efficiency (B4), and grabbing and holding (B5) received the highest median scores among patients (5.0), while these metrics showed the lowest median scores among HCPs (3.0). Participant comments were specific to individual visual elements, with several suggestions for refinement. For example, one HCP proposed adding a tortoise and rabbit to the speed visualization to increase clarity.

Set 3: Worsening Scenarios

Participants evaluated 3 concepts for communicating worsening outcomes: C1 (text only), C2 (progress bar), and C3 (emoji+progress bar). Among patients, C2 received the highest median ranking (median 1.5, IQR 1.0 - 2.0), while HCPs preferred C3 (median 2.0, IQR 1.0 - 2.0). C1 was ranked lowest by both groups (median 3.0, IQR 2.0 - 3.0). Likert-scale ratings showed that concepts with visual elements (C2 and C3) were generally rated higher in visual appeal, informativeness, and understandability compared to the text-only C1. Across most dimensions, patients gave higher ratings than HCPs. Participant comments added context; HCPs described C3 as a "good visualization," appreciating the emphasis on positive aspects, though some felt the worsening was shown too strongly. Several suggested revising the emoji design, eg, using "neutral-colored, smiling emojis." For C1, HCPs stressed the need for quantitative data, "always show values," and "we always want to see exact values." Patients also preferred visuals. For C3, they liked the color-coded improvements but recommended neutral smiles. One noted, "too much indicated the negative parts." Regarding C1, a patient said, "I don't want text, it is too negative. I prefer emojis and colors." Participants also rated a text explanation stating that worsening results may reflect normal daily fluctuations. Understandability was rated at a median of 4.0 (IQR 3.0 - 4.5) by HCPs and a median of 4.5 (IQR 3.5 - 5.0) by patients; the median motivational value was 4.0 (IQR 3.0 - 4.0) and 4.5 (IQR 4.0 - 5.0), respectively. HCPs suggested making the message more encouraging and replacing "measurement variability" with relatable terms like environmental or daily performance factors. Patients asked for simpler language and generally found the text helpful. General feedback about the app development was also positive. One HCP noted, "The interface is a very nice opportunity for everyone; I am glad to be part of the optimizing process," while

XSL•FO
RenderX

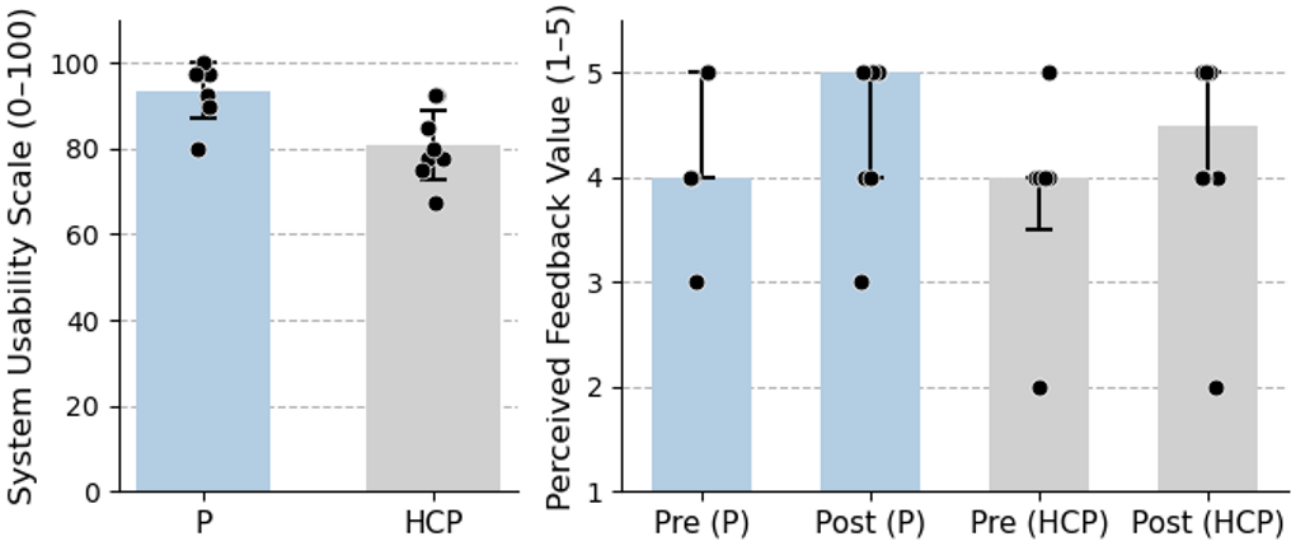
a patient commented, “exciting project with a lot of informative insights into the therapy progress.”

Feedback Session 3: Usability Evaluation of the App Prototype

The main goal of this feedback session was to evaluate the usability of the first functional app prototype. During this final structured feedback session, participants interacted with the fully functional app prototype, which featured short animations in place of static illustrations to visualize digital health metrics. Usability was evaluated using the SUS. Patients reported a mean SUS score of 93.6 (SD 6.4), corresponding to “best imaginable” usability, while HCPs reported a mean score of 80.9 (SD 8.1), corresponding to “good” usability, according to established benchmarks [67] (Figure 6). Participants were also invited to suggest improvements to the prototype. One HCP requested the inclusion of absolute values alongside percentages in performance bars: “I would like to see an absolute number with units in every bar, not only the percentage indicating improvement or decline.” Another HCP highlighted the clarity of the interface, stating:

> *The implementation of the user interface is really nice. It shows just the right amount of key information, it’s super easy to get a good overview.* [An HCP]

Further suggestions included:



> *Consider adding brief explanations when milestones are not reached, or positive reinforcement when progress is made. I’d also like to see training recommendations as videos, such as: ‘Watch this video again to improve parameter A/B/C.’* [An HCP]

Another comment was:

> *Could the system automatically assign milestones based on initial assessments? And for chronic patients, could past data from earlier years be integrated?* [An HCP]

Patients also contributed feedback. One commented, “Compliment! There’s nothing I would want to change.” Another noted, “Can you include both the absolute values and percentage improvements in the bars?” Participants were asked to rate their perceived belief in the potential value of structured feedback in a clinical setting, reflecting attitudinal measures of perceived utility rather than demonstrated clinical benefit. Patients were specifically questioned on whether they believed such feedback could enhance their motivation during therapy, while HCPs were asked if it could aid clinical decision-making. This question was previously posed to participants of feedback session 1, before any feedback concepts were introduced, enabling a pre-post comparison. Median ratings from patients increased from 4.0 (IQR 4.0 - 5.0) to 5.0 (IQR 4.0 - 5.0), while HCPs’ median ratings rose from 4.0 (IQR 3.5 - 4.0) to 4.5 (IQR 4.0 - 5.0). Additionally, HCPs rated the potential of structured feedback to enhance patient motivation at a median of 4.5 (IQR 4.0 - 5.0). Participants were also asked whether they would find value in performance comparisons to (1) age-matched healthy individuals or (2) other patients with similar conditions. Patients rated comparisons to healthy individuals at a median of 5.0 (IQR 5.0 - 5.0) and to other patients at a median of 4.0 (IQR 3.0 - 5.0). HCPs assigned corresponding median ratings of 4.0 (IQR 4.0 - 4.5) and 3.0 (IQR 2.0 - 4.0). Finally, the perceived benefit of celebrating therapeutic milestones within clinical settings was evaluated. Patients rated this concept at a median of 4.0 (IQR 3.0 - 5.0), while HCPs provided a slightly lower median rating of 3.5 (IQR 3.0 - 4.5).

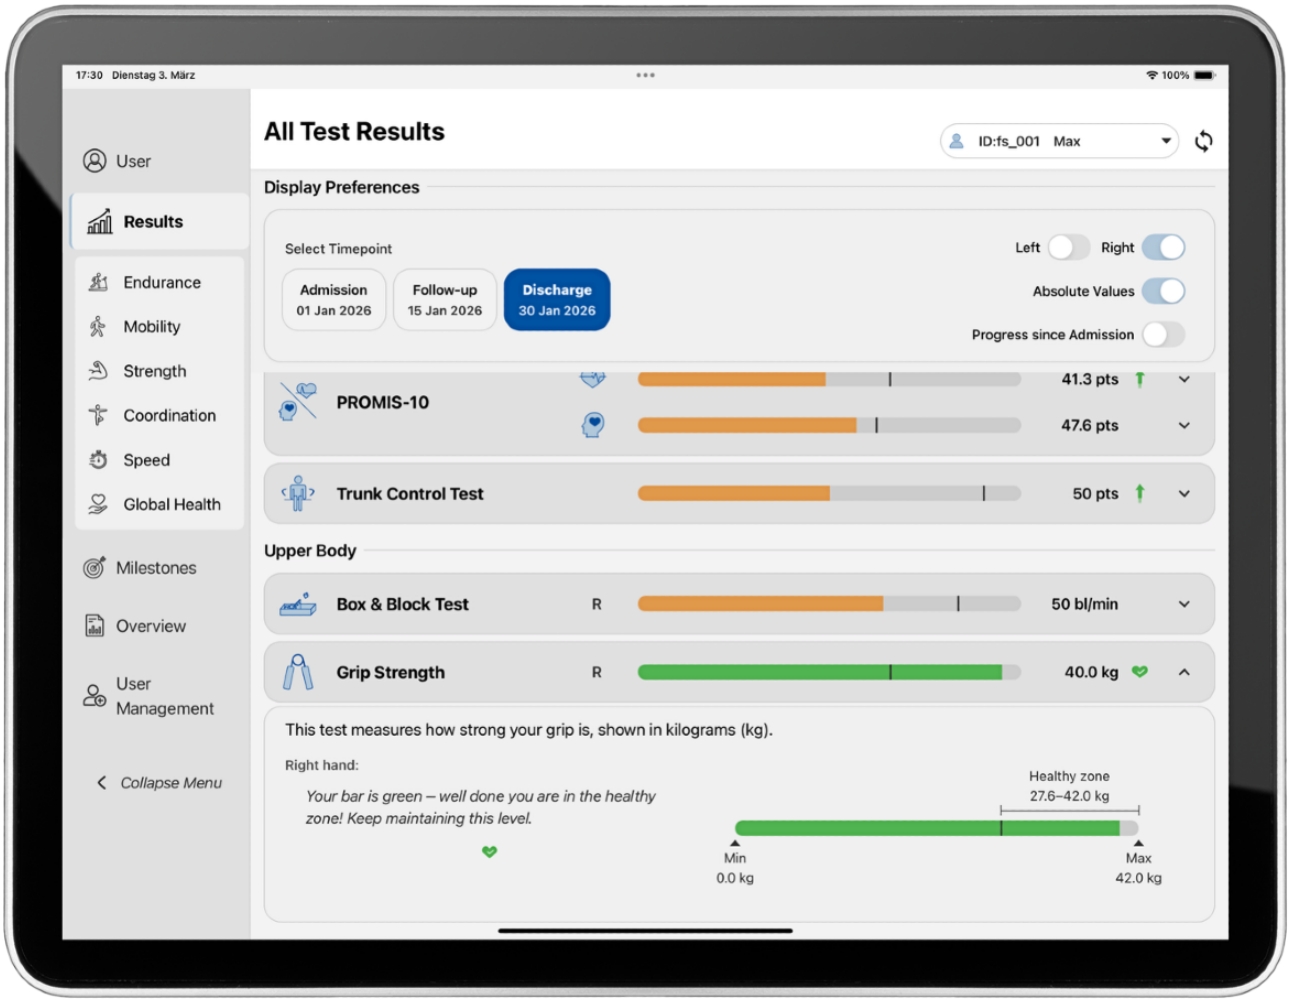
Figure 6. Evaluation of app usability and perceived value of structured feedback. The left panel shows System Usability Scale (SUS) scores for the app prototype as rated by patients (P) and health care practitioners (HCPs) in feedback session 3. The right panel presents pre–post ratings on the perceived value of structured assessment feedback in clinical routine, separately for patients and HCPs. Specifically, patients were asked if structured feedback about performed assessments could enhance their motivation to perform therapy on a more regular basis, and HCPs were asked if such feedback could aid them in decision-making processes. Patients and HCPs rated feedback value on a 5-point Likert scale before exposure to the feedback concepts (feedback session 1) and again after app testing (feedback session 3). Bars for the SUS score represent group means; error bars indicate SDs. Bars for the perceived value of structured feedback represent medians, error bars represent IQRs. Individual responses are shown as jittered black dots. HCP: health care practitioner; P: patient.

XSL•FO
RenderX

Cross-Session Themes

Across all 3 feedback sessions, several cross-cutting themes emerged. First, participants consistently preferred visually guided formats, particularly progress bars and color-coded indicators, over text-heavy or abstract representations such as spider plots or emoji-only designs, a pattern that was evident across all sessions and both stakeholder groups. Second, a set of competing demands was observed throughout: both patients and HCPs repeatedly requested access to absolute values and normative comparisons alongside simplified visuals. Third, the appropriate communication of worsening outcomes was a persistent concern across all sessions, raised by both groups from the earliest conceptual discussions through to the final prototype evaluation, ultimately informing the adoption of a neutral, color-coded feedback strategy without emotionally loaded symbols. Fourth, the perceived value of structured feedback grew across the course of the study, with both patients and HCPs rating its potential benefit more highly after exposure to the app prototype than before. Fifth, a consistent divergence in assumptions between patients and HCPs was observed. HCPs tended to recommend simpler formats out of concern that more detailed visualizations might overwhelm patients, while patients themselves consistently expressed a preference for richer, more informative representations.

Final Implementation of the Digital Feedback App



The final RehaLink app incorporated input from both patients and HCPs across all 3 structured feedback sessions. It was implemented as a mobile iOS app with 2 distinct user interfaces, one for patients and one for HCPs. The primary difference lies in data management functionality, which is available only to HCPs. This includes the ability to create new patient accounts and manage user credentials, such as resetting passwords.

The app was developed using React Native (version 15.1.3; Meta Platforms) [68], leveraging the Expo framework (version 52.0.23; Expo) [69] to facilitate efficient cross-platform development, deployment, and maintenance. It was optimized for tablet use to ensure seamless integration into clinical workflows, including bedside consultations. The backend infrastructure was implemented with Django (version 5.1.5; Django Software Foundation) [70] and a structured SQLite3 (version 3.45.3; Hwaci) database [71], providing robust mechanisms for secure data storage, user authentication, and real-time data synchronization.

Data from technology-based assessments (eg, the VPIT) is automatically analyzed and then visualized in the app interface. By contrast, data from conventional assessments is currently extracted manually from the hospital information system and exported to the app. The final digital feedback app integrates all iterative refinements from the 3 performed structured feedback sessions (Figure 7).

XSL•FO
RenderX

Figure 7. Final feedback app. Screenshot of the final RehaLink interface. The app is in normative mode; that is, shown progress bars indicate the users' functionality compared to an assessment-specific normative population, including age, gender, and handedness factors. Drop-down menus provide assessment and visualization explanations. Assessments are grouped by body region and can be filtered by functional domain (left panel). The left panel can be collapsed to show icons only.

Following session 1, findings were reviewed in a joint discussion with HCPs, resulting in a shared visual interface for both patients and HCPs to support use during consultations, with the HCP interface additionally including a patient selector and a user management tab. Navigation depth was reduced from 3 to 2 levels, with a login screen leading directly to an assessment overview. Assessments were grouped into upper body, lower body, and general categories, with a sidebar panel enabling filtering by functional domain (eg, strength and coordination) and access to personal health data (eg, BMI and weight) and the 3 primary therapy goals defined at admission. Color-coded bar charts were selected as the primary visualization format, supplemented by emoji-based indicators where appropriate.

Following session 2, a standardized format was introduced for digital health metrics, combining a recognizable icon, concise descriptive text, and an on-demand animated visualization illustrating key performance features (eg, jerky vs smooth movements). The VPIT metrics were visually aligned with conventional assessments, and all entries were supplemented with icons to support faster navigation. A left-right toggle was added for bimanual assessments to reduce visual clutter. Performance declines are indicated solely through color changes, without emotive symbols, accompanied by an explanatory note clarifying that fluctuations may reflect normal day-to-day variability. An overview panel was added displaying all assessment results in tabular format, including the patient's absolute values, the corresponding normative reference values, and the minimal detectable change (MDC) or minimal clinically important difference (MCID) thresholds as explicit columns. Values falling outside the normative range are highlighted in bold red; directional arrows indicate whether changes exceed the MDC or MCID threshold, flagging clinically significant improvements or deteriorations. This panel supports rapid clinical review and is designed to serve as a printable summary.

Following session 3, information buttons were replaced with expandable drop-down menus providing on-demand contextual explanations. VPIT metrics were grouped into a single assessment block with distinct subcategories to prevent visual overemphasis. Value labels were added next to performance bars, available in both absolute and percentage formats with a user toggle between the two. A tab-based navigation system was introduced to enable longitudinal browsing across assessment time points, with the most recent results displayed by default.

Two display modes were implemented. The progress mode, shown by default, displays changes in performance relative to

XSL•FO
RenderX

the patient's baseline at admission, using a color-coding scheme based on the MDC or, where unavailable, the MCID. Improvements beyond the threshold appear as green bars extending right, changes within the threshold range in orange, and deteriorations beyond the threshold in red extending left. The normative mode maps each outcome to a 0 - 100 scale referenced against an age-, gender-, condition-, and handedness-matched healthy population, where 100 represents the median healthy performance and the lower bound of the healthy range is defined as the median minus 2 SDs. Scores within the healthy range appear in green, values below the healthy threshold but above 50% in orange, and scores below 50% in red. Normative values for the VPIT were derived from a healthy reference database (n=120); norm values for conventional assessments were taken from previously published reference data [6,9,72-79]

To promote accessibility and personalization, the app includes user-adjustable settings such as dark mode, scalable font sizes, and high-contrast color schemes. Users can additionally hide assessment entries for tests that have not yet been performed, reducing visual clutter and cognitive load. Further, the default displayed unit (absolute vs percentage), hand side, and mode (normative vs progress) can be set for each user account. The interface is available in 4 languages, German, French, Italian, and English, to reflect the multilingual reality of Swiss rehabilitation settings.

Discussion

This study presents a 3-step, iterative, user-centered approach to designing a digital app that delivers structured feedback on assessment results to patients and HCPs in neurorehabilitation. After defining clinical and user requirements, we conducted three structured feedback sessions to evaluate: (1) the type, amount, and visual format of information presented; (2) the integration and representation of digital health metrics from technology-based assessments; and (3) the usability of a digital app prototype delivering this feedback. The final application presents assessment outcomes in a co-designed format tailored to both stakeholder groups. Likert-scale ratings indicate a growing perceived value across all sessions.

The motivational and clinical benefits of personalized feedback are well supported in rehabilitation literature. Moreover, feedback that is timed, personalized, and performance-related improves engagement and motor outcomes and reduces patient anxiety [27,28,30,31]. While prior work mainly focused on real-time feedback during therapy, our app delivers post-assessment feedback. Nevertheless, similar benefits are expected, including increased motivation, better understanding of progress, and enhanced shared decision-making. Structured feedback has also been recognized as a tool for more evidence-based, value-based health care (VBHC) [32], which our co-designed digital app supports.

To ensure these expected benefits translate effectively into practice, our main focus was to evaluate how feedback is presented to users. Users preferred clear visuals such as bar charts with optional, layered explanations over more complex formats like line or spider graphs, which can be harder to interpret [63,64]. Beyond confirming general preferences for visual simplicity, our findings provide context-specific insights into why particular visualization formats failed in this neurorehabilitation setting. Spider plots were consistently ranked lowest by both groups, likely because radial layouts mask the directionality and magnitude of change, information that is particularly relevant for patients tracking rehabilitation progress over time. Text-only formats were rejected not only because they lacked visual appeal, but also because participants associated plain text with negativity, particularly when communicating worsening outcomes, consistent with prior findings on the psychological impact of health data framing [80,81]. Emoji-only formats failed because both groups considered quantitative information essential for meaningful interpretation, a finding that contrasts with their common use in consumer health apps. Extended text formats were specifically rejected by HCPs due to information overload in time-constrained clinical workflows, while patients were more tolerant of detailed explanations, reinforcing the divergence in informational needs between the 2 groups. Importantly, this divergence itself represents a finding that extends beyond established heuristics; HCPs consistently underestimated patients' wishes for detailed, quantitative visualizations, suggesting that clinician judgments about patient interface preferences may be systematically biased toward oversimplification. More broadly, while existing literature addresses specific aspects of health data visualization in isolation, such as general patient preferences for chart types or usability of consumer health apps, our study takes a more comprehensive approach. Specifically, it is distinctive in evaluating the full pipeline from information selection and visualization design through to prototype usability, simultaneously engaging both patients and HCPs in a rehabilitation-specific context centered on the presentation of assessment outcomes. To our knowledge, no prior work has examined this complete process in this clinical setting, particularly with the integration of technology-based assessment metrics alongside conventional clinical assessments.

In contrast to many digital health tools that offer static or device-specific reports, our digital feedback app applies strategies like expandable content design and visual simplification [64] to preserve clinical utility without sacrificing usability. Compared to typical device-generated reports, our solution emphasizes personalization, clarity, and emotional neutrality. These preferences align with usability literature, especially for patients and older adults, key populations given the increasing prevalence of age-related neurological disorders. They tend to favor icon-driven navigation, high-contrast layouts, and intuitive visuals [46,49,50,82]. In line with these recommendations, RehaLink incorporates adjustable font sizes, high-contrast color options, and dark mode support, features shown to improve readability and reduce visual fatigue in older and neurologically impaired users [49,50]. The observed divergence between HCP assumptions and patient preferences underscores the importance of iterative, inclusive stakeholder engagement throughout the design process. Features like toggleable views—between absolute and normalized scores or between progress and normative benchmarks—allowed personalization without cognitive overload. These solutions

XSL•FO
RenderX

addressed users' varied informational needs while preserving interpretability and clinical relevance. Ramesh et al [83] used a symbolic, metaphor-driven approach that omitted numerical data and involved patients only at the final evaluation stage. In contrast, our participants were engaged throughout the full design process and explicitly requested access to raw scores. By combining quantitative metrics with intuitive visuals, our tool meets diverse informational needs and promotes transparency. Moreover, our larger, more diverse sample supports a broader generalizability. A key design insight was the need to balance simplicity with sufficient depth.

These design preferences not only influenced visual choices but also highlighted the importance of emotional tone and clinical context in delivering feedback. Participants were not just passive recipients of information but active stakeholders who were concerned with how their performance data were presented, especially when it involved sensitive or potentially discouraging results. As such, our co-design process extended beyond aesthetics to encompass the psychological and clinical dimensions of feedback delivery. While emojis were appreciated for reinforcing positive progress, participants favored more neutral, color-coded indicators and supportive language when feedback indicated worsening. This reflects prior findings that uncontextualized or overly negative feedback can increase patient anxiety [80,81] and should be carefully framed. Co-design allowed visual elements to be emotionally contextualized—emojis for improvement, neutral tones for decline—supporting engagement and comprehension. To ensure appropriate support, this digital feedback app is designed for use during patient consultations rather than in isolation.

In addition to emotional sensitivity, participants expressed a desire for actionable guidance and goal-setting tools. Patients valued reassurance during setbacks and the ability to track their own progress, while HCPs stressed the importance of clinically meaningful metrics and normative comparisons. This aligns with evidence supporting goal setting as a key motivator [27,84] and broader recommendations for embedding digital tools within VBHC frameworks [26]. Despite VBHC's potential, its implementation remains challenging due to fragmented infrastructure and limited outcome tracking [3,33].

By combining conventional and digital health metrics in a co-designed tool, our approach addresses these gaps and has the potential to support data-driven, patient-centered care. A central aim of this work was to demonstrate how digital health metrics can be meaningfully integrated into clinical routines. Digital health metrics, such as those exemplified by the VPIT, contribute objective, fine-grained, and repeatable measurements that can enhance the sensitivity and clinical utility of outcome tracking [11,21,56,59]. Their standardized format allows for automated longitudinal monitoring, eliminating the need for manual digitization or additional data processing, and supports meaningful comparisons across patients and time points. While the VPIT specifically targets upper limb sensorimotor function, its metric design is conceptually aligned with other technology-based assessments, such as those using wearable sensors for upper limb monitoring [85,86]. These approaches share the goal of capturing movement quality and functional performance through quantifiable, reproducible measures. Moreover, the principles guiding the presentation and interpretation of VPIT metrics are broadly applicable to other rehabilitation domains, for example, including lower limb function and cognitive assessments, where a wealth of digital health metrics has been proposed [87-90]. As such, the use of digital health metrics in feedback tools offers significant potential to advance VBHC by improving outcome transparency, personalization, and clinical efficiency.

The final digital app, refined through iterative feedback, achieved high usability scores from both stakeholder groups (SUS: patients 93.6, SD 6.4; HCPs 80.9, SD 8.1). Users highlighted ease of navigation, clear interface design, and appropriate feedback granularity. Importantly, even participants with low digital literacy reported no major interaction issues, supporting the tool's accessibility. Implementation feedback prioritized interoperability with electronic health records, inclusion of therapy recommendations, and milestone tracking. These additions, including automatic goal setting and benchmarking, enhance clinical integration and self-management.

While promising, this study is subject to several limitations. The patient cohort consisted only of persons with MS, recruited from a single neurorehabilitation center, which represents a limitation with respect to the direct generalizability of findings to other neurorehabilitation populations such as stroke or traumatic brain injury. However, several aspects of the study support broader applicability. First, no design decisions were specific to MS or restricted by condition-specific cognitive or motor profiles; the only practical prerequisite for app use is sufficient cognitive capacity to interact with a tablet-based interface, which applies across neurorehabilitation populations. Second, the HCPs involved were diverse neurorehabilitation therapists, and the conventional assessments integrated into the app are routinely used across neurorehabilitation conditions. Third, the VPIT, used here as a proof of concept for technology-based assessment integration, has been validated in individuals with different neurological disorders, such as MS, stroke, and ataxia. Moreover, while this evaluation was conducted using mock data, future studies should assess the app's real-world impact on clinical decision-making, patient adherence, and therapeutic outcomes. The clinical utility of the selected conventional and technology-based assessments also remains to be established through routine use and empirical testing. Additionally, interpreting the digital health metrics, particularly their prognostic relevance and implications for therapy adaptation, requires larger datasets and further investigation. Understanding how these metrics translate into actionable clinical decisions is crucial for the tool's long-term adoption and effectiveness. A limitation of the implementation is that data from conventional assessments requires manual extraction from the hospital information system to be exported to the app. While this introduces an additional workflow step, direct integration with clinical management systems was out of the scope of this work and not feasible at this stage of development due to data protection and information technology security constraints, which commonly apply in clinical settings. Should the ongoing evaluation demonstrate sufficient clinical benefit, integration of the app into the clinic's existing

XSL•FO
RenderX

information technology infrastructure is planned, which would enable automated data transfer and eliminate this manual step.

In summary, we demonstrate the feasibility and value of a co-designed tool for rehabilitation. Through structured feedback and iterative design, we developed a digital app that aligns with clinical workflows, enhances patient engagement, and has the potential to advance digital health integration. While these findings are promising, especially in terms of usability and stakeholder acceptance, further research is needed to evaluate the tool's impact in real-world settings, across broader patient populations, and in fully integrated clinical infrastructures. Our results offer a foundational step toward embedding patient-centered feedback systems into clinical routine, with potential to support data-driven decision-making and VBHC.

Acknowledgments

We thank all patients and health care practitioners who participated in this study for their valuable contributions. We also thank Franziska Riegel and Daniel Riese for their input during discussions on the study design. Abstract

Background: Fibromyalgia (FM) causes widespread pain, fatigue, and cognitive abnormalities. Cervical pain is a common and debilitating symptom.

Objective: This study aims to evaluate the effectiveness of virtual reality (VR) as a treatment for chronic cervical pain experienced by patients with FM.

Methods: A single-blind randomized clinical trial was conducted. A total of 56 women were randomly assigned to 3 groups: G1 (VR+cervical mobility exercises), G2 (cervical mobility exercises), and the control group. Therapy was administered twice a week for 4 weeks. Variables such as disease impact, quality of life, kinesiophobia, pain, range of motion, fatigue, and treatment adherence were measured.

Results: The mean age of the participants was 54.26 (SD 7.7) years. Participants were overweight, with a mean BMI of 28.7 (SD 7.8). The mean visual analog scale value was 6.72 (SD 1.8). The baseline values for age, BMI, visual analog scale, algometric measures, and functional capacity (measured using the Timed Up and Go test, cervical rotation, and lateral displacement) were similar across the 3 groups. Following the intervention therapy, the control group did not exhibit notable improvement (mean 3.5, SD 1.4; differences of mean values –0.46, 95% CI –1.1 to 0.2; *P*=.15), particularly in pain perception, while both therapy groups did show improvements (G1: mean 3.8, SD 1.1; differences of mean values 1.2, 95% CI 0.78-1.54; *P*<.001; G2: mean 2.8, SD 1.8; differences of mean values 1.2, 95% CI 0.66-1.7; *P*<.001). Both intervention groups improved significantly compared to control postintervention in FM impact (CG vs G1: differences of mean values 9.31, 95% CI 14.7-3.8; *P*<.001; CG vs G2: differences of mean values 8.4, 95% CI 13.84-3.06; *P*<.001), central sensitization (CG vs G2: differences of mean values 7.53, 95% CI 12.12-2.95; *P*<.001), and cervical disability (CG vs G2: differences of mean values 6.44, 95% CI 9.93-2.94; *P*<.001). However, at 1 month, only G1 maintained superior improvements across all measures, including a reduction in kinesiophobia (G2: differences of mean values 6.2, 95% CI 4.7-9.8; *P*<.001), indicating a more sustained effect of the combined approach.

Conclusions: The combination of VR with cervical mobility and strengthening exercises produced superior and sustained improvements in women with FM compared to exercise alone or control. Significant benefits were observed in disease impact, central sensitization, cervical disability, and kinesiophobia, with effects maintained at 1 month only in the VR group. These findings support VR as an effective adjunct to enhance symptom management and treatment adherence in FM.

Introduction

Fibromyalgia (FM) is a disease that causes widespread chronic pain and intense fatigue along with many other symptoms [1-3]. Historically, there was some skepticism among health care professionals regarding the existence of this disease and its classification as a mental disorder. Such skepticism may have arisen from concerns about the optimal use of resources in providing care for individuals with FM [3,4]. It is estimated that this disease affects between 2% and 4% of the Spanish population, making it the most common cause of diffuse chronic musculoskeletal pain. Notably, the prevalence is much higher in women, with a ratio of 8:1 [5-7]. Its incidence is increasing because of the improvements in diagnostic criteria and advances in research that are bringing this pathology to light [7,8]. Given its high prevalence, this disease represents a significant public health concern [9,10].

Currently, there are no specific diagnosis tests available for confirming an FM diagnosis. Historically, an FM diagnosis was based on the presence of widespread pain in at least 11 of 18 designated tender points for a duration of 3 months. However, this criterion proved insufficient to capture the complexity of the disorder. Consequently, more comprehensive diagnostic frameworks have been developed, including a range of associated symptoms such as fatigue, joint stiffness, cervical and lumbar pain, muscle weakness, depressive symptoms, gastrointestinal issues, cognitive impairments, and balance alterations. Collectively, these manifestations significantly compromise the quality of life of individuals affected by FM. This pain can become disabling during flare-ups and even become chronic, often being a cause of recurrent absences from work [11].

Unlike pain associated with a sedentary lifestyle or poor posture, neck pain in FM results from a complex interplay between physiological, neurological, and psychological factors. Chronic pain often involves the cervical spine, leading to acute and prolonged pain episodes, along with muscle tension in the suboccipital, trapezius, and elevator scapulae muscles. It is thought that several factors may contribute to this chronic pain, including central pain sensitization, nervous system dysregulation, sleep disturbances, musculoskeletal changes, and psychological and emotional factors [11-13].

In recent years, new therapeutic approaches have been explored to improve symptomatology and thus patients' quality of life. One of the main challenges in treating patients with chronic pain, particularly those with FM, is their low adherence to physical therapy exercises. This may be due to factors such as severe pain and fatigue, a fear of worsening symptoms, a lack of understanding about exercise benefits, inadequate support and supervision, and frustration with slow improvement. To address these issues, it would be beneficial to adopt a comprehensive approach that involves educating patients regarding the benefits of exercise, customizing programs according to individual needs, providing ongoing support via health care professionals, managing pain and fatigue during exercise, setting realistic expectations, and recognizing achievements [14-16]. It may be beneficial to consider a treatment plan that incorporates aerobic activities, strength training, and stretching exercises [17-19]. However, this type of therapy may be limited by kinesiophobia. One possible solution to this issue could be the use of virtual reality (VR) technology. Exercise interventions delivered through VR have shown superior efficacy in alleviating the core symptoms of FM, including pain, fatigue, and stiffness, while also promoting improvements in balance and postural control [20]. The affordability of portable VR devices, combined with their sustained effectiveness as a nonpharmacological intervention for chronic pain management, positions VR as a promising tool with potential future applications as an analgesic modality [21]. Numerous randomized controlled trials have demonstrated that VR constitutes an alternative and accessible therapeutic approach for pain management [22].

Immersive VR is an innovative and interactive technology that generates 3D scenarios, enabling patients to experience highly realistic simulations while interacting with the virtual environment using their own hands. VR has been researched and applied in various contexts for pain management, demonstrating considerable potential as a therapeutic tool. The effectiveness of this therapeutic approach has been demonstrated for patients with chronic pain, as it addresses several factors, such as fatigue, kinesiophobia, and range of motion (ROM) [23]. This therapy can be adapted to suit the specific requirements of each patient, providing the option to adjust the level of difficulty from low to intermediate or high. Additionally, it offers a variety of game modes that could be beneficial in targeting different clinical conditions, such as low back pain, neck pain, and balance disorders [24,25].

The therapeutic mechanisms and components of VR are distraction, activity management and behavioral activation, skills-based cognitive behavioral therapy, relaxation training and biofeedback, positive emotion induction, neuromodulation, physical rehabilitation, and reduction of kinesiophobia [8,23,26].

VR can be categorized into 2 main types: immersive and nonimmersive. Immersive VR involves the use of head-mounted displays or VR goggles that fully cover the visual field and may include motion sensors for the hands or feet. In contrast, nonimmersive VR is accessed through conventional screens or computers, without any device that isolates the user from the external environment [27] .

Chronic pain has been extensively investigated over the past decades, and research efforts persist in identifying novel strategies to mitigate its impact and enhance patients' quality of life. VR in both modalities has demonstrated efficacy in reducing chronic musculoskeletal pain. These findings support the integration of VR as a therapeutic tool in clinical populations affected by conditions associated with this type of pain [28].

Patients may perceive amplified motion in the virtual world, depending on the configuration of the headset used. This could result in small neck flexion in real life being rewarded with greater apparent motion in VR, which might increase kinesiophobia [26]. Studies have indicated that for patients with chronic low-back pain, kinesiophobia may be addressed through VR interventions [20,29,30]. VR helps to distract an individual from painful stimuli while exercising in a way that improves

XSL•FO
RenderX

their perception of pain [31]. In addition, there have been indications that improvements in fatigue, sleep quality, and ROM may also be achieved [9].

In this study, we aimed to evaluate the effectiveness of VR as a therapeutic option for neck pain in patients with FM. We hypothesized that VR could decrease cervical pain and kinesiophobia and increase ROM, facilitating improvements in quality of life and adherence to treatment.

Methods

Trial Design

A single-blind, randomized experimental clinical trial was conducted among women diagnosed with FM recruited through the Association of Fibromyalgia, "AFINSFACRO," in Móstoles, Spain. Following the selection of patients who met the inclusion criteria and the collection of informed consent forms and information sheets, according to ethical standards, the patients were randomly assigned to 1 of the 3 groups. The first group performed 20 minutes of exercise plus 10 minutes of VR (G1), the second group performed 30 minutes of exercise (G2), and the control group (CG) did not perform any exercise or VR treatment.

This study was registered at ClinicalTrials.gov (NCT05933941) and approved by the Clinical Research Committee of the Hospital Clínico San Carlos (Madrid, Spain; ID: VRTCNPPFM-13/07/2023). The research was conducted from April 1, 2024, to January 30, 2025. All participants gave informed consent, and the general scope of this study was explained to them via a participant information sheet. This clinical trial was designed and reported in accordance with the CONSORT (Consolidated Standards of Reporting Trials) guidelines, with specific adherence to the CONSORT-Harms (Consolidated Standards of Reporting Trials Harms Extension) 2022 statement (Checklist 1) to ensure transparent and comprehensive reporting of adverse events and safety outcomes.

Participants

The QuestionPro survey software (QuestionPro, Inc) was used to calculate the required sample size, considering a 95% CI and a 5% α error. The sample size calculation was based on the study by Gulsen et al [8]. A total of 56 women were enrolled, of whom 2 withdrew for personal reasons unrelated to the study. The inclusion criteria comprised female patients aged 20 to 65 years with a confirmed diagnosis of FM and chronic cervical pain lasting more than 3 months. The exclusion criteria included vertigo, claustrophobia, epilepsy, pregnancy, or refusal to provide informed consent.

Type of Sampling

A consecutive, nonprobabilistic convenience sampling strategy was applied to participants who met the inclusion criteria.

Variables and Outcomes

Sociodemographic variables included age, height, weight, BMI, marital status, pain medication use, employment status, smoking history, and comorbid conditions such as restless legs syndrome, chronic fatigue syndrome, temporomandibular joint dysfunction, migraines, irritable bowel syndrome, multiple chemical sensitivity, anxiety, and depression. All these sociodemographic variables were collected using a self-administered survey.

The following tools were used in this study:

1. Pain: we used a visual analog scale (VAS) to assess self-reported pain intensity, ensuring maximum reproducibility among different observers [32]. Furthermore, we used an analog pressure FPK 20 algometer (Wagner algometer, Force Dial FDK 20; Wagner Instruments) to evaluate pain among individuals diagnosed with FM. This instrument allows the assessment of a patient's central sensitivity to pain. Measurements focused on tender points in the occipital and upper trapezius regions bilaterally [33-35].
2. Subjective intensity of effort was assessed using the Borg Category-Ratio Scale (CR-10), which quantifies the subjective intensity of effort experienced during physical exercise or functional testing. Participants were asked to rate their exertion immediately after each test or exercise session on a 0 to 10 scale, where 0 indicates "no exertion at all" and 10 represents "maximal exertion" [36].
3. Neck Disability Index (NDI): the validated Spanish version of this questionnaire was used to assess pain and neck-related disability [37].
4. Fear of movement: the Tampa Scale for Kinesiophobia (TSK) was used to assess the fear of movement [38].
5. Exercise adherence: we used the Exercise Adherence Rating Scale, which is a validated questionnaire with 2 sections, one assessing exercise performance and another evaluating frequency, motivation, and consistency [39].
6. Impact of FM: the Fibromyalgia Impact Questionnaire (FIQ) was used to assess the impact of FM on health-related quality of life [40-42].
7. Quality of life: we used EQ-5D (EuroQol 5-Dimensions) questionnaire, which is a tool that allows the evaluation of a patient's overall quality of life in primary care settings [43-45].
8. Symptoms of central sensitization: we used the validated Spanish version of the Central Sensitization Inventory (CSI). This questionnaire assesses symptoms using a scale of 0 ("never") to 4 ("always"). The total score ranges from 0 to 100. A score above 40 indicates the presence of central sensitization [46].
9. ROM: cervical flexion, extension, lateral flexion, and rotation were assessed using a goniometer [47]. This instrument is used to evaluate one's degree of joint mobility, thereby facilitating the determination of an individual's restrictions.
10. Time Up Go test: the test consisted of measuring the time it took participants to get up from a chair with a height of 46 cm, walking 3 meters, turning around a cone, and sitting down again. This test was performed to assess physical performance, gait, and dynamic balance [48,49].

Procedure

The intervention was conducted over a period of 1 month. G1 and G2 participated in 2 sessions per week. G1 performed 20 minutes of cervical mobility and strengthening exercises

XSL•FO
RenderX

(Multimedia Appendix 1), followed by 10 minutes of immersive VR therapy. G2 completed 30 minutes of cervical mobility and strengthening exercises. The CG did not perform any cervical mobility or strengthening exercises nor participate in immersive VR therapy. The immersive VR therapy was delivered using Meta Quest 2000 headsets, using the game "Interkosmos 2000." In the game, participants assumed the role of a spacecraft pilot navigating through a series of rings while avoiding meteoroids by performing neck movements according to the game's instructions. The difficulty level was adjusted as follows: the first 3 sessions were carried out in "easy" mode, allowing a maximum cervical mobility of 30°. The subsequent 3 sessions were conducted in "medium" mode, allowing up to 60° of cervical mobility. The final 2 sessions were performed in "hard" mode, which not only increased the spacecraft's speed but also enabled a full cervical range of motion. All groups underwent assessments of cervical ROM including flexion, extension, right and left lateral inclination, and right and left rotation. In addition, pain intensity in the upper trapezius (bilaterally) and in the right and left occipital regions was quantified using an algometer. Evaluations were conducted at 4 time points: baseline (preintervention), immediately after the intervention, 15 days postintervention, and 1 month postintervention. All follow-up assessments were performed at the association's premises. After each session, participants from G1 and G2 reported their perceived levels of cervical pain and fatigue. All outcome measures were collected by a research assistant blinded to the study objectives and group allocations.

Evaluations were conducted at 4 time points: baseline (preintervention), immediately postintervention, 15 days postintervention, and 1-month postintervention. All follow-up assessments were conducted at the association's headquarters. After each session, participants in G1 and G2 reported perceived levels of cervical pain and fatigue.

All outcome measures were collected by a research assistant who was blinded to both the study's objectives and the participants' group assignments.

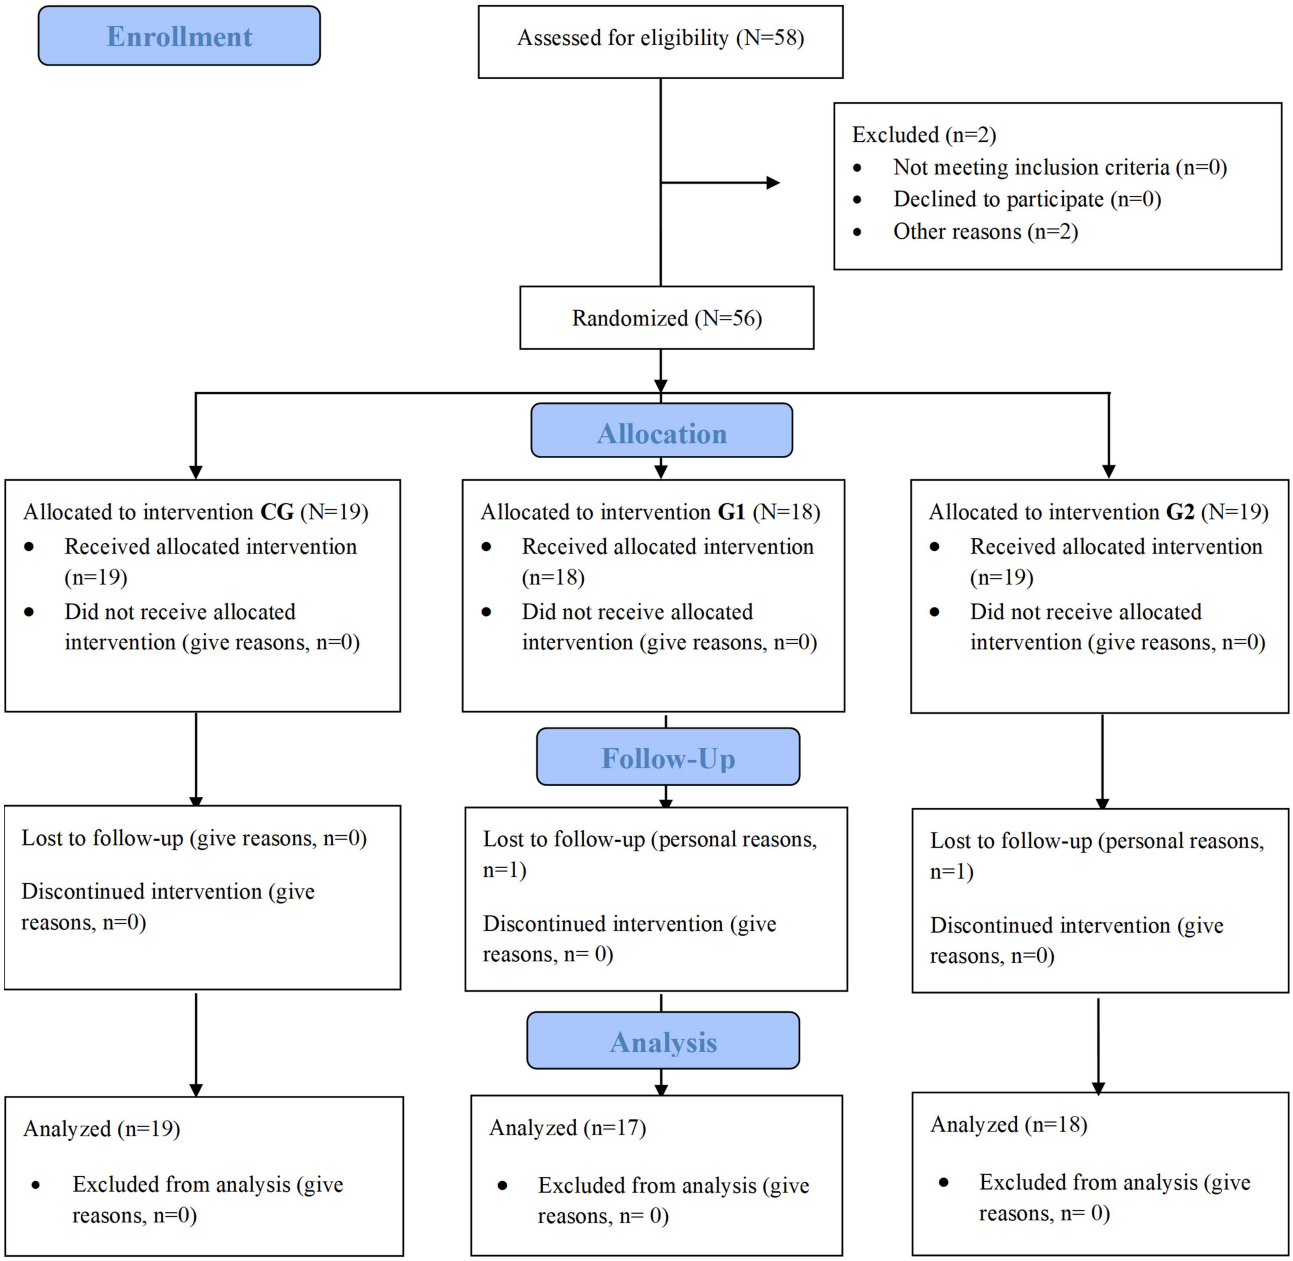
Statistical Analysis

Statistical analyses were performed using SPSS 29.0 (IBM Corp). The normality of quantitative variables was assessed with the Kolmogorov-Smirnov test. Depending on distribution, data were described using means and SDs or medians, IQRs, and ranges. Qualitative variables were expressed as percentages and absolute values. Baseline comparisons between the groups were conducted using chi-squared tests or ANOVA with Bonferroni post hoc analysis. Temporal changes in outcomes were analyzed with paired tests, and intergroup differences were analyzed using ANOVA, Bonferroni post hoc, or Kruskal-Wallis tests, as appropriate. Correlations between quantitative variables were assessed using the Pearson or Spearman tests, and associations between qualitative variables were assessed using chi-squared tests. Statistical significance was set at $P<.05$.

Ethical Considerations

This study received approval from the institutional review board of Hospital Clínico San Carlos (23 - 458 EC) and was conducted in accordance with the Spanish legislation, including Law 41/2002 on patient autonomy and Organic Law 3/2018 on data protection and digital rights. These laws prohibit the processing of sensitive personal data such as racial or ethnic origin, political or religious beliefs, biometric identifiers, health information, and sexual orientation. The study also adhered to the ethical principles outlined in the World Medical Association's Declaration of Helsinki 2014 [50]. All procedures conducted in this study complied with applicable ethical standards. Informed consent was obtained from all participants prior to their inclusion in the study. Participant privacy and confidentiality were strictly protected, and all data were handled and stored in accordance with relevant data protection regulations. No personally identifiable information was collected or disclosed. Participants did not receive any financial or material compensation for their participation.

Results



Participant and Baseline Characteristics

The final sample included 54 women with a mean age of 54.26 (SD 7.7) years. Participants were distributed among the groups by computer-generated random number sequence (Figure 1).

Among the participants, 33 (61%) presented chronic fatigue syndrome, 37 (68%) had temporomandibular joint dysfunction, and 16 (33%) reported restless legs syndrome. Regarding the psychological comorbidities, 33 (61%) participants presented anxiety and 13 (24%) depression. Baseline comparisons revealed no statistically significant differences among groups in age, BMI, or other demographic variables. However, subjective measures showed group-level differences in several baseline scales, including FIQ, EQ-5D, CSI, NDI, and Borg scale. Almost all variables at baseline start from similar values, although G1 has a value of 1 point lower on the VAS scale, indicating that they have less pain at the outset. However, in variables such as algometry, the averages reflect similar values compared to the other 2 groups (Multimedia Appendix 2).

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) flow diagram. CG: control group.

Postintervention Outcomes

Table 1 shows the differences in the mean values measured before therapy and immediately after its end. We found significant differences in all groups that received intervention in FIQ, CSI, NDI, right and left trapezius, occipital algometer, and in all movements in which ROM was evaluated. For the right and left trapezius and occipital muscles, algometric measurements were obtained, and ROM was assessed across all evaluated movements. About the treatment adherence variable, G1 obtained an average of 94 points out of 100, compared to G2, whose post-treatment average was 74.72. The summary of the comparison between baseline measures and measures immediately after intervention (intragroup comparisons). Shown are the differences in the mean values between both time points (Multimedia Appendix 3).

[a]CG: control group.

[b]FIQ: Fibromyalgia Impact Questionnaire.

[c]EQ-5D: EuroQol 5-Dimensions.

[d]TSK: Tampa Scale for Kinesiophobia.

[e]CSI: Central Sensitization Inventory.

[f]NDI: Neck Disability Index Questionnaire.

After confirming the effect of both interventions, we compared the intervention groups to see whether VR had a significant influence on the effect of the therapy. Table 3 shows that the ANOVA between groups was significant for FIQ, CSI, and NDI at both postintervention and 1-month follow-up (*P*<.001). Immediately after treatment, both intervention groups (G1 and G2) improved significantly compared with the CG, with no differences between G1 and G2. At 1 month, G1 maintained superior outcomes across all measures, showing significantly better scores than both GC and G2 (*P*<.001), while G2 no longer differed from GC for FIQ and CSI. For NDI, all pairwise comparisons were significant (*P*<.001), confirming that both interventions reduce neck disability, with the VR-enhanced program providing the greatest and most sustained benefit.

XSL•FO

[b]CSI: Central Sensitization Inventory.

[c]NDI: Neck Disability Index Questionnaire.

[d]CG: control group.

Discussion

Principal Findings

This study evaluated the effectiveness of VR as an adjunctive therapy for cervical pain in women with FM. The main findings revealed that combining VR with mobility and strengthening exercises produced significant improvements in pain perception, ROM, and functional performance compared with physical therapy alone. These benefits were also sustained at 1-month follow-up, emphasizing the potential of immersive VR interventions to enhance therapeutic outcomes in individuals with FM.

In the intergroup analysis, the G1 consistently outperformed both G2 and CG in those outcomes most closely related to global disease impact and NDI. Specifically, G1 showed significantly greater and more sustained improvements in FIQ and CSI scores than both CG and G2, whereas improvements in G2 tended to converge toward control values at 1-month follow-up. Similarly, NDI scores decreased in both intervention groups immediately after treatment, but at follow-up, a clear gradient GC>G2>G1 was observed, indicating the largest and most persistent reduction in neck-related disability in the combined intervention. These effects were paralleled by a recurrent pattern of superior gains in cervical ROM and higher-pressure pain thresholds in the trapezius and occipital in G1, while the Time Up Go test

XSL•FO
RenderX

improved in both intervention groups compared with CG and TSK decreased more markedly in G1 at 1 month. By contrast, the VAS and Borg scale showed only limited discrimination between the groups, suggesting that the added value of VR was more evident in multidimensional impact and sensitization-related and functional domains than in isolated pain ratings.

This intergroup pattern is consistent with previous evidence in FM and chronic neck pain, indicating that VR, particularly when used as an adjunct to active exercise, preferentially enhances global impact, disability, and pain-modulation outcomes. In patients with FM, a study reported that fully immersive VR combined with aerobic and pilates training produced greater improvements in pain, kinesiophobia, fatigue, physical activity levels, and mental quality of life than exercise alone, while both groups improved in FM impact, supporting an adjunctive role of immersive VR in comprehensive rehabilitation programs [8]. Other studies showed that, in individuals with chronic neck pain, VR-based cervical training led to larger gains in pressure pain thresholds at the upper cervical levels and greater reductions in functional limitation compared with motor control exercises, despite the absence of between-group differences in pain intensity and quality of life, which parallels our finding of more robust intergroup differences in pressure pain thresholds, ROM, and disability than in VAS score [51]. Furthermore, a randomized crossover trial in women with FM found that VR increased cold pain thresholds and tolerance in both FM patients and pain-free controls, whereas effects on pain intensity were limited, reinforcing the notion that VR may primarily modulate pain processing rather than consistently decreasing reported pain intensity [52]. Taken together, these converging results suggest that combining immersive VR with targeted cervical exercise may primarily potentiate mechanisms related to central sensitization, motor control, and the global impact of FM rather than merely amplifying short-term analgesic effects.

VR has emerged as a promising nonpharmacological intervention for the symptom management of FM. Its immersive and interactive features provide cognitive distraction, emotional engagement, and motor stimulation, which together enhance adherence and reduce pain intensity. Previous studies have demonstrated that VR can improve mood, motivation, and functional capacity when applied alongside traditional rehabilitation or psychological therapies. This approach not only benefits patients with FM but may also be applicable to other chronic pain conditions [49,50,53].

The use of VR has been demonstrated to significantly influence pain relief, motor function, and joint mobility among patients with a range of chronic pathologies [53]. The primary applications of VR in health care include the management of pain and anxiety as well as the enhancement of patient motivation [47,54,55].

While it is not possible to make direct comparisons between this study and research conducted by other authors, the described implementation of an 8-session intervention resulted in statistically significant outcomes for the variables under investigation. This suggests VR is effective when combined with active exercise therapy.

The comparative analysis concerning VR and physical exercise indicated that there was minimal divergence in the measured variables. In a separate study [56], 44 patients underwent an intervention for 4 weeks, with 2 sessions per week. The intervention was divided into 2 groups: G1 (whose members performed only cervical mobility exercises) and G2 (whose members conducted a treatment based solely on VR exercises). The findings indicated that there were no statistically significant differences between the 2 groups across the different variables, including pain, ROM, neck disability, incapacitating pain, and anxiety. However, in this study, the combination of VR with cervical mobility exercises yielded a significantly better outcome. Furthermore, these improvements were maintained over time (1 month) to a greater degree in the group subjected to both therapies combined when compared to the group that performed only mobility exercises. It is important to highlight that the study with which this investigation was compared implemented its intervention in a population without FM. Consequently, the observed discrepancy in outcomes could be due to this factor. A similar study was conducted [51], with an equivalent number of sessions implemented. The outcomes observed in this research were analogous to those obtained in our research, as the investigators combined active therapy and VR exercises for patients with FM [55]. However, the FM cohort in that report comprised only 20 patients. In addition, the active component focused on aerobic training and Pilates instead of the cervical exercises used in our research.

Another study assessed the efficacy of VR for patients with chronic neck pain versus a CG that performed motor control exercises. In this case, the study spanned a period of 6 weeks, comprising 3 weekly sessions. Their findings revealed that the utilization of VR was advantageous when measuring pain due to pressure with an algometer at C1-C2 and C5-C6, and it was also beneficial when considering functional limitations. However, no significant differences were observed between the groups with respect to pain intensity, muscle performance, or quality of life (36-Item Short Form Health Survey). It is evident that the results of this study deviate from those previously observed. However, it should be noted that the mentioned study did not include the population with FM, and no group underwent combined VR and active therapy [51].

Following a thorough review of the scientific literature, we found no studies addressing the use of VR in the cervical region using this protocol. Other studies have applied VR in FM use, games, and global exercises, focusing on observing aspects such as anaerobic capacity, balance, or fatigue [7,54,55]. In this study, the focus was pain in the cervical region and other more global variables such as fatigue, VAS, and FIQ. Therefore, our study offers a novel contribution to this field of research by addressing this gap in the existing literature. Given that patients with FM experience cervical pain, headaches, and tender points in the occipital regions, it is imperative to reduce the associated symptoms.

The limitations of this study lie in the fact that the results are not representative of a heterogeneous population with FM, since the cohort of participants in this research consisted solely of women. Due to the challenging nature of the disease, it was not possible to consider medication used by participants, which

XSL•FO
RenderX

may have influenced the results. Finally, the study did not include a group that used only VR, so we cannot conclude that the results are attributable to the VR component or its combination with exercise.

This approach not only benefits patients with FM but may also be applicable to other chronic pain conditions [49,50,53].

Conclusions

Virtual reality, when added to cervical mobility and strengthening exercises, produced greater and more sustained improvements in disease impact, neck disability, central sensitization, kinesiophobia, and functional outcomes in women with FM than exercise alone or no intervention. The improvements were maintained for 1 month in the G1 group in the variables evaluated. These findings support VR as an effective adjunct to active therapy, with potential benefits for symptom reduction and warrant further research on long-term effects, cost-effectiveness, and applicability to broader chronic pain populations.

Abstract

Background: Exergames integrate motor, cognitive, and postural-control demands; however, how specific task-demand manipulations influence gaze allocation during exergame performance remains insufficiently characterized.

Objective: This exploratory pilot study used a within-participant design to examine whether gaze allocation and task performance differed across baseline, concurrent cognitive-task, and unilateral-squat conditions during squat-based exergaming in healthy young adults.

Methods: Eight healthy adults (mean age 20, SD 1 years; 7 men and 1 woman) used a squat-based exergame (*Ring Fit Adventure*; Nintendo) under 3 randomized conditions: baseline, concurrent cognitive task, and unilateral squats. In the concurrent cognitive task condition, participants performed serial subtraction during squatting. In the unilateral-squat condition, participants performed single-leg squats, which were intended to increase support-leg muscular demand as well as postural and motor-control requirements. Execution time, squat score, arithmetic performance, and eye-tracking metrics were recorded. Primary gaze outcomes were the proportion of fixation time and fixation counts allocated to predefined areas of interest (AOIs; command, avatar, and score) and to regions outside these areas across the entire trial. Differences from the baseline condition were examined using Dunnett tests or paired Wilcoxon signed-rank tests with Holm adjustment, and effect sizes were reported.

Results: Exergame execution time increased from 31.0 (SD 3.3) seconds in the baseline condition to 38.2 (SD 6.1) seconds in the concurrent cognitive task condition and to 34.3 (SD 6.0) seconds in the unilateral-squat condition. In contrast, the squat score decreased from 98.8 (SD 2.8) in the baseline condition to 69.6 (SD 18.3) in the unilateral-squat condition. For fixation counts, allocation to the command AOI decreased from 44.8% (SD 11.4%) in the baseline condition to 32.1% (SD 8.9%) in the concurrent cognitive task condition and 36.2% (SD 8.5%) in the unilateral-squat condition. Outside AOI fixation counts increased in the concurrent cognitive task condition (55.7%, SD 8.6%) relative to the baseline condition (36%, SD 16.9%).

Conclusions: In this exploratory within-participant pilot study, adding a concurrent cognitive task and performing unilateral squats resulted in different patterns of performance change and fixation count redistribution during squat-based exergaming. These preliminary findings suggest that AOI-based gaze allocation metrics may help characterize task demand–related attentional shifts in this setting. Larger confirmatory studies with more diverse samples and individual-level validation are needed before these metrics can be considered for adaptive or clinical applications.

Introduction

Background

Some studies suggest that certain video game experiences may enhance attention, memory, and executive function [1,2]. Exergames inherently involve dual-task demands because they require simultaneous motor execution and visually guided cognitive processing [3-6]. Evidence from systematic reviews, meta-analyses, and controlled studies suggests that exergame-based dual-task training can improve balance, executive function, and dual-task performance in older adults [7-10]. However, the cognitive demands imposed by exergames can vary substantially depending on specific game features, such as feedback density, pacing, and concurrent cognitive tasks, as well as individual user characteristics. Without adequately characterizing these demands, it is difficult to interpret performance changes or to adjust task difficulty rationally. Quantifying in-game cognitive load may therefore help clarify how specific task manipulations influence attentional allocation during gameplay.

Despite its importance, the internal cognitive load imposed by specific exergame task configurations remains poorly characterized [11]. Most previous studies have relied on performance metrics or subjective workload measures [12,13], which do not directly capture moment-to-moment attentional allocation during gameplay [14]. In serious game and exergaming research, cognitive load has been assessed using complementary approaches, including subjective workload ratings, performance-based indices (eg, dual-task costs and in-game accuracy or speed), and physiological measures (eg, heart rate, pupillometry, and electroencephalogram or functional near-infrared spectroscopy). However, each approach has practical limitations in dynamic whole-body tasks, including limited temporal resolution, reliance on outcome-level inference, and susceptibility to motion artifacts. Eye tracking offers a behavioral marker of moment-to-moment overt visual attentional allocation and may help characterize how specific game manipulations redistribute visual attention across task-relevant display elements.

In dual-task paradigms [15], cognitive load is often inferred from performance decrements such as slower execution time or reduced motor accuracy [16]. Although informative, these measures reflect outcome-level interference rather than the underlying dynamics of attention [17]. Objective real-time indicators of cognitive load during complex motor tasks remain an active area of investigation [18-21].

Eye tracking has increasingly been used to assess attentional allocation under cognitive load in dynamic contexts such as driving [22-24], walking [19,21], and real-world task performance [20,25]. Previous studies have reported load-dependent changes in fixation duration [20], gaze dispersion [26], and the allocation of gaze to task-relevant versus irrelevant stimuli [25]. However, findings have been inconsistent: some studies report longer fixation durations under higher cognitive load, whereas others report reduced fixation time and greater gaze variability [20,27]. In addition, relatively few studies have examined gaze allocation during whole-body exercise tasks or in exergaming contexts [21,28]. Thus, it remains unclear whether different task demand manipulations within an exergame, such as adding a concurrent cognitive task or increasing unilateral motor and postural-control requirements, are associated with distinct and measurable patterns of gaze redistribution across task-relevant display elements.

Objectives

This pilot study aimed to examine whether area of interest (AOI)–specific gaze allocation differs across baseline, concurrent cognitive-task, and unilateral-squat conditions within a squat-based exergame. The study was not designed to isolate purely cognitive versus purely physical load. Rather, it was intended to explore whether AOI-based gaze allocation is sensitive to different task-demand manipulations within a single exergame context. By characterizing condition-dependent patterns of gaze redistribution in healthy young adults, this study sought to provide preliminary effect estimates and hypothesis-generating evidence to inform future confirmatory studies.

Hypotheses

It was expected that the concurrent cognitive-task condition would be associated with redistribution of gaze away from task-relevant AOIs and/or increased viewing outside predefined AOIs. In contrast, the unilateral-squat condition was expected to be associated with altered sampling of task-relevant feedback, particularly the score AOI, because single-leg squatting may increase support-leg muscular demand as well as postural- and motor-control requirements. Given the exploratory pilot design, these hypotheses were directional rather than confirmatory.

Methods

Participants

This study was designed as an exploratory pilot study to obtain preliminary effect size estimates rather than to test hypotheses definitively. Eight young adults (mean age 20, SD 1 years; 7 men and 1 woman) were recruited from Tokyo Professional University of Health Sciences. Participants were healthy university students with no self-reported history of neurological, vestibular, or musculoskeletal disorders that could affect balance or squat performance and no known cognitive impairment. On the testing day, participants confirmed that they were free from acute illness, pain, dizziness, or excessive fatigue that could substantially affect task performance. To ensure eye-tracking data quality, contact lens users were excluded. Participants who usually wore eyeglasses performed the task without glasses because of eye-tracking requirements; those unable to clearly view the display under this condition were excluded.

Ethical Considerations

This study was approved by the Ethics Committee of Tokyo Professional University of Health Sciences (TPU-25-002). All participants provided written informed consent before participation. No direct personal identifiers, such as names or contact information, were included in the study dataset. Participants were assigned study identification numbers, and all study data were managed and analyzed using these numbers.

Only aggregate data are reported in this manuscript. Each participant received a gift card valued at ¥1000 (US $6.24 as of June 15, 2026) as compensation for participation. The study was conducted in accordance with the ethical principles of the Declaration of Helsinki.

Experimental Protocol

The experimental procedure is shown in Figure 1. The study used a repeated measures design with condition as the within-participant factor. Participants first completed 1 familiarization set under the baseline condition to become accustomed to the exergame task and interface. After familiarization, they performed 1 experimental set under each of 3 conditions: baseline, concurrent cognitive-task, and unilateral-squat conditions. The order of the 3 experimental conditions was randomized using a counterbalanced schedule, rather than administering the baseline condition first, to minimize potential order effects, including practice or familiarization effects, fatigue, and expectancy, that could systematically bias condition comparisons. A seated rest period of 3 minutes was provided between conditions to reduce immediate fatigue and potential carryover effects from the preceding condition. This interval was selected because each exergame set was brief, consisting of 10 squat repetitions, and was consistent with the use of short rest intervals in previous exergame-based rehabilitation protocols involving squat and single-leg balance tasks [29].

Figure 1. Study protocol. Baseline condition: exergame performed in a bilateral stance without an additional task; cognitive task condition: exergame performed with serial subtraction during squatting; and unilateral squat condition: exergame performed in a single-leg stance.

Across all conditions, squat execution was standardized. Participants held the Ring-Con (Nintendo) with both hands in front of the chest throughout the task. Stance width was set at approximately shoulder width. Squat tempo was guided by in-game visual cues (“lower,” “keep,” and “return”), resulting in a constant externally paced movement rhythm. Participants were instructed to aim for a squat depth corresponding to approximately 90° of knee flexion.

In the concurrent cognitive-task condition, participants performed a mental arithmetic task requiring serial subtraction of 7 from a 2-digit starting number [30,31]. For each set, a different starting number (range 70-99) was selected from a prepared list (eg, 83 and 76). Participants responded aloud in a self-paced manner as quickly and continuously as possible during squatting. Task prioritization followed a motor-first approach: participants were instructed to prioritize squat execution while continuing the arithmetic task as much as possible without compromising squat performance. No feedback on response accuracy was provided. If a participant was unable to provide a response within 5 seconds, they were instructed to skip the current subtraction and continue with the next calculation.

In the unilateral-squat condition, participants performed the same exergame squat set (10 repetitions) in a single-leg stance. This condition was intended to increase support-leg muscular demand as well as the postural stability and motor-control requirements inherent to unilateral squatting [32,33]. The supporting leg was fixed on the left side because the leg sensor was attached to the left thigh, and this standardization ensured consistency in motion capture and scoring. The nonsupporting leg was maintained in a flexed position behind the body, and no external balance support was allowed.

Apparatus and Exergame Program

The experimental setup is shown in Figure S1 in Multimedia Appendix 1. The exergame was conducted using *Ring Fit Adventure* for the Nintendo Switch (Nintendo) [34-37], with the squat task selected from the custom mode. The Ring-Con, a ring-shaped controller held with both hands, and a leg sensor attached to the left thigh enabled participants’ movements to be reflected by an on-screen avatar. The squat program required repeated squats in response to visual cues and provided a squat score (0-100 points) that primarily reflected squat depth and timing relative to the cues.

The squat program in the custom mode of *Ring Fit Adventure* was selected for 3 reasons. First, the user interface layout remains stable in this mode, facilitating consistent definition of AOIs for eye-tracking analysis. Second, the task structure is simple and repetitive, allowing the serial-subtraction and unilateral-squat manipulations to be implemented within the same exergame task while minimizing changes in task rules and visual content. Third, the program was set to 10 repetitions

XSL•FO
RenderX

to keep each trial brief, thereby reducing eye-tracking data loss and fatigue, which was appropriate for this pilot study. With respect to difficulty settings, the custom mode allows selection of the number of squat repetitions but does not provide additional difficulty parameters. Therefore, task demands were standardized across participants by using 10 repetitions in all conditions.

The game was projected onto a 130 × 230 cm screen, with participants positioned 2.5 m away. The projection was adjusted so that the center of the display was approximately at eye level during standing. Ambient lighting conditions were standardized using indoor lighting, and window light was minimized by drawing curtains to reduce glare and fluctuations in screen luminance. To reduce extraneous visual stimuli that could influence gaze dispersion, posters and other nonessential visual materials around the screen were removed, and the area surrounding the display was kept as visually uncluttered as possible.

Eye movements were recorded using a wearable eye tracker (Tobii Pro Glasses 3, Tobii Technology; sampling rate 100 Hz), and the device was recalibrated before each test condition. Gaze data were processed offline using Tobii Pro Lab (Tobii Technology) to extract fixation metrics.

Outcome Measures

Feasibility outcomes were recorded to characterize the practical implementation of mobile eye tracking during squat-based exergaming. These outcomes included (1) completion rate, defined as the proportion of participants who completed all 3 conditions; (2) calibration success, defined as successful eye tracker calibration before each condition; and (3) technical issues, defined as any device or software malfunction or recording failure requiring restart, repeat calibration, or trial exclusion.

The primary gaze outcomes were the proportion of fixation time and the proportion of fixation counts allocated to each predefined AOI (command, avatar, and score) and to regions outside these AOIs across the entire exergame trial. These proportions were calculated by dividing fixation time or fixation count within each AOI by the total fixation time or count recorded across the whole screen during the trial. This normalization was used to characterize relative gaze allocation while reducing potential bias from condition-dependent differences in trial duration and total fixation behavior. Accordingly, proportional AOI metrics should be interpreted as indexes of relative allocation rather than absolute gaze exposure. Fixations were defined using the velocity-threshold identification (Attention) filter based on eye angular velocity (threshold 100°/s) [38].

AOI metrics (fixation duration and fixation count) were exported for each AOI. Invalid samples due to blinks or temporary tracking loss were treated as missing by the software and were not manually interpolated. No additional data cleaning beyond the software's standard validity handling was applied. No outlier removal (eg, winsorization or participant-level exclusion based on gaze metrics) was performed.

Three AOIs were defined in Tobii Pro Lab: the command area displaying the next movement cue, the avatar area mirroring the participant's movement, and the score area presenting squat performance points (Figure S2 in Multimedia Appendix 1). AOI dimensions were estimated from photographed screen measurements and converted to degrees of visual angle using the viewing distance of 2.5 m. The resulting AOI sizes were approximately 9.0°×21.6° for the command AOI, 15.5°×10.7° for the avatar AOI, and 11.2°×12.2° for the score AOI.

To provide an intuitive visualization of gaze distribution, scanpaths and heat maps were generated from aggregated gaze data across participants. However, these served only as qualitative supplementary materials and were not subjected to statistical testing.

Secondary outcomes were exergame execution time (seconds) and squat score (0-100 points), recorded at the end of the squat program.

Manipulation Check

To examine whether the concurrent cognitive task and unilateral-squat manipulations altered task performance, additional performance indexes were assessed.

For the concurrent cognitive task condition, arithmetic performance was used as an objective manipulation check of the added cognitive task. Accuracy was calculated as percentage correct, defined as the number of correct responses divided by the total number of spoken responses during the set. Scoring was performed sequentially: a response was counted as correct if it was exactly 7 less than the immediately preceding response, regardless of whether the participant had made an earlier error. As individual response time stamps were not recorded, response latencies could not be calculated. Instead, the total number of responses during the set was reported together with execution time as indirect performance-based indicators related to response timing. Squat score and execution time were also analyzed as task performance indicators during the concurrent cognitive task.

For the unilateral-squat condition, squat score and execution time were analyzed as indicators of movement performance under increased unilateral motor- and postural-control requirements. In this pilot study, direct physiological indexes of exertion (eg, heart rate, ratings of perceived exertion, and electromyography) were not collected. Accordingly, the unilateral-squat condition should not be interpreted as a directly quantified increase in physiological load or as a purely physical load manipulation. Instead, changes in execution time and squat score were used as objective performance-based markers indicating that the unilateral-squat manipulation altered task difficulty relative to baseline.

Statistical Analysis

Normality for each outcome was assessed using the Shapiro-Wilk test. For outcomes meeting the normality assumption, a 1-factor repeated measures analysis of variance with condition as the within-participant factor was performed, followed by Dunnett multiple comparison tests using the baseline condition as the reference (concurrent cognitive task

XSL•FO
RenderX

condition vs baseline condition and unilateral-squat condition vs baseline condition). For outcomes violating the normality assumption, paired Wilcoxon signed-rank tests were used to compare each condition with baseline condition, and *P* values were adjusted using the Holm procedure for the 2 planned comparisons. Descriptive statistics are presented as mean (SD). Effect sizes for comparisons with the baseline condition are reported as Hedges *g* for paired samples. For each planned within-participant comparison, Hedges *g* was calculated using complete paired observations as the standardized mean change, defined as the mean within-participant difference score divided by the SD of the corresponding difference scores. Difference scores were calculated as the task demand condition minus the baseline condition, and Hedges small-sample correction was applied. Thus, positive values indicate higher values in the task demand condition than in the baseline condition, whereas negative values indicate lower values. Individual participant data were visualized alongside summary statistics (mean and SD) to enhance transparency.

Exploratory correlation analyses were conducted to examine associations between gaze allocation metrics and performance outcomes. Given the small sample size, these analyses were considered hypothesis generating; Spearman ρ and corresponding *P* values are reported, and findings were interpreted cautiously.

All analyses were performed in R (version 4.4.2; R Foundation for Statistical Computing) [39] using the effectsize package and related statistical functions [40-42].

Results

Feasibility Outcomes

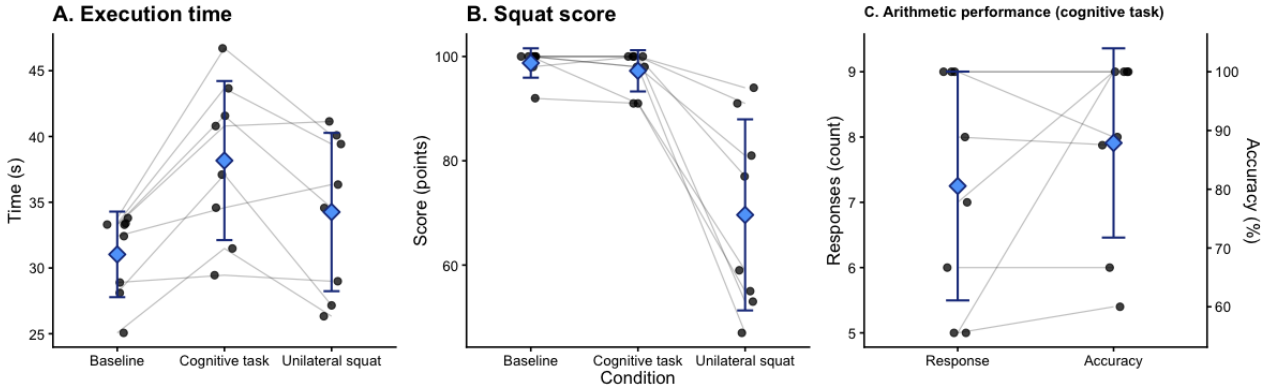
All participants (n=8) completed all 3 conditions. Eye tracker calibration was successful in 100% (24/24) of attempts, with calibration performed before each condition for each participant. No technical issues (eg, device or software malfunction, or recording failure) occurred, and no trials were excluded for technical reasons.

Manipulation Check

Manipulation check outcomes are summarized in Table 1. As shown in Figure 2, participants performed the arithmetic task with high accuracy (mean 87.9, SD 16.1) and a consistent number of responses (mean 7.3, SD 1.8). Execution time was longer in the concurrent cognitive task condition than in the baseline condition (mean difference 7.1 seconds, 95% CI 3.7-10.5; *P*=.002), indicating measurable dual-task interference.

Table 1. Manipulation check outcomes for performance measures across conditions (n=8)[a].

Outcome	Baseline, mean (SD)	Cognitive task, mean (SD)	Unilateral squat, mean (SD)	Cognitive task–baseline, mean difference (95% CI)	*P* value	Hedges *g*	Unilateral squat–baseline, mean difference (95% CI)	*P* value	Hedges *g*
Exergame execution time (s)	31.0 (3.3)	38.2 (6.1)	34.3 (6.0)	7.1 (3.7 to 10.5)	.002	1.55	3.2 (0.5 to 5.9)	.02	0.88
Squat score (0 to 100)	98.8 (2.8)	97.2 (4.0)	69.6 (18.3)	−1.5 (−4.3 to 1.3)	.23	−0.4	−29.1 (−43.9 to −14.3)	.002	−1.46
Arithmetic accuracy (%)	N/A[b]	87.9 (16.1)	N/A	—[c]	—	—	—	—	—
Arithmetic responses (n)	N/A	7.3 (1.8)	N/A	—	—	—	—	—	—



[a]Baseline: exergame performed in a bilateral stance without an additional task. Cognitive task: exergame performed with serial subtraction during squatting. Unilateral squat: exergame performed in a single-leg stance. Comparisons with baseline were performed using Dunnett test when parametric assumptions were met; otherwise, paired Wilcoxon signed-rank tests with Holm adjustment were used. Effect sizes represent Hedges *g* for paired comparisons. Arithmetic measures were collected only during cognitive task.

[b]N/A: not applicable (arithmetic outcome was not applicable because it was measured only in the cognitive task condition).

[c]No comparison with baseline was performed.

XSL•FO
RenderX

Figure 2. Manipulation check outcomes across conditions: (A) exergame execution time (seconds), (B) squat score (0-100 points), and (C) arithmetic task performance under the concurrent cognitive task condition. Individual participant data are shown as jittered points connected by thin lines to illustrate within-participant changes across conditions (A and B) and between arithmetic metrics (C). Diamonds indicate mean values, and error bars represent the mean+SD and mean−SD. Baseline: exergame performed in a bilateral stance without an additional task; cognitive task: exergame performed with serial subtraction during squatting; and unilateral squat: exergame performed in a single-leg stance.

In the unilateral-squat condition, squat score was markedly lower than in the baseline condition (mean difference −29.1 points, 95% CI −43.9 to −14.3; *P*=.002), and execution time was also longer (mean difference 3.2 seconds, 95% CI 0.5-5.9; *P*=.02), although the magnitude of this increase was smaller than that observed in the concurrent cognitive task condition. Together, the substantial reduction in squat score and the smaller but significant increase in execution time suggest that the unilateral-squat condition increased movement difficulty relative to baseline.

Gaze Allocation Across AOIs

Proportion of Fixation Time per AOI

To further characterize the redistribution of visual attention under different task demand conditions, the proportion of fixation time allocated to each predefined AOI (command, avatar, and score) and to regions outside these AOIs was analyzed (Table 2; Figure 3). In the concurrent cognitive task condition, the proportion of fixation time directed outside the predefined AOIs showed a descriptive increase relative to the baseline condition, whereas the proportions allocated to the command and score AOIs showed descriptive decreases. However, these changes were modest and did not reach statistical significance. In contrast, in the unilateral-squat condition, the proportion of fixation time allocated to the score AOI showed a descriptive increase relative to the baseline condition, accompanied by a slight descriptive decrease in fixation time directed outside the predefined AOIs. The plotted data suggested greater interindividual variability in fixation time allocation in both task demand conditions than in the baseline condition.

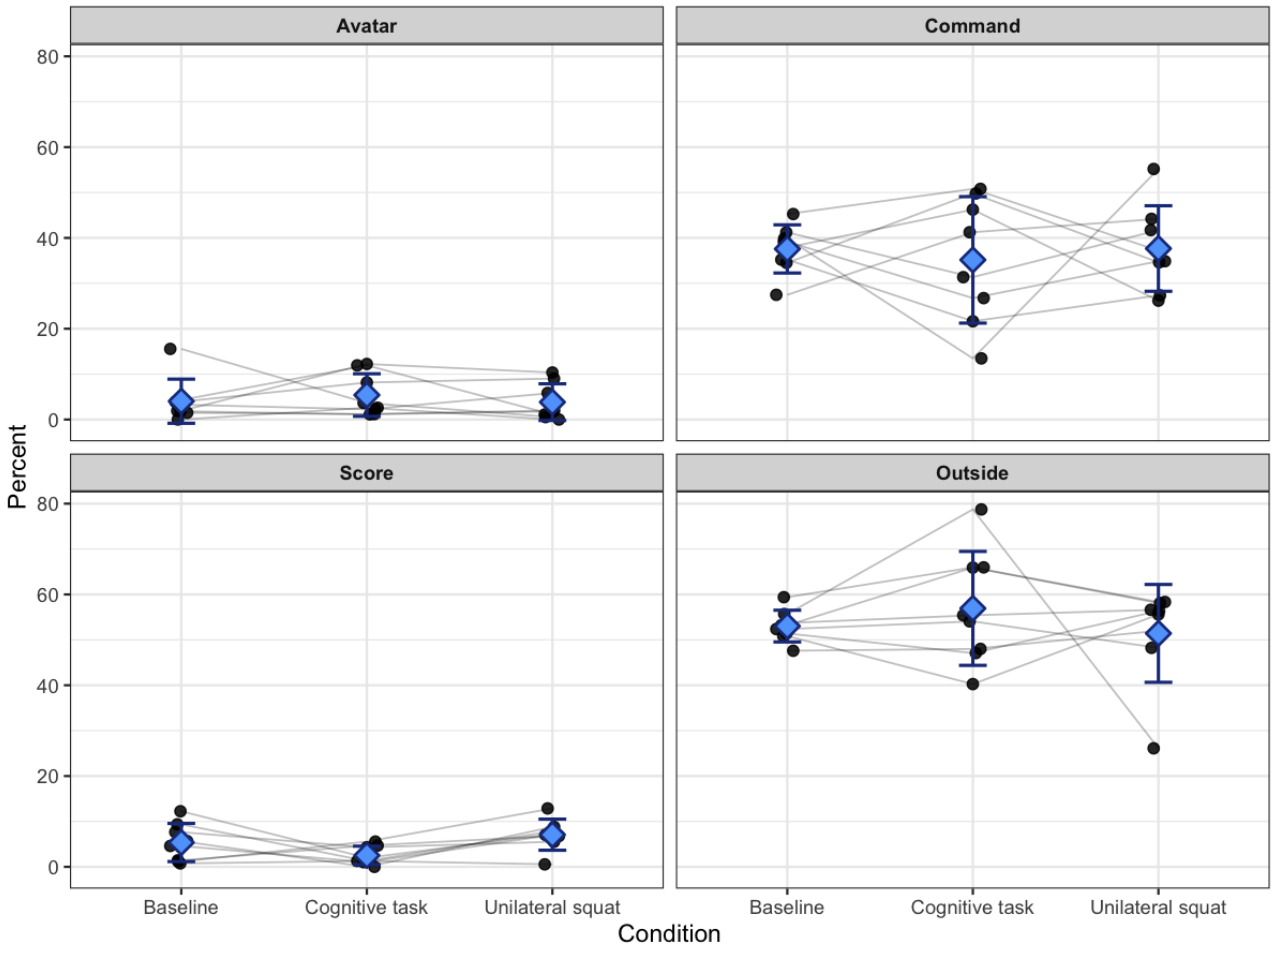


Table 2. Proportion of fixation time allocated to each area of interest (AOI) across task demand conditions (n=8)[a].

AOI	Baseline, mean (SD)	Cognitive task, mean (SD)	Unilateral squat, mean (SD)	Cognitive task minus baseline, mean difference (95% CI)	*P* value	Hedges *g*	Unilateral squat minus baseline, mean difference (95% CI)	*P* value	Hedges *g*
Command	37.6 (5.3)	35.2 (13.9)	37.7 (9.4)	−2.4 (−15.1 to 10.3)	.99	−0.14	0.1 (−8.8 to 9.0)	.99	0.01
Avatar	4.0 (4.9)	5.4 (4.7)	3.8 (4.0)	1.4 (−4.3 to 7.0)	.99	0.18	−0.2 (−6.0 to 5.6)	.99	−0.03
Score	5.4 (4.2)	2.5 (2.0)	7.1 (3.4)	−2.8 (−7.2 to 1.5)	.34	−0.48	1.7 (−2.6 to 6.1)	.38	0.29
Outside	53.0 (3.5)	56.9 (12.6)	51.4 (10.8)	3.9 (−4.8 to 12.6)	.64	0.33	−1.6 (−11.5 to 8.2)	.71	−0.12

[a]Baseline: exergame performed in a bilateral stance without an additional task. Cognitive task: exergame performed with serial subtraction during squatting. Unilateral squat: exergame performed in a single-leg stance. Values are presented as mean (SD) of the proportion (%) of fixation time within each AOI across the entire exergame trial. Proportions were calculated by dividing whole fixation duration within each AOI by the total fixation duration recorded across the entire exergame trial. Mean differences were calculated as each task demand condition minus the baseline condition. The 95% CIs were calculated from within-participant difference scores. Comparisons with baseline were performed using Dunnett test when parametric assumptions were met; otherwise, paired Wilcoxon signed-rank tests with Holm adjustment were used. Effect sizes are reported as Hedges *g* for within-participant comparisons. The “outside” category represents fixation time allocated outside the 3 predefined AOIs (command, avatar, and score).

XSL•FO
RenderX

Figure 3. Proportion of fixation time allocated to each area of interest under baseline, concurrent cognitive task, and unilateral squat conditions. Baseline: exergame performed in a bilateral stance without an additional task; cognitive task: exergame performed with serial subtraction during squatting; and unilateral squat: exergame performed in a single-leg stance. Individual participant data are shown with mean (SD). Proportions were calculated relative to total fixation time across the entire exergame trial.

Proportion of Fixation Counts per AOI

The proportion of fixation counts allocated to each AOI varied across conditions (Table 3; Figure 4). Compared with the baseline condition, the concurrent cognitive task condition showed a lower proportion of fixation counts directed to the command AOI (mean 44.8%, SD 11.4% vs mean 32.1%, SD 8.9%; *P*=.04) and score AOI (mean 14.4%, SD 9.8% vs mean 4.9%, SD 4.3%; *P*=.04), and a higher proportion directed outside the predefined AOIs (mean 36%, SD 16.9% vs mean 55.7%, SD 8.6%; *P*=.02). The unilateral-squat condition also showed a lower proportion of fixation counts directed to the command AOI than the baseline condition (mean 36.2%, SD 8.5% vs mean 44.8%, SD 11.4%; *P*=.04), but it did not show the same increase in outside viewing observed under the concurrent cognitive task condition. Instead, fixation count allocation in the unilateral-squat condition showed small descriptive increases in the score and avatar AOIs.

Table 3. Proportion of fixation counts allocated to each area of interest (AOI) across task demand conditions (n=8)[a].

AOI	Baseline, mean (SD)	Cognitive task, mean (SD)	Unilateral squat, mean (SD)	Cognitive task minus baseline, mean difference (95% CI)	*P* value	Hedges *g*	Unilateral squat minus baseline, mean difference (95% CI)	*P* value	Hedges *g*
Command	44.8 (11.4)	32.1 (8.9)	36.2 (8.5)	−12.7 (−23.7 to −1.7)	.04	−0.86	−8.6 (−17.3 to 0.0)	.04	−0.74
Avatar	5.4 (2.5)	7.4 (6.4)	6.2 (6.8)	2.0 (−3.6 to 7.6)	.66	0.27	0.9 (−3.8 to 5.6)	.92	0.14
Score	14.4 (9.8)	4.9 (4.3)	15.7 (9.0)	−9.5 (−19.9 to 0.9)	.04	−0.68	1.4 (−7.4 to 10.2)	.90	0.12
Outside	36.0 (16.9)	55.7 (8.6)	41.9 (18.4)	19.7 (4.4 to 35.0)	.02	0.95	5.9 (−8.0 to 19.7)	.62	0.32

[a]Baseline: exergame performed in a bilateral stance without an additional task. Cognitive task: exergame performed with serial subtraction during squatting. Unilateral squat: exergame performed in a single-leg stance. Values are presented as mean (SD) of the proportion (%) of fixation counts within each AOI across the entire exergame trial. Proportions were calculated as the number of fixations within each AOI divided by the total number of fixations recorded across the entire exergame trial. Mean differences were calculated as each task demand condition minus the baseline condition. The 95% CIs were calculated from within-participant difference scores. Comparisons with baseline were performed using Dunnett test when parametric assumptions were met; otherwise, paired Wilcoxon signed-rank tests with Holm adjustment were used. For outcomes analyzed with paired Wilcoxon signed-rank tests, *P* values are based on ranked paired differences and may not correspond directly to the mean difference 95% CIs, which are presented descriptively. Effect sizes are reported as Hedges *g* for within-participant comparisons. The "outside" category represents fixation counts allocated outside the 3 predefined AOIs (command, avatar, and score).

Figure 4. Proportion of fixation counts allocated to each area of interest (AOI) across task demand conditions. The proportion of fixation counts directed to the command, avatar, score, and outside AOIs across the entire exergame trial is shown for the baseline, concurrent cognitive task, and unilateral squat conditions. Baseline: exergame performed in a bilateral stance without an additional task; cognitive task: exergame performed with serial subtraction during squatting; and unilateral squat: exergame performed in a single-leg stance. Each proportion was calculated as the number of fixations within an AOI divided by the total number of fixations recorded during the trial.

Supportive Analyses

Exploratory Correlation Analyses

Correlation analyses between gaze allocation metrics and performance outcomes were conducted on an exploratory basis to generate hypotheses for future studies (Figure S3 in Multimedia Appendix 1). Given the small sample size, these findings should not be interpreted as confirmatory evidence.

Descriptive Gaze Distribution

Heat maps and scanpaths are presented as descriptive visualizations to contextualize the quantitative AOI allocation results (Figures S4 and S5 in Multimedia Appendix 1). As these qualitative displays are sensitive to visualization parameters and do not directly quantify gaze allocation, they were not used as stand-alone evidence. Qualitative patterns were interpreted only when consistent with the AOI-based metrics reported in Tables 2 and 3.

Discussion

Principal Results

This pilot study suggests that different task demand manipulations within a squat-based exergame may be associated with distinct patterns of gaze redistribution across task-relevant display elements, rather than a uniform reduction in visual attention. Specifically, adding a concurrent cognitive task and performing the task in a unilateral-squat condition produced different descriptive patterns of performance and gaze allocation. By quantifying AOI-specific proportions of fixation time and fixation counts standardized to the entire trial, this approach was intended to reduce potential bias arising from condition-dependent differences in execution time and to generate preliminary, hypothesis-generating estimates for future confirmatory exergame studies.

The manipulation check suggested that the concurrent cognitive task and unilateral-squat conditions affected performance in partially different ways. Specifically, the concurrent cognitive task condition was associated primarily with prolonged execution time while squat performance (score) was largely preserved, whereas the unilateral-squat condition was associated with a more pronounced reduction in squat score together with a modest but significant increase in execution time relative to baseline. Taken together, these patterns suggest that the 2 manipulations may have altered task demands through different mechanisms rather than simply producing a uniform increase in overall difficulty. However, the unilateral-squat condition should not be interpreted as a pure physical load condition because single-leg squatting inherently involves balance control, postural stability, and motor-control processes that may also require cognitive engagement.

The pattern observed in the concurrent cognitive task condition—significantly prolonged execution time, greater fixation allocation outside predefined AOIs, and reduced sampling of the command and score AOIs—is broadly consistent with real-world dual-task evidence showing increased off-task or task-irrelevant fixations when mental arithmetic is superimposed on everyday actions [21,43]. In the present exergame context, this pattern may indicate that the added cognitive task reduced visual sampling of goal-relevant instructional and feedback information while shifting gaze toward non-AOI regions. However, because the Outside category aggregated all fixations outside the 3 predefined AOIs, this interpretation remains tentative. This analysis cannot determine whether these fixations were directed toward peripheral screen areas, visually neutral regions, or other nondefined targets. Therefore, the increase in outside viewing warrants nuanced interpretation. On the one hand, it may reflect weakened top-down attentional selection, whereby limited processing resources reduce the ability to maintain gaze on goal-relevant AOIs. On the other hand, it may reflect strategic gaze aversion. As suggested by Müller et al [21] and Glenberg et al [44], individuals may avert their gaze toward visually neutral or noninformative regions to deliberately reduce external visual input, thereby facilitating demanding internal cognitive processes such as mental arithmetic. In contrast, some laboratory studies using static or tightly controlled stimuli have reported longer fixation durations and fewer fixations under higher cognitive load [45,46], suggesting that gaze responses to cognitive task demands may depend on task dynamics and constraints. One plausible explanation is that squat-based exergaming is both visually dynamic and motorically constrained, requiring intermittent postural-control and feedback sampling, which may promote context-dependent gaze redistribution rather than a single uniform gaze response [47]. Accordingly, these findings are best interpreted as preliminary evidence of context-dependent gaze reallocation during a cognitive dual-task exergame condition rather than as a universal gaze marker of cognitive load [11,20].

By contrast, the unilateral-squat condition showed a different pattern: squat performance decreased significantly, whereas gaze allocation did not show the same increase in outside viewing observed in the concurrent cognitive task condition. Instead, fixation counts directed to the command AOI were reduced, with modest descriptive increases in allocation to other task-relevant AOIs, such as the score and avatar regions. Although these shifts were small and should be interpreted cautiously, they may suggest that unilateral squatting prompted redistribution of visual attention within task-relevant display elements rather than away from them [18,47]. This interpretation is compatible with a tentative self-monitoring explanation, whereby participants may have sampled performance-relevant feedback more frequently as movement difficulty increased. However, this pattern should not be attributed solely to increased physical load because single-leg squatting involves a composite set of demands, including support leg muscular demand, balance control, postural stability, and motor planning. Therefore, the qualitative contrast between the concurrent cognitive task and unilateral-squat conditions should be interpreted as evidence of condition-dependent gaze reallocation under different task demands, not as definitive evidence distinguishing pure cognitive from pure physical load.

These pilot data suggest that gaze metrics may help characterize how users reallocate attention under different task demand conditions during exergaming, which may be useful for hypothesis generation and for identifying candidate features for

XSL•FO
RenderX

adaptive systems. However, this study did not evaluate real-time gaze-based adaptation metrics, such as latency, reliability, or within-trial detection, nor did it examine decision thresholds or downstream benefits of adaptation. Therefore, any implications for personalized difficulty adjustment remain speculative and should be reserved for future work.

Limitations

This study has several limitations. First, the sample was very small and homogeneous, with a marked gender imbalance, which limits generalizability and may influence estimates of multitasking performance and squat execution in some contexts. Replication in a larger, more gender-balanced sample is therefore warranted. Second, statistical power was limited and CIs were often wide. Accordingly, nonsignificant findings should be interpreted cautiously and should not be considered definitive evidence of no effect. The use of proportional AOI metrics is another important limitation. Although normalization by total fixation time or count helped reduce the influence of unequal trial durations across conditions, proportional metrics change the interpretation of the outcome from absolute gaze exposure to relative gaze allocation. Consequently, a decrease in the proportion of fixations directed to a given AOI does not necessarily indicate a decrease in the absolute amount of gaze directed to that AOI. In addition, the AOI-specific findings should be interpreted as exploratory evidence of relative gaze redistribution rather than as independent AOI-specific effects.

Third, the unilateral-squat condition represents a central interpretive constraint of this study. Although single-leg squatting likely increased support leg muscular demand, it cannot be interpreted as a pure physical load manipulation. Single-leg squatting inherently requires balance control, postural stability, motor planning, and continuous movement regulation, all of which may involve cognitive engagement. Therefore, the study design cannot disentangle muscular or physiological load from postural and motor-control demands. In addition, physiological indexes such as heart rate, ratings of perceived exertion, and electromyography were not collected; thus, physiological load differences between conditions could not be directly quantified. Future studies should incorporate objective physiological markers and use designs that can better distinguish muscular effort, postural-control demands, and concurrent cognitive load.

Fourth, the supporting leg in the unilateral-squat condition was fixed to the left side to maintain consistency with the leg sensor and game scoring. This may have introduced unilateral effects because single-leg squat performance can differ between dominant and nondominant limbs. If the left leg was nondominant for some participants, the unilateral-squat condition may have disproportionately increased movement difficulty, potentially contributing to larger decrements in squat score and altered execution time. Such unilateral performance differences could also have secondarily influenced gaze behavior, for example, by increasing monitoring of feedback AOIs such as the score region or by increasing off-AOI viewing, thereby limiting generalizability. Future studies should assess leg dominance and unilateral asymmetries and either counterbalance the supporting leg or include dominance as a covariate.

Finally, standard feasibility indexes such as eye-tracking data loss (eg, fixation coverage) were not systematically quantified in this pilot study. Future studies should prospectively record and report these metrics to better characterize measurement robustness, recruit larger and more diverse cohorts, and examine whether gaze-derived features reliably predict performance or learning at the individual level.

Conclusions

These pilot data provide preliminary evidence that different task-demand manipulations may be associated with distinct patterns of gaze redistribution during squat-based exergaming in healthy young adults. The findings are hypothesis generating and require replication in larger and more diverse samples. Future studies should determine whether gaze-derived features can be measured robustly at the individual level and translated into validated adaptive difficulty algorithms that improve user outcomes. However, this study does not provide direct evidence for real-time adaptation or clinical utility.

Abstract

Background: Indonesia has the second-highest prevalence of stroke in Southeast Asia, with 4,918,487 people (1.7% of the population) living with this condition as of 2025. This is attributable to the living conditions in Indonesia, where limited health care workers and facilities are available to assist with stroke rehabilitation via mobile health (mHealth) interventions.

Objective: This study designed an mHealth app to facilitate stroke rehabilitation in Indonesia.

Methods: In this mixed methods study, interviews were conducted with 10 experts (doctors, therapists, and medical students) and 8 patients who have experienced a stroke to explore the need for stroke rehabilitation management apps. Using a design science research approach, we conducted 3 iterative design cycles, each comprising design, development, and evaluation, to construct an mHealth app for stroke rehabilitation. The first iteration produced a low-fidelity app prototype informed by intervention theory. The prototype, which comprised 13 features for patients and 12 for medical personnel, was evaluated through interviews with medical personnel. The second iteration produced a design for a high-fidelity app prototype based on feedback from the first iteration. The third iteration yielded an improved app based on feedback from the second iteration.

Results: This study identified app features that support patient rehabilitation, including patient training programs with progress monitoring in functional, speech, and occupational therapy, along with consultations and home visits to connect rehabilitating patients with medical personnel. Other features of the app include onboarding, gamification, users' authentication, user profile management, schedule reminders, activity targets, therapeutic progress reports, and educational materials and videos. The prototypes received a System Usability Scale score of 71.83 ("good") and average scores of 2.32 (system usefulness), 2.39 (information quality), 2.42 (interface quality), and 2.35 (overall).

Conclusions: This study provides guidance for health care facilities and regulators to improve the quality of rehabilitation services for patients with stroke in Indonesia.

Introduction

Background

Stroke can cause a wide range of long-term symptoms and remains a significant global health burden, requiring comprehensive and innovative rehabilitative approaches to optimize recovery outcomes [1]. The World Health Organization (WHO) [2] reports that every patient with acute stroke or cognitive dysfunction should undergo an initial functional assessment to determine rehabilitation needs and develop an individualized rehabilitation plan. The Barrow Neurological Institute [3] argues that most patients with stroke (80% - 90%) require some form of rehabilitation, whether acute, subacute, inpatient, or outpatient.

Various types of rehabilitation are available for patients with stroke, including occupational therapy, speech therapy, and physiotherapy [4]. Occupational therapists teach patients with stroke how to carry out daily living activities, such as cooking, cleaning the house, and taking care of themselves [4]. Speech therapists draw on scientific and technological knowledge to help patients communicate (touching on speech, voice, fluency, and other aspects of language) and cope with swallowing disorders [5]. However, the implementation of stroke rehabilitation faces significant and persistent challenges, including patient noncompliance and the gap between the need for post–inpatient intensive therapy and its actual availability in health care systems [6]. Globally, the cost of treating stroke in the year 2022 was estimated to reach more than US $721 billion, or about 0.66% of the world's gross domestic product [7].

XSL•FO
RenderX

Indonesia has the second-highest incidence and prevalence of stroke in Southeast Asia, with 642,943 new cases recorded and 4,918,487 people living with stroke between 2017 and 2022 [8]. In 2023, stroke ranked third among catastrophic diseases in Indonesia [9]. Stroke prevalence differs by age group, with individuals aged 75 years and older demonstrating the highest prevalence (41.3 per 1000 people) and the 15 to 54 years age group exhibiting the lowest at less than 9 per 1000 [10].

The challenges of stroke rehabilitation in developing countries, such as Indonesia, include health care factors, such as the demands of a growing health system and a lack of income for specialized training, rehabilitation facilities, and rehabilitation staff [11]. Other challenges include a lack of adequate learning opportunities and formal education programs for nurses, therapists, and even doctors [12]. There are also internal challenges on the patient side. Kayola et al [11] note that individual-level factors, such as low health literacy, can increase drug and rehabilitation costs as well as caregiver wages. Poststroke traumatic stress disorder can lead to nonadherence to treatment, increase disability rates, and increase the frequency of lesions in the right brain and brainstem [13].

Mobile health (mHealth) can provide innovative solutions to improve rehabilitation efficiency, offer more personalized services, and help health care facilities better understand patient needs [14-16]. Szeto et al [17] explain that the most beneficial apps integrate therapeutic elements such as social interaction, real-time feedback, rhythmic cues, and multisensory stimulation, as well as repetitive, task-specific, and/or goal-oriented exercises. However, user compliance with rehabilitation remains relatively low, and existing apps lack interoperability with electronic health records [17]. Song et al [18] discuss apps that specify daily rehabilitation exercises via asynchronous video recordings monitored by clinicians and offer reminder features to boost patient adherence. However, most of these studies were conducted in developed countries, including Spain, the Netherlands, the United States, and the United Kingdom [15].

Design science research (DSR) is a methodology that seeks to overcome real-world challenges through the design and evaluation of innovative artifacts [19]. DSR was used as this study's main methodological framework to ensure that the artifact, in this study named as a prototype, would be developed appropriately for users in Indonesia. Additionally, intervention theory is used as a foundation for designing more effective problem-solving systems [20]. Intervention theory holds that user behavior can be influenced through 3 main principles: the provision of valid and useful information, the freedom of the user to act based on the information obtained, and the formation of an internal commitment to the chosen action [20].

Objective

This research aimed to design an mHealth app for stroke rehabilitation management, focusing on the promotive, preventive, curative, and rehabilitative aspects. Our research question was as follows: How can an mHealth app for stroke rehabilitation in Indonesia be designed based on DSR and intervention theory? This research provides guidance for the development of health apps that meet the needs and expectations of patients with stroke in Indonesia.

Methods

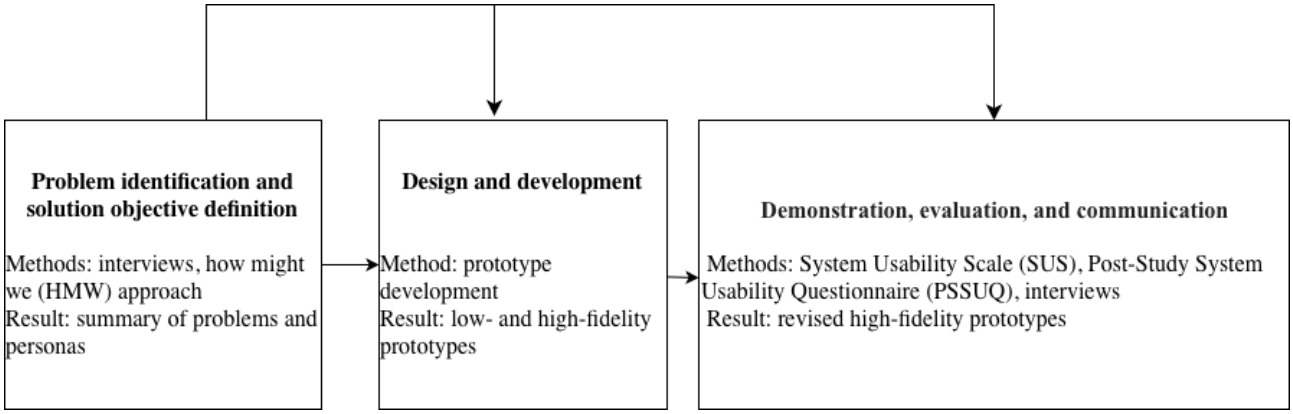
Ethical Considerations

This research was carried out in collaboration with Indonesia's National Brain Center Hospital and received ethical approval from Mahar Mardjono on September 26, 2025 (reference DP.04.03/D.XXIII.9/208/2025). All respondents provided written informed consent to participate, and the data submitted were anonymous. The respondent data were used only for the purposes of this research.

Study Design

This mixed methods study used both quantitative and qualitative approaches. This research followed the 5 stages of the DSR methodology: problem identification and motivation, definition of solution objectives, design and development, demonstration, and evaluation and communication [21]. We collected data at each stage through interviews. However, for the evaluation and communication stage, we used both interviews (qualitative approach) and questionnaires (quantitative approach) to evaluate the prototypes. We triangulated the results to ensure that the prototypes aligned with the respondents' needs.

Using design science research, we conducted 3 iterative design cycles, each comprising design, development, and evaluation, to construct an mHealth app for stroke rehabilitation. The first iteration—the problem identification and motivation stage—was carried out through a literature review, application benchmarking, and interviews with patients with stroke and experts (including doctors, therapists, and medical students), who provided written consent. A thematic analysis [22] of the interview data was conducted to group the speakers' statements into problem categories. These categories allow for the simplification of open-ended data and indicate the problems' frequencies and levels of validation. Based on these findings, we proceeded to define the objectives and establish what would qualify as solutions, following the "how might we" (HMW) approach [23]. Mapping with the HMW approach offered solutions and ideas for features of the proposed app. To ensure the relevance of the app to user needs, we defined personas. Personas represented concrete pictures of user characteristics [24], making the entire mHealth solution design process more targeted and contextual. The next stage was design and development; we aimed to develop solutions in the form of low-fidelity prototypes, using the principle of the 8 golden rules as the interface design principle [21]. The last stage of the first iteration was demonstration, as we tested the prototype through interviews with doctors, therapists, and health students. Each stage of the first iteration included an evaluation and validation mechanism to ensure that the developed artifact matched the users' needs.



The second iteration focused on refining the prototype design based on the evaluation results from the first phase. The second iteration returned to design and development, using input in the form of feedback on the previous low-fidelity prototype [21]. This feedback guided the design of a higher-fidelity prototype in accordance with the 8 golden rules [21]. After the artifacts were repaired and determined suitable for our purposes, we proceeded to evaluation and communication [21]. This stage

XSL•FO
RenderX

included usability testing via the System Usability Scale (SUS), as well as interviews with patients and experts (doctors, therapists, and medical students). This evaluation aimed to explore user perceptions and experiences and to map obstacles and potential improvements to the interface and features [25]. This iteration yielded more targeted design recommendations and laid the foundation for the third phase.

The third and final iteration of the DSR development process began with design and development based on feedback and recommendations from the second stage. We then returned to evaluation and communication by measuring the satisfaction and effectiveness of the system [21]. For this, we used the Post-Study System Usability Questionnaire (PSSUQ) with various respondents. After ensuring that the evaluation results met the criteria, we proceeded to formulate design principles. This involved cross-iteration analysis to develop conceptual design principles based on user needs, feature responses, and solution effectiveness. SUS and PSSUQ have been widely adopted to assess the usability of digital systems [25]. The final stage was the preparation of conclusions and recommendations that summarized all findings [21]. Figure 1 describes the research flow based on DSR.

Figure 1. Research flow based on design science research.

Inclusion Criteria

We recruited patients who have experienced a stroke, experts in stroke rehabilitation, and respondents interested in stroke rehabilitation to obtain in-depth data. Patients treated at the National Brain Center Hospital were selected if they were 18 to 80 years old, had experienced a stroke, and experienced cognitive or physical impairments. Experts were selected if they were medical rehabilitation specialists, therapists, or students with a health-related major who were willing to participate (purposive sampling). Table 1 describes the respondent demographics for each DSR stage.

Analysis Methods

The data were analyzed using 2 approaches. Qualitatively, we identified important characteristics or features required in the app design; quantitatively, we evaluated and measured the quality of the app prototypes. The analysis process began in the first iteration with semistructured interviews to identify user needs. In the next stage, we implemented a thematic analysis technique proposed by Ozuem et al [22]. This involved classifying and grouping problems while counting the number of respondents who confirmed each problem. Once categorized, the problems were mapped onto questions. The HMW framework was used as a guide to develop answers to each question [23]. We then converted the data into persona profiles that described the users' characteristics. The information architecture design was also developed at this stage to systematically organize the app content and facilitate user accessibility according to the corresponding personas. Semistructured interviews were conducted as a form of design evaluation in the second and third iterations. The evaluation was carried out using 2 evaluation tools—SUS and PSSUQ—to analyze 3 key components: system usability, information quality, and interface quality [25].

Research Instruments

Questionnaires and interviews were used during the evaluation stage. The questionnaire was conducted in the second and third iterations. In the second iteration, the questionnaire consisted of questions about demographics and the use of health apps. This section addressed patients who experienced stroke. The demographic questions touched on age, residence, occupation, number of devices, and email. Questions about the use of health apps covered experiences with mHealth related to stroke rehabilitation (such as app names and disadvantages). In the third iteration, results from the SUS questionnaire in the second iteration and the PSSUQ in the third iteration were used to test usability levels and questions about stroke rehabilitation. The SUS uses a 5-point Likert scale, where 1 indicates "strong disagreement" and 5 indicates "strong agreement," while the PSSUQ uses a different Likert scale, where 7 indicates "strong disagreement" and 1 indicates "strong agreement." Multimedia Appendix 1 further explains SUS, and Multimedia Appendix 2 details PSSUQ. Multimedia Appendix 3 presents the interview questions used for each respondent.

Results

Identifying Problems and Defining Solutions

This stage began with a literature review on the epidemiology of stroke globally and in Indonesia, as well as challenges in handling stroke rehabilitation. We also conducted interviews with 10 health workers (general practitioners, medical students, and therapists) and 8 patients who have experienced a stroke (or their caregivers as intermediaries) to understand patients' needs and challenges. Multimedia Appendix 4 summarizes the problems emerging from interviews with 18 respondents, comprising 10 experts and 8 patients. These respondents identified various problems in stroke rehabilitation, including a lack of self-rehabilitation exercises at home, low patient compliance with exercises, unclear roles and low willingness among medical personnel, the decreased ability of patients to undergo rehabilitation in the hospital due to age, limited health care facilities, the variety of conditions among patients who have experienced a stroke, and the absence of evidence on home exercises as a form of evaluation, which leaves evaluations reliant solely on patient reports, which are often subjective and not always accurate.

Problem solution mapping was used to understand these problems and find solutions. This study adopted the HMW method, in which questions were formulated based on identified problems. The research continued by exploring all possible solutions that were relevant and effective for solving the problems. The solutions discovered through the HMW method are summarized in Multimedia Appendix 5.

Subsequently, personas were constructed to understand users' needs, motivations, and goals in stroke rehabilitation. Based on the previous stages, 2 main personas with different characteristics were identified: health care workers and patients who experienced a stroke. These 2 types have different roles and needs in stroke rehabilitation management. Thus, the app was designed for these individuals.

The patient persona represents a man who had a stroke at the age of 56 years and worked as a lawyer. Currently, he is undergoing a physical rehabilitation process at home with the support of his family members. The stroke he experienced impacted his physical abilities, especially in terms of mobility and body coordination. In addition, he experiences communication disorders, which make his pronunciation unclear. Such conditions make it hard for patients to remember the frequency and types of exercise that need to be performed after discharge from the hospital, while also making it difficult to visit the hospital due to cognitive impairment. This persona has 2 basic needs in his rehabilitation process: the support and encouragement of his family or friends to maintain his spirit, and the presence of his family to help guide him through the rehabilitation process.

The persona of the medical personnel represents a female who is aged 23 years and lives in Jakarta. As a professional in physical rehabilitation, she has 2 years of experience as a physiotherapist. She has treated several patients who have experienced a stroke, but the rehabilitation process has not always proceeded smoothly. She recognizes the challenges in dealing with patients who have experienced a stroke, which involve both internal patient factors and external factors that affect the recovery process. She has 2 basic needs in carrying out her duties as a physiotherapist: the ability to effectively manage post-stroke rehabilitation, and the need to improve both her nonclinical and clinical skills to offer optimal care. Because she is motivated, she has a realistic perspective and always appreciates patients' progress. However, she has difficulty motivating patients to undergo stroke rehabilitation consistently and is unable to monitor patients' exercises at home.

Design and Development

Based on the mapping of problems and solutions in the previous stage, this stage involved translating user needs into an initial design that could be tested and evaluated. The low-fidelity (lo-fi) app prototype from the first iteration was designed to visualize the flow of user interaction and ensure that every feature and flow was user-friendly. The high-fidelity (hi-fi) prototypes from the second and third iterations were used to determine how users would interact with an app featuring visual elements and interactivity. This design also tested user flow and design consistency. Figures 2-4 present examples of the lo-fi prototype design, featuring the home screen, stroke education, and stroke rehabilitation activity targets. Figures 5-7 display examples of the hi-fi prototype design with the same content.

Demonstration, Evaluation, and Communication

In the demonstration stage, we showed interviewees the lo-fi app prototype, and they provided feedback on the design in the evaluation and communication stages. This yielded various inputs regarding the initial design features. All reviews submitted by the interviewees were validated and analyzed to determine improvement priorities. Table 2 summarizes the lo-fi prototype evaluation, which led to improvements in the hi-fi version.

Table . Summary of low-fidelity prototype evaluations.

Improved features	Improvements
Authentication	• Using a registration certificate number (STR) instead of a practice license number
User profile management features	• Adding data on patients' disease history, drug allergies, and medical records • Adding an STR number for medical personnel data • Linking to the national data system and restricting access to authorized medical personnel
Therapy results report submission feature	• Connecting to a consultation or home-visit service • Sending examination results to medical personnel in video format
Gamification (pop-up quiz)	• Adding a "Skip" button for questions
Activity target features	• Improving concision • Adding long- and short-term activity targets
Consultation and home-visit features	• Adding patient medical record data to the home-visit feature • For consulting services, removing rehabilitation progress trackers

The evaluation and communication stages were carried out using surveys and interviews to collect feedback on the design. Both quantitative (SUS) and qualitative methods were used. Evaluation data for SUS were collected from 146 respondents from November 1, 2025, to November 7, 2025. The respondents who filled out the SUS questionnaire included a balanced number of men and women, with 73 respondents aged 26 to 35 years (n=146, 50%). The average SUS score was 71.83, a "Good" result [26]. Based on these results, we interviewed 20 medical personnel and 5 patients with stroke from November 7, 2025, to November 9, 2025. Multimedia Appendix 6 summarizes the recommended improvements.

The final evaluation was carried out using the PSSUQ to measure app design quality based on the users' perceptions of ease of use and information quality. The PSSUQ was distributed from November 17, 2025, to November 21, 2025, and was returned by 128 respondents, including 69 (54%) women and 59 (46%) men. Participants aged 26 to 35 years comprised the largest group with 40 (31%) respondents, followed by the 17 to 25 group with 33 (26%) respondents. Table 3 indicates that these participants found the improved app easy to implement and use.

Table . Post-Study System Usability Questionnaire results.

Category	System usefulness	Information quality	Interface quality	Overall system
Red	2.32	2.39	2.42	2.35
Lower limit	2.12	2.19	2.23	2.16
Upper limit	2.52	2.9	2.60	2.54

The app's features were grouped into 4 categories of health service approaches, namely promotive, preventive, curative, and rehabilitative. Promotion focuses on knowledge, awareness, and user participation so that they are proactive in maintaining their health. Prevention pertains to the avoidance or early detection of health problems through routine monitoring and assessment. Curative care concerns the treatment of conditions through access to medical services. Rehabilitation focuses on restoring cognitive, emotional, and social functions through fun, therapeutic activities.

The entire list of app features mapped to each persona is listed in Multimedia Appendix 7. Promotion is supported by onboarding, video and text education features, and rehabilitation progress monitoring. Prevention is facilitated by target activity, gamification, and rehabilitation schedule reminder features. Curative care is supported by consultation, therapy results reports, and home-visit service features. Rehabilitation is facilitated by a rehabilitation training program and user profile management to tailor rehabilitation interventions to the individual circumstances of each patient. In addition, we implemented authentication features that allow each user to securely log in and access the system with a verified identity, thereby ensuring the security and personalization of patients' rehabilitation data.

XSL•FO
RenderX

All features were mapped onto intervention theory principles to ensure that the features had a strong interventional basis. Intervention theory focuses on 3 main aspects: valid and useful information; free, informed choices; and internal commitment [20]. Valid and useful information requires that the data provided by the system or intervention must be accurate, trustworthy, and relevant to the needs of the user [20]. Free, informed choice means that users have the liberty to make decisions without coercion or manipulation [20]. Internal commitment mandates that users have the internal motivation and commitment to carry out and complete intervention programs without any external pressure or coercion [20]. Feature mapping was carried out to document the theoretical basis of each feature, ensure the completeness of behavioral change components, and provide theoretical justifications for design decisions. Mapping each feature onto the aforementioned principles (Table 4) allowed us to evaluate how well each feature contributed to an effective intervention process.

XSL•FO
RenderX

Table . Feature mapping with intervention theory.

Persona, principle of intervention theory, and feature	Theoretical justification
Patients who experienced a stroke	
Valid and useful information	
Onboarding	Provides accurate initial information on the app's functionality and a thorough introduction to the app's features prior to direct use by patients who have experienced a stroke.
General educational video features related to stroke and stroke rehabilitation	Provide education in video format about stroke and stroke rehabilitation that is relevant to patients performing stroke rehabilitation.
General educational articles	Provide education in article format about stroke and stroke rehabilitation that is relevant to patients performing stroke rehabilitation.
Rehabilitation progress monitoring	Provides detailed information related to the patient's rehabilitation progress based on the condition and the latest assessment of medical personnel.
Rehabilitation training program	Provides education in the form of articles, videos, and short videos on stroke rehabilitation exercises at home.
Free, informed choice	
Pop-up quiz (gamification)	Provides freedom for patients who have experienced a stroke to fill out pop-up quizzes or skip them.
Reminders	Provide freedom for patients who have experienced a stroke to manage schedules, whether exercise schedules, consultations, or home visits.
User profile management	Provides freedom for patients who have experienced a stroke to manage their personal data.
Therapy reports	Provide freedom for patients who have experienced a stroke to submit therapy results to medical personnel in video format.
Health consultation	Provides freedom for patients who have experienced a stroke to consult with and choose available medical personnel.
Home-visit service	Provides freedom for patients who have experienced a stroke to conduct home visits and choose available medical personnel.
Internal commitment	
Activity targets	Giving patients control over setting personal goals creates a sense of ownership, so that the motivation to achieve them comes from their own intrinsic desires, not external compulsions.
Medical personnel	
Valid and useful information	
Onboarding	Provides accurate initial information on the app's functionality and a thorough introduction to the app's features before being used directly by medical personnel.
General educational video	Allows medical personnel to manage education in video format about stroke and stroke rehabilitation by ensuring that the information provided to patients remains accurate and relevant.
General educational articles	Allow medical personnel to manage education in article format on stroke and stroke rehabilitation by ensuring that the information provided to patients remains accurate and relevant.
Rehabilitation progress monitoring	Allows medical personnel to update patient rehabilitation progress data validly and accurately according to the patient's current condition.
Rehabilitation training program	Allows medical personnel to manage education in the form of articles, videos, and short videos on home stroke rehabilitation exercises by ensuring that the information provided to patients remains accurate and relevant.
Pop-up quiz (gamification)	Allows medical personnel to add pop-up quiz questions with correct answers.
Therapy results report	Allows medical personnel to provide verified and accurate evaluation results for rehabilitation progress.
Medical consultation	Allows medical personnel to serve patients who have experienced a stroke and provide accurate and verified evaluation results.
Home-visit service	Allows medical personnel to serve patients who have experienced a stroke and provide accurate and verified evaluation results.
Free, informed choice	

XSL•FO
RenderX

Persona, principle of intervention theory, and feature	Theoretical justification
User profile management	Provides freedom for medical personnel to manage their personal data in accordance with the decisions of medical personnel.
Internal commitment	
Activity target	Allows medical personnel to provide recommendations for targeted activities tailored to the patient's condition. This encourages patients to have a personal stake in completing predetermined rehabilitation activities.

Discussion

Principal Findings

Across 3 iterations involving doctors, therapists, medical students, and individuals interested in stroke rehabilitation issues, this study collected feedback to build an app based on patients' and related stakeholders' feedback. The app's main features are grouped into several interface categories, including exercise and progress monitoring programs, consultation and home-visit services, and educational content designed to support poststroke rehabilitation. These features were mapped onto the principles of intervention theory, namely valid information; free, informed choice; and internal commitment. The evaluations of the app design suggested an increase in usage and user satisfaction, as well as success in addressing the challenges and limitations identified in previous research.

In addition, this study discovered a new problem: decreased patient ability to undergo rehabilitation in hospitals due to age. This problem was overcome by adding a feature for home visits, which remains rarely addressed in stroke rehabilitation apps [17,18,27]. Another new problem in the Indonesian context concerns the mental struggles of patients, which impede rehabilitation. For example, low patient motivation to carry out stroke rehabilitation was overcome by adding activity targets to the app, thus ensuring consistency and triggering patient motivation.

In Indonesia, there is a lack of objective evidence regarding home care because evaluations rely on subjective patient reports. This problem was addressed by designing a rehabilitation progress monitoring feature and therapy result reports, integrated with patient medical records in the app; this allows patient progress to be evaluated properly, rather than relying solely on oral testimonials. Thus, several features of the app were adapted to the context in Indonesia, including home-visit features, rehabilitation training programs, gamification (pop-up quizzes), rehabilitation progress monitoring, activity targets, and therapy reports.

Theoretical Implications

Researchers have previously conducted systematic reviews or usability assessments of existing systems using various evaluation frameworks [15,17,18,27,28]. In contrast, this study designed a stroke rehabilitation management app by consulting patients and medical personnel using DSR. Thus, the feedback obtained represents the true needs of patients who experienced a stroke, including recovery processes and mechanisms underlying behavioral changes, as well as the promotive, preventive, curative, and rehabilitative aspects of health promotion. This study also expands the limited literature on stroke rehabilitation in developing countries [11].

There is a gap in the research [15,17] regarding the low adherence of users to rehabilitation procedures, which we addressed by adding activity target features and schedule reminders. This will help patients, families, and caregivers monitor patient rehabilitation in a more structured and scheduled manner. Another gap [18] is the limited variety of content for different stages of stroke and patient conditions, which we addressed by providing a range of educational content and exercises to suit individual needs. The app also provides tutorials on usage and onboarding, which were not included in the research conducted by Song et al [18]. Furthermore, previous research used relatively small samples and did not include all relevant respondents, especially patients [28]. Our app also minimizes or eliminates certain challenges of stroke rehabilitation. The app overcomes the limitations of health facilities by providing consultation and home-visit services and increasing digital literacy and compliance with rehabilitation exercises. The app can also mitigate the impact of stroke on patients by optimizing the body's functionality and preventing complications.

The importance of this study stems from the high prevalence of stroke in Indonesia and the lack of applications that support patient-centered stroke rehabilitation. Research in Canada [17], Belgium [15], and the United States [18] has discussed various mHealth apps for stroke rehabilitation, covering improved physical function, physical activity, and patient quality of life. However, these are all developed countries, and no previous work has focused on Indonesian patients with stroke. The problems identified in our interviews reflect those noted in previous works [15,17]. Furthermore, the app offers solutions such as schedule reminder features, gamification in the form of pop-up quizzes, and rehabilitation progress monitoring.

Practical Implications

For health care facilities, such as hospitals, therapy clinics, and health centers, our app can be used to monitor patients undergoing stroke rehabilitation or to help prevent recurrent strokes. For medical personnel, the app can help carry out rehabilitation services both online (through messages or voice media) and offline (by visiting the patient's home). This would make rehabilitation services more efficient and help evaluate the rehabilitation process based on patient medical data. Medical personnel can also provide education and training on stroke rehabilitation at home. Zeng et al [29] noted that improved health literacy among stroke survivors and caregivers improves self-management for survivors.

XSL•FO
RenderX

For patients, families, and caregivers, the app can provide educational information about stroke rehabilitation, including exercises that can be performed at home easily and affordably. Stroke apps should involve online communities to support survivors and caregivers [16,30]. Moreover, the app facilitates consultation services and home visits from medical personnel. There are also schedule reminders, activity targets, and progress-tracking features for patients, families, and caregivers to monitor speech, occupation, and function.

For mHealth developers, this app is built to serve the needs and expectations of users in Indonesia. Likewise, for the government or policymakers, it can be connected to hospitals and official services. The app can be used to collect data on patient activity patterns after stroke and to provide evidence of its effectiveness in supporting stroke rehabilitation. The government should consider the value of medical personnel being able to access educational and training information for patients, families, and caregivers.

Limitations

Despite these strengths, the study has limitations, such as limited digital literacy among participants, which made it difficult for them to understand certain features or use the app independently. Therefore, training on using the system is needed. Other difficulties included technical limitations when using the application, such as internet connection problems, device availability, operating system compatibility, and device storage capacity.

Digital apps can be difficult for older adults to use. Most of our participants were young adult caregivers of patients with stroke, which explains the lack of older participants. It was difficult to accommodate all users due to the limited accessibility of technology in remote areas and the age of patients who experienced a stroke. Although older patients may have difficulty using the app independently, caregivers, families, or online communities can help them use features that present challenges, ensuring that the collected data represent the needs of all age groups.

Further research is recommended to conduct longitudinal analyses measuring long-term adherence, app usage sustainability, and the impact on rehabilitation outcomes among patients who have experienced a stroke. Researchers could also adopt supportive technologies, such as wearable devices, to make the app accessible to users with limitations.

Abstract

Background: Gait impairment is a prevalent sequela of stroke. Although observational gait analysis remains a standard clinical practice for assessing neuromotor impairments in people with stroke, it is prone to subjective bias. Consequently, objective assessment is required to inform effective rehabilitation protocols.

Objective: This study aimed to validate a deep learning framework for automating clinical gait assessment using kinematic data.

Methods: This study was conducted in a university-affiliated gait analysis laboratory. Kinematic data were collected from 51 individuals with hemiparetic stroke and 18 healthy controls using wearable inertial measurement units, and video recordings were obtained for the Wisconsin Gait Scale (WGS) scoring. WGS scores, rated by 2 experienced physiotherapists, were used to establish the expert reference standard. A statistical graph convolutional network (STAT-GCN), incorporating a STAT-Attention Head module, was developed to predict WGS items 2 to 14 from kinematic data. Model evaluation was performed using a stratified, participant-level 5-fold cross-validation protocol, with all gait cycles from the same participant kept within the same fold. Model performance was assessed at the participant level using exact accuracy, mean absolute error, and weighted κ metrics. A descriptive comparison involving 4 final-year physiotherapy students was also conducted.

Results: Among participants with stroke, STAT-GCN achieved an overall exact accuracy of 75.42% for WGS items 2 to 14, with a mean absolute error of 0.290 score levels. Across the participant-level 5-fold cross-validation test sets, STAT-GCN achieved a mean exact accuracy of 75.64% (SD 6.58%), whereas the 4 student evaluators achieved mean accuracies ranging from 56.19% (SD 7.03%) to 67.09% (SD 4.03%).

Conclusions: The proposed STAT-GCN framework demonstrated reasonable preliminary performance for automated WGS item prediction in individuals with stroke. The results suggest that kinematic data–driven models may support more standardized gait assessment, but performance should be interpreted cautiously given the limited sample size, class imbalance across WGS score items, and absence of external validation. Further studies with larger and more clinically diverse stroke cohorts are needed before clinical implementation.

Introduction

Stroke is a principal contributor to global mortality and long-term disability [1,2]. It constitutes a major public health challenge, imposing substantial societal and health care burdens worldwide. The complications of stroke are debilitating and commonly include muscle weakness, spasticity, and limb apraxia, which contribute to gait impairments [3,4]. These impairments present as reduced cadence and speed, resulting in an abnormal gait pattern. These impairments may also lead to difficulties in maintaining balance [5-7]. Consequently, gait impairments affect the level of community integration in patients with stroke [8].

Observational gait analysis remains a conventional clinical practice for assessing neuromotor impairments in people with stroke; however, this methodology is prone to subjective bias in clinical assessments [9]. Thus, for greater systematicity, standardized gait analysis tools such as the Wisconsin Gait Scale (WGS) have been adopted to evaluate videotaped gait patterns in individuals with stroke [10]. The WGS [11] is a widely adopted assessment tool for evaluating gait abnormalities. It comprises 14 items, of which 13 are related to gait performance and gait patterns and are rated through observation of gait. The WGS is clinically efficient, requiring minimal instrumentation, and has demonstrated high intrarater reliability (intraclass correlation coefficient [ICC]=0.83) in poststroke validation studies [12]. However, manual scoring by a rehabilitation specialist is not only time-consuming but also subject to bias in subjective clinical judgment [13]. Furthermore, rating many WGS items requires the observation of subtle changes in joint angles, such as the rotation angle of a specific joint. The visual identification of these subtle changes is highly challenging.

AI has been increasingly used to automate and reduce subjective bias in clinical assessment [14,15]. A multimodal graph fusion network was proposed in a previous study [16] to detect the freezing of gait, a disabling symptom of Parkinson disease. The graph fusion network comprised 4 modalities, each corresponding to a distinct data source. Graph fusion networks have also been used successfully to determine the severity of parkinsonism [17,18]. Similarly, a study [19] successfully distinguished Parkinson disease cases from controls using a novel model, namely a multiview graph convolutional network (GCN). Human motion analysis represents an evolving computational paradigm where skeleton-based kinematic time-series data serve as critical inputs for emerging action recognition algorithms [18,20-22]. GCN-based models have demonstrated state-of-the-art performance on established motion analysis benchmarks, achieving >93% accuracy on the NTU RGB+D dataset [23]. However, translational applications in clinical gait assessment remain limited [24], primarily due to the fundamental disparity between action classification and quantitative clinical evaluation. Evaluating an action in clinical settings requires a more nuanced level of analysis than simple recognition, as it involves complex assessments of quality, precision, and clinical relevance [25]. Standard deep learning architectures, such as convolutional neural networks and recurrent neural networks, often struggle with this level of granularity because they treat skeletal data as flat sequences or grids, ignoring the intrinsic biomechanical connectivity between joints. This loss of topological information makes it difficult to quantify the subtle deviations in interjoint coordination that characterize pathological gait.

To address this gap, we propose a novel statistical graph convolutional network (STAT-GCN) for the automation of WGS scoring. By using gait kinematic data collected from inertial measurement units (IMUs) [26], this model enables the representation of joint angular trajectories as spatiotemporal features on a graph structure. By preserving the topological structure of lower-limb joints, this approach is intended to improve the model's ability to learn clinically relevant gait features for automated WGS item scoring.

Methods

Ethical Considerations

This study was conducted in accordance with the Declaration of Helsinki and was approved by the Institutional Review Board of The Hong Kong Polytechnic University (approval number HSEAR20210715003). All participants provided written informed consent. Participants' privacy and confidentiality were maintained throughout the study. All collected data were deidentified and stored securely, and only authorized members of the research team had access to the data. Participants received reimbursement for transportation expenses associated with study participation.

Participants

This study enrolled individuals with stroke according to the following criteria: (1) aged 18 to 80 years, (2) diagnosis of ischemic or hemorrhagic stroke confirmed by magnetic resonance imaging or computed tomography more than 6 months before assessment, (3) able to walk 10 m independently or with assistance, and (4) capable of providing informed consent. Individuals were excluded if they had any medical conditions that hindered their ability to participate in the assessment. In addition, 18 healthy individuals were recruited according to the following criteria: (1) aged 18 to 80 years, (2) no history of stroke or other diseases that may affect gait patterns, (3) able to walk independently, and (4) capable of providing informed consent. From March to August 2024, eligible participants were recruited through convenience sampling with assistance from local self-help groups.

Because no consensus has been established on sample size calculations in studies focused on developing deep learning models for various clinical applications [24], we referred to our previous study, which included 40 participants. In addition, an AI model using gait kinematic data achieved an accuracy of 84% in predicting the outcomes of clinical assessments of functional mobility conducted by physiotherapists [14]. Based on the sample sizes of these previous studies, for the development of a deep learning model, our trial aimed to recruit 51 participants. The study protocol was conducted in accordance with the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines (Checklist 1).

Outcome Measures

Gait Assessment and Clinical Measures

In this study, gait kinematics were measured in participants with stroke. Gait analysis and kinematic assessment were conducted using the MTw Awinda system (Xsens Technologies B.V.). This system consists of an IMU containing a 3D gyroscope, 3D accelerometer, and 3D magnetometer. Data were sampled at a frequency of 60 Hz. According to the official guidelines, body motion was captured by attaching 17 wireless sensors to the head, shoulders, sternum, upper arms, forearms, hands, pelvis, upper legs, lower legs, and feet of the individual. The IMUs were secured using MTw Velcro Body Straps and tape. Data were transmitted between the wireless tracker and the Awinda Station using the patented Awinda radio protocol, which was specially developed to ensure accurate 3D motion tracking even with unstable data transmission [27], and were processed using Xsens MVN 2024 software for gait analysis and kinematic assessment.

This study also used 2 distinct outcome measures:

1. WGS served as the primary outcome measure and our modeling target.
2. The Motor Subscale of the Fugl-Meyer Assessment of the Lower Extremity (FMA-LE) was used as a supplementary assessment to provide a broader characterization of participants' motor impairment.

WGS

The WGS is a gait assessment tool specifically designed for individuals with hemiplegia (Multimedia Appendix 1). The scale comprises 14 items and is designed to measure clinically relevant gait patterns during the stance phase, toe-off, swing phase, and heel strike of the gait cycle. Rodriguez et al [28] first introduced the WGS using videotaped gait recordings obtained in the frontal and sagittal planes. Each item is rated on an ordinal scale of either 1 to 3 or 1 to 4. The total score ranges from 14 to 45, with higher scores indicating greater gait impairment. As the primary outcome measure, WGS scores were assigned based on participants' gait. The ground truth was established based on consensus WGS scores agreed upon by 2 Hong Kong–registered physiotherapists, each with more than 10 years of clinical experience. Additionally, 4 final-year physiotherapy students provided WGS ratings to represent the perspectives of inexperienced raters.

FMA-LE

As a supplementary measure to characterize participants, the FMA-LE was used. Although the full FMA-LE evaluates motor function, sensation, range of motion, and pain [29], the motor subscale specifically is widely used to assess poststroke lower extremity motor impairment. This subscale evaluates reflex activity, movement in and out of synergy, as well as coordination and speed. It comprises 17 items, each rated on a 3-point ordinal scale (0‐2), summing to a maximum total score of 34 (indicating normal function) [30]. It demonstrates excellent intrarater reliability (ICC=0.99) and interrater reliability (ICC=0.91) [31].

Study Procedures

Prior to kinematic analysis using the Xsens MVN 2024 software, participants with stroke underwent a standardized assessment using the motor subscale of the FMA-LE [32]. Subsequently, following the Xsens user manual [33], 17 sensors were attached to the corresponding body segments of each participant for motion capture. Participants were instructed to walk back and forth in a straight line at a self-selected, comfortable speed over a flat 10 m surface. Three trials were recorded, ensuring that participants completed at least 5 full gait cycles in each direction. All walking trials were videotaped in both the sagittal and frontal planes. Finally, each trial was reviewed by 2 experienced physiotherapists to generate a consensus WGS score. The gait kinematic data exported from the software were then used to develop a deep learning model, namely, the STAT-GCN model, to predict WGS scores for participants with stroke. Item 1 of the WGS (ie, use of a walking aid) was excluded from the analysis because this item is easier to rate through direct observation.

Model Training and Testing

Cross-Validation and Data Partitioning

To ensure a rigorous evaluation of the proposed model, we implemented a stratified, participant-level 5-fold cross-validation protocol across the entire cohort (51 individuals with stroke and 18 healthy controls). The dataset partitioning was executed strictly at the participant level; that is, all gait cycles originating from a single participant were assigned exclusively to either the training set D_{train} or the testing set D_{test}. This participant-isolated strategy guarantees that the model was tested solely on unseen individuals, thereby eliminating the risk of intraparticipant data leakage.

The cross-validation folds were stratified by clinical groups to maintain an approximately balanced proportion of patients and controls across the folds. During the inference phase, a majority-voting mechanism was applied to aggregate cycle-level predictions into a definitive participant-level clinical score. The most frequent prediction across all available gait cycles for a given participant was designated as the final predicted score for each WGS item.

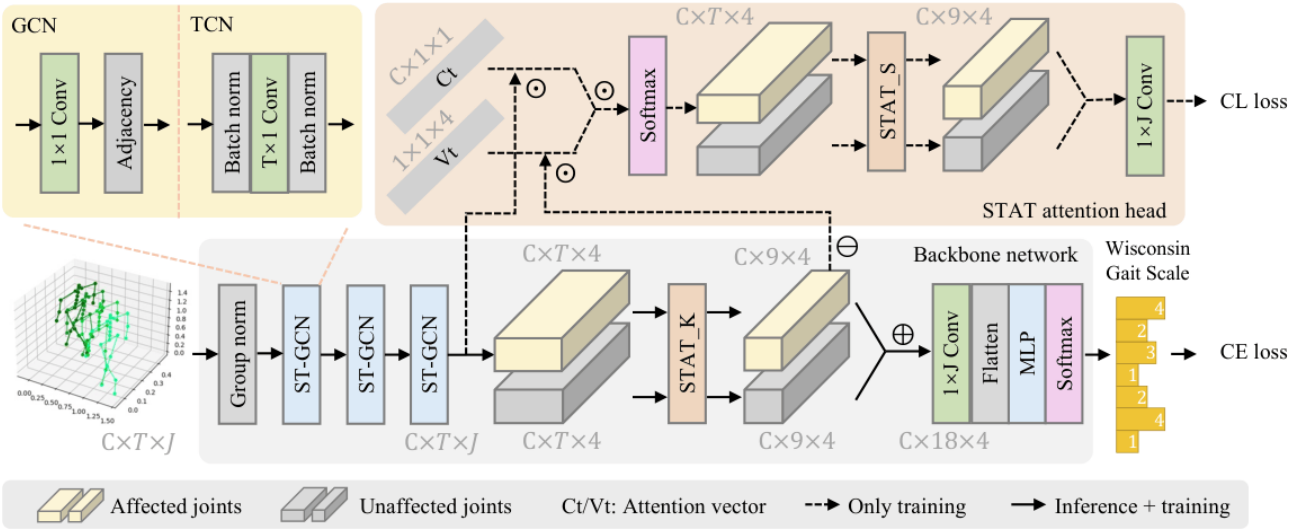
Data augmentation was applied only to the training gait cycles within each cross-validation fold [34]. Three time-series augmentation strategies were used to simulate natural gait variability and sensor measurement noise: jittering, scaling, and time warping. Jittering added small Gaussian noise to the original gait trajectories, scaling adjusted feature amplitudes to represent variations in stride intensity, and time warping introduced smooth temporal distortions to simulate cadence fluctuations within a gait cycle. Through these augmentation procedures, the number of training gait cycles increased from 979 to 10,152. No augmented samples derived from test participants were included in the training set, and test set performance was evaluated using nonaugmented gait cycles from unseen participants.

To reduce the risk of overfitting, the STAT-GCN was designed as a compact model. It consists of 3 spatiotemporal graph convolutional blocks followed by a statistical head, with channel

XSL•FO
RenderX

widths of 24, 48, and 48 across the 3 blocks. The STAT-Attention module was implemented as a lightweight feature-scaling mechanism rather than a dense pairwise self-attention layer. The same model configuration and hyperparameter settings were applied across all cross-validation folds. The model was trained with a batch size of 16 for 40 epochs. The initial learning rate was set to 1×10^{-3}, with a step decay factor of 0.8, and the weight decay was set to 0.1 for L2 regularization. No fold-specific hyperparameter tuning or test set–based model selection was performed.

Backbone Network



For our model, a batch of skeleton data, $D \in R^{(B\times C\times T\times J)}$, is used as input, where B is the batch size, C represents the number of raw features, T represents the number of frames in 1 gait cycle, and J is the number of joints. The backbone network is adapted from previous studies [18,35], with an additional statistics module.

The role of a spatio-temporal graph convolutional network (ST-GCN) block is 3-fold. It embeds low-level features into a high-dimensional hidden space, facilitates the exchange of information between joints, and aggregates features along the temporal dimension for each joint. By stacking multiple ST-GCN blocks, the model can gradually expand its receptive field and learn meaningful features.

STAT-GCN

To address the inadequate performance of prior data-driven approaches due to limited clinical data, we propose STAT-GCN (Figure 1). This model processes input skeleton data derived from motion capture to predict WGS scores. The inference architecture consists of a backbone network built from multiple ST-GCN blocks followed by a statistics module. To enhance feature discrimination, we introduce a STAT-Attention Head (SA Head) exclusively during training. This module uses contrastive loss and attention mechanisms to explicitly extract critical statistical features and highlight significant joints. Furthermore, by leveraging clinical labels regarding the affected side in participants with stroke, we segregate joint features into "affected" and "unaffected" categories to minimize misinterpretation. Consequently, STAT-GCN generates highly representative features tailored to each patient's specific mobility characteristics.

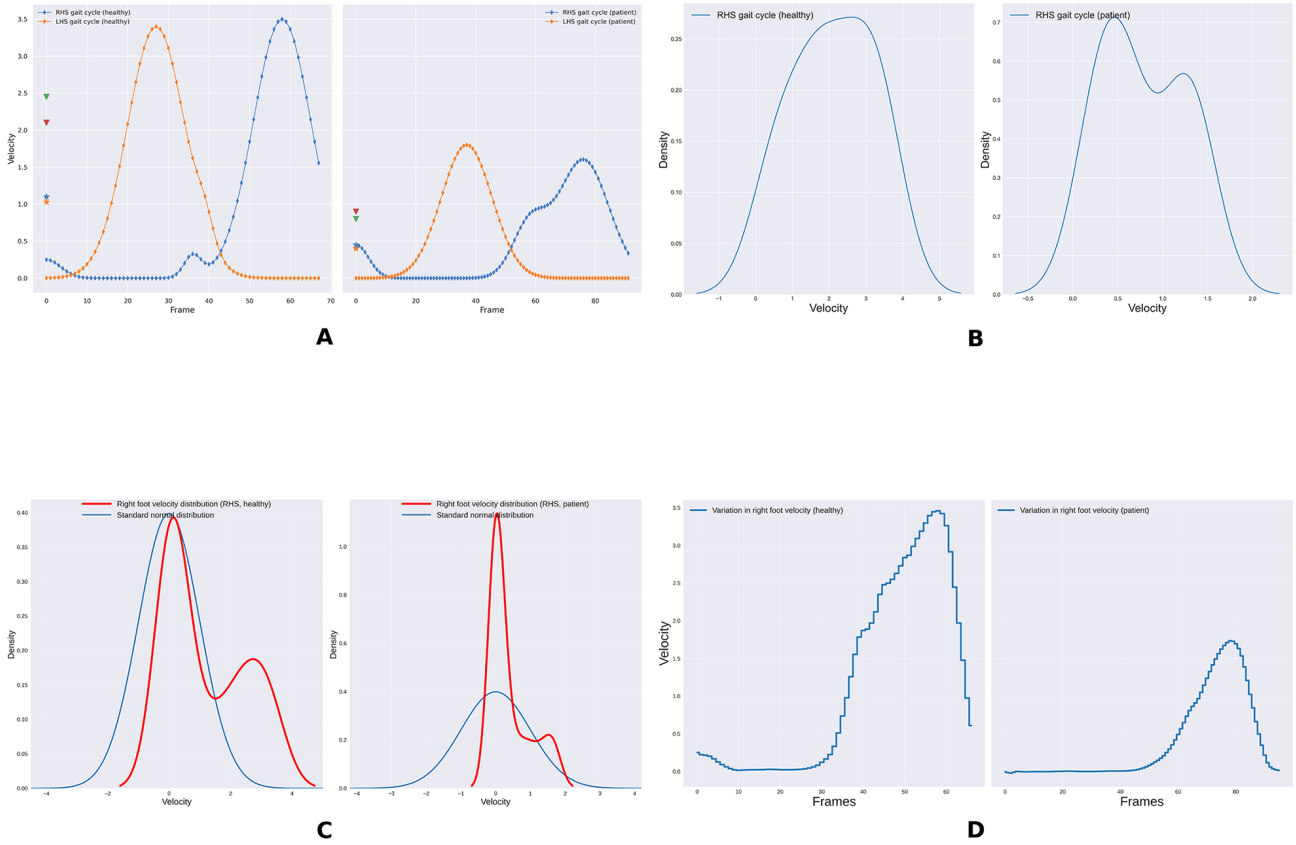


Figure 1. Proposed STAT-GCN architecture. CE: cross-entropy loss; CL: contrastive loss; Ct: channel attention vector; MLP: multilayer perceptron; ST-GCN: spatio-temporal graph convolutional network; STAT-GCN: statistical graph convolutional network; TCN: temporal convolutional network; Vt: vertex attention vector (graph vertex=joint).

The statistics module summarized gait trajectories using commonly used statistical measures, including range, maximum, mean, median, SD, and the 25th and 75th percentiles (IQR), as previously described [36]. These statistical descriptors were used to provide cycle-level summaries that were less dependent on the starting point of the gait cycle. As illustrated in Figure 2, gait cycles initiated from different events, such as right heel strike and left heel strike, may have different temporal representations despite reflecting comparable movement patterns.

RenderX

Figure 2. Gait pattern visualizations based on velocity. (A) Comparison of right foot velocity across gait cycles and health conditions. The symbol ∇ indicates the first and third quartiles of the corresponding pattern, and the symbol indicates the median and mean. (B) Kernel density estimate of the combined left and right velocities during the right-heel-strike gait cycle for both healthy individuals and patients with stroke. (C) Comparison between the right foot velocity distribution and the standard normal distribution. (D) Variations in right foot velocity during the right-heel-strike gait cycle for both healthy individuals and patients with stroke.

To further characterize gait trajectory patterns, skewness, kurtosis, and total variation were incorporated into the statistics module. Skewness was used to summarize distributional asymmetry, kurtosis to describe the peakedness of the distribution, and total variation to depict joints' ranges of motion across the gait cycle. These additional descriptors were intended to capture complementary characteristics of poststroke gait patterns beyond the standard statistical measures. The captured IMU data were categorized into joint position and joint angle modalities, and separate models were trained for each modality. The output probabilities from both modalities were then combined to generate the final prediction.

Contrastive Learning

In the subsequent phase of the SA Head module, the global prototype for label *k* is refined by incorporating the prototypes of true-positive (TP) samples in *D* through an exponential moving average. Let DTPk be the set of TP samples for label *k* in a batch with size nTPk. The exponential moving average operation can be defined as follows:

(1)Pk=(1−α)·1nTPk∑i∈ DTPkFi+α·Pk

where F_i is the prototype of the *i*th sample, and P_k is the global prototype for label *k*. P_k will converge to a consistent representation after training. For the false-negative (FN) and false-positive (FP) samples of label *k*, only a local cluster at the center is computed. Similarly, for the 2 types of samples, the cluster at the center is calculated:

(2)μFPk=1nFPk∑i∈ DFPkFi, μFNk=1nFNk∑i∈ DFNkFi

The FN and FP samples, which are often referred to as ambiguous samples, are calibrated by increasing the distance between the TP prototype and the FP samples, while decreasing the distance between the TP prototype and the FN samples. Given a confident TP sample F_i, the compensation term for the FN samples is as follows:

(3)φi={1−dis (Fi,μFNk)if i∈ ITPk∧nFNk>00otherwise

The penalty term for the FP samples is as follows:

(4)βi={1+dis (Fi,μFPk),if i∈ ITPk∧nFPk>00otherwise

The cosine similarity function is used to calculate the distance between the TP prototype and the FP samples. The cosine distance is maximized to ensure a shorter distance between the center of the FN cluster and the confident TP samples, thus minimizing the compensation term. Moreover, the penalty term should be minimized. Finally, the contrastive learning loss for the confident sample F_i is defined as follows:

[illegible]

Here, p_{ik} is the probability of the sample F_i for label *k*, and τ is the temperature. The final training objective is to simultaneously minimize the cross-entropy and contrastive learning loss.

Model Interpretation Analysis

To quantitatively evaluate the faithfulness of the STAT-Attention module, we conducted an attention-guided

XSL•FO
RenderX

occlusion analysis using the trained participant-level 5-fold cross-validation models. For each WGS item, attention weights were aggregated into a 2×4 grid representing 2 modalities, joint position and joint angle, and 4 lower-limb joint groups, including upper leg, lower leg, foot, and toe. For each test participant, these modality-joint cells were ranked according to their attention weights. Single-cell occlusion was then performed by masking the input features corresponding to the selected cell. Four occlusion conditions were examined: the highest-attention cell, the second-highest-attention cell, the lowest-attention cell, and the average across the remaining cells. Faithfulness was evaluated by calculating the decrease in true-class probability after occlusion. A larger decrease indicated that the occluded feature group was more important to the model's prediction.

Statistical Analysis

Model performance was evaluated at the participant level. Accuracy was defined as the proportion of predicted WGS item scores that exactly matched the expert reference scores. Because WGS item scores are ordinal, mean absolute error (MAE), linear weighted κ, and quadratic weighted κ were additionally calculated to account for the magnitude of disagreement between predicted and reference scores. Item-level performance was reported for WGS items 2 to 14, and overall performance was calculated by pooling all participant-level item predictions across these items.

To provide a robust estimate of model generalizability, performance metrics were summarized across the participant-level 5-fold cross-validation folds as the mean (SD). The distribution of expert reference scores for each WGS item was also reported to characterize potential class imbalance. To contextualize model performance against expert-level agreement, interrater reliability between the 2 experienced physiotherapists was assessed using their independent ratings. ICCs were calculated using a 2-way random-effects model with absolute agreement and single measures (ICC [2,1]) for each WGS item, the total WGS score, and the summed score of WGS items 2 to 14.

Data Availability

The raw clinical gait data associated with this study are not publicly available because they contain participant-level movement recordings and are subject to ethical and institutional data-sharing restrictions. Deidentified processed data may be made available from the corresponding author upon reasonable request and subject to institutional approval.

Results

This study included 51 patients with stroke and 18 healthy individuals. The mean age was 60.3 (SD 10.2) years in healthy individuals and 62.7 (SD 9.5) years in patients with stroke. The poststroke duration was 9.0 (SD 7.2) years. In this sample, 21 patients with stroke and 9 healthy individuals were men. The median FMA-LE score was 24 (IQR 21-29), and the median WGS score was 22 (IQR 18-26; Table 1).

Figure 3 summarizes the experimental workflow and results. Using instrumented gait data as input, we achieved higher accuracy in WGS ratings compared to 4 final-year physiotherapy students. As presented in Table 2, the STAT-Net model was descriptively compared with 4 final-year physiotherapy students across the participant-level 5-fold cross-validation test sets. The STAT-Net model achieved a mean exact accuracy of 75.64% (SD 6.58%), whereas the 4 student evaluators achieved mean accuracies of 67.09% (SD 4.03%), 65.90% (SD 6.50%), 56.19% (SD 7.03%), and 58.72% (SD 4.22%), respectively. These findings suggest that the model showed higher exact agreement with the expert reference scores than the student evaluators in this novice-rater comparison.

Table 3 presents the item-level prediction performance of STAT-Net among participants with stroke. Across WGS items 2 to 14, the model achieved an overall exact accuracy of 75.42%, with an MAE of 0.290 score levels. The overall linear and quadratic weighted κ values were 0.625 and 0.660, respectively, indicating moderate ordinal agreement with the expert reference scores.

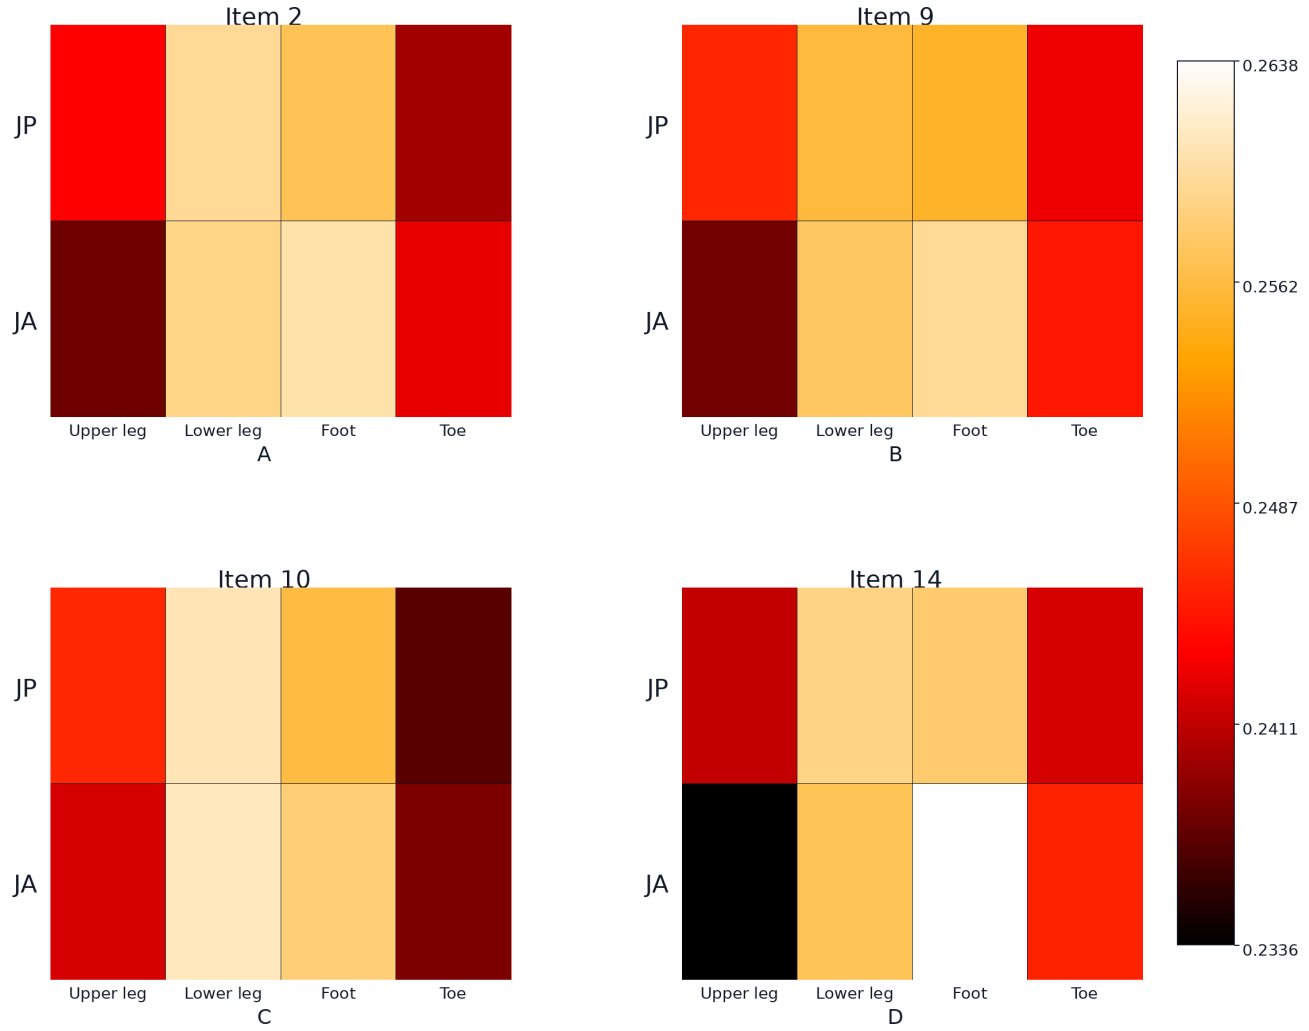
[b]MAE: mean absolute error.



Item-level performance varied across WGS items. Higher agreement was observed for items 9, 10, and 14, whereas items 8 and 13 showed relatively lower weighted agreement. The distribution of expert reference scores for WGS items 2 to 14 is presented in Table S1 of Multimedia Appendix 2. The score distribution was imbalanced, with lower score categories more frequently represented and severe score categories underrepresented. Score 4 was observed only for item 11 and was absent from the remaining items. The 2 experienced physiotherapists demonstrated high interrater reliability, with ICC (2,1) values of 0.981 for the total WGS score and 0.975 for the summed score of WGS items 2 to 14. Item-level ICC (2,1) values ranged from 0.829 to 0.944, as shown in Table S2 of Multimedia Appendix 2.

The training and testing loss curves for representative WGS items are shown in Figure S1 in Multimedia Appendix 2. The training loss generally decreased across epochs, whereas the testing loss remained relatively stable without clear late-stage divergence, providing supporting evidence for stable model convergence.

To provide an exploratory interpretation of the learned attention mechanism, we performed qualitative attention-weighted visualizations and a post hoc feature occlusion analysis. As illustrated in Figure 4, the attention heatmaps show the normalized weights assigned to different lower-limb feature groups across representative WGS items. In each subplot, the rows represent joint-related feature types, and the columns represent lower-limb regions, including the upper leg, lower leg, foot, and toe. Darker pixels indicate lower-attention weights, whereas lighter pixels indicate higher-attention weights. The attention maps show item-specific weighting patterns across lower-limb regions. For example, the model assigned relatively higher weights to foot-related features for item 14, which is consistent with the clinical relevance of foot position during initial contact. These visualizations suggest that the model assigns different levels of priority to lower-limb features across WGS items.

XSL•FO
RenderX

Figure 4. STAT attention heatmaps for selected Wisconsin Gait Scale items. (A-D) Post-Softmax attention heatmaps for WGS Items 2, 9, 10, and 14, respectively. The heatmaps visualize how the model distributes attention across lower-limb joints in the joint-angle (JA) and joint-position (JP) modalities, where warmer colors indicate higher normalized attention weights and suggest the regions that contribute more strongly to the corresponding item prediction.

To further evaluate whether the learned attention weights reflected functionally important input features, an attention-guided occlusion analysis was performed for representative well-performing WGS items. As shown in Table 4 and Figure 5, occluding the highest-attention feature group generally produced larger decreases in true-class probability than occluding the lowest-attention feature group or the remaining feature groups. This pattern was most evident for items 2, 9, and 14. For item 2, top-1 occlusion produced the largest decrease in true-class probability (Δp_true=0.0792), compared with top-2nd (0.0381), bottom-1 (0.0015), and rest-avg (0.0178). Similar patterns were observed for item 9 and item 14. Item 10 showed a less distinct pattern, suggesting that attention faithfulness may vary across WGS items.

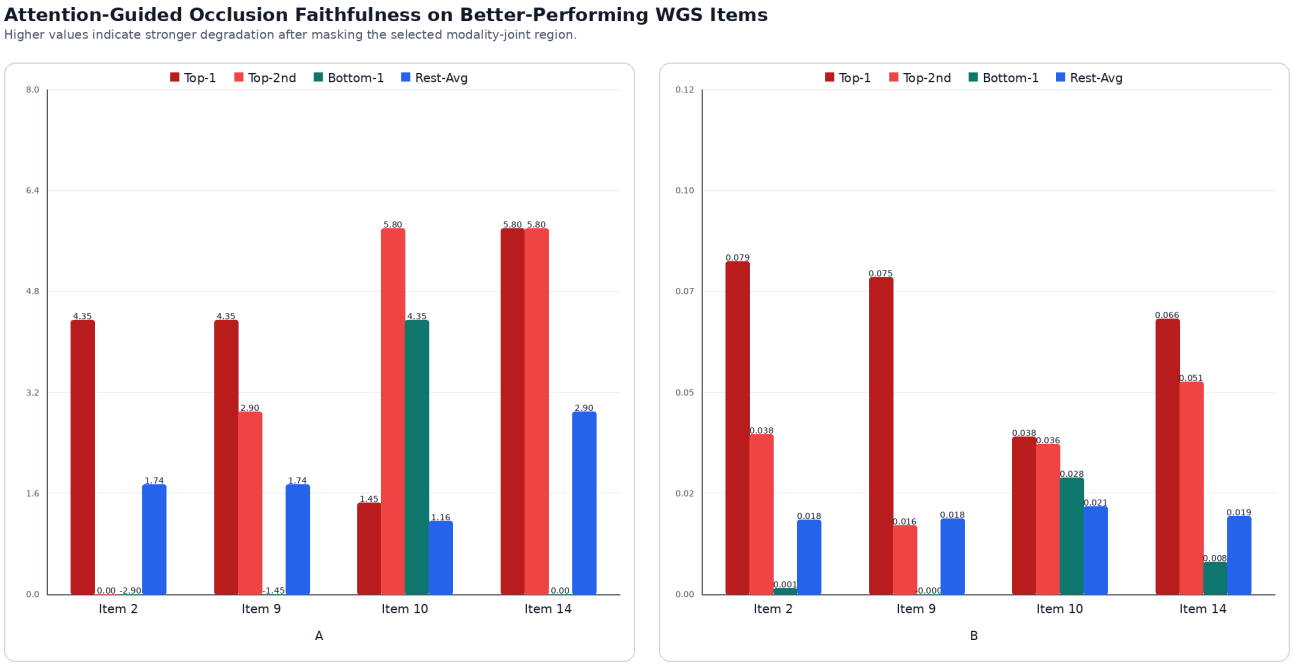


Table . Single-cell attention-guided occlusion faithfulness on selected Wisconsin Gait Scale (WGS) items[a].

Item	Top-1 Δp_true	Top-2nd Δp_true	Bottom-1 Δp_true	Rest-avg Δp_true
Item 2	0.0792	0.0381	0.0015	0.0178
Item 9	0.0754	0.0164	−0.0001	0.0180
Item 10	0.0375	0.0358	0.0277	0.0210
Item 14	0.0655	0.0505	0.0077	0.0186

[a]Δp_true indicates the decrease in the predicted probability of the true class after occlusion. Top-1 and Top-2nd refer to the modality-joint cells with the highest and second-highest-attention weights, respectively. Bottom-1 refers to the cell with the lowest-attention weight. Rest-avg represents the average occlusion effect across the remaining cells. Larger positive values indicate a greater reduction in true-class probability after masking and therefore suggest a greater functional contribution of the corresponding feature group to the model prediction.

Discussion

Principal Findings

In this study, we developed and evaluated STAT-GCN, a deep learning framework for automated WGS item prediction using IMU-derived kinematic data. Using a stratified, participant-level 5-fold cross-validation protocol, all gait cycles from the same participant were kept within the same fold to reduce the risk of intraparticipant information leakage. The findings suggest that kinematic data-driven models may provide preliminary support for more standardized WGS item scoring; however, they should be interpreted cautiously, given the limited sample size and absence of external validation. Previous work on digital WGS assessment has also suggested that technology-assisted approaches may help reduce subjectivity in observational gait evaluation [37].

The comparison with 4 final-year physiotherapy students was interpreted as a descriptive novice-rater comparison. In this dataset, the model showed higher agreement with the expert reference scores than did the novice raters. However, this comparison should be interpreted cautiously, as the students represent a novice-rater benchmark rather than an expert clinical standard. The high interrater reliability between the 2 experienced physiotherapists indicates that expert-level WGS assessment remains more consistent than that of the current automated model. Therefore, the findings should not be interpreted as evidence that STAT-GCN has achieved expert-level clinical performance. Instead, the model may provide preliminary support for more standardized WGS item scoring, particularly when expert raters are unavailable or when repeated assessments are required.

Item-level performance varied across WGS items, suggesting that some gait components were more difficult for the model to predict than others. Relatively low agreement was observed for items 8 and 13, both of which involve rotational components. Item 8 assesses external rotation during the initial swing phase of the affected leg, whereas item 13 assesses pelvic rotation during terminal swing. These transverse-plane movements may be challenging because they are difficult to estimate visually and may also be sensitive to sensor placement and movement variability. In addition, item 11, which assesses knee flexion from toe-off to mid-swing by comparing the affected and unaffected limbs, may require more explicit bilateral and phase-specific information than the current model input provides. Future model development may benefit from incorporating clinically informed features, such as inter-limb ratios, phase-specific joint trajectories, or additional transverse-plane kinematic descriptors.

The distribution of expert reference scores also indicated class imbalance across WGS items. Lower score categories were more frequently represented, whereas severe score categories were underrepresented. This imbalance may have affected both model learning and performance interpretation, because the model had fewer examples from which to learn severe gait deviations. Similar concerns have been reported in other gait-related machine learning studies, where class imbalance and limited representation of severe cases were found to influence model performance and stability, highlighting the importance of balanced datasets and appropriate augmentation strategies [38]. It may also explain why exact accuracy alone could provide an incomplete picture of model performance. For this reason, ordinal metrics such as MAE and weighted κ were included to better account for the magnitude of disagreement between predicted and expert reference scores. Future studies should include larger and more clinically diverse samples and may consider class-balanced training strategies, cost-sensitive learning, or carefully validated data augmentation methods.

The attention-guided occlusion analysis provided partial quantitative support for the faithfulness of the STAT-Attention

XSL•FO
RenderX

module. In several representative WGS items, masking high-attention modality-joint regions produced larger reductions in true-class probability than masking low-attention regions, suggesting that the model relied more heavily on features assigned higher attention weights. However, this pattern was item-dependent and should not be interpreted as complete evidence of clinical explainability. In addition, aggregating attention weights into a 2×4 modality-joint grid may obscure more detailed joint-specific and time-specific information. Therefore, the attention maps should be considered supportive indicators of feature relevance rather than definitive explanations of the model's decision-making process. Future studies should compare this approach with established explainability methods and further examine whether the highlighted features correspond to specific clinically defined WGS gait deviations.

Although automated WGS item prediction may help reduce subjectivity and improve the standardization of repeated gait assessments, the present study did not directly examine whether model-predicted WGS scores improve rehabilitation decision-making, treatment planning, or clinical outcomes. Therefore, the translational value of the proposed framework remains preliminary. Future studies should investigate whether automated item-level WGS predictions can be linked to individualized exercise prescription, longitudinal treatment response, or clinically meaningful functional recovery.

Limitations

This study has several limitations. First, although participant-level cross-validation and training-only data augmentation were used to reduce the risk of overly optimistic performance estimates, the sample size remained limited for deep learning model development, and no external validation dataset was available. The limited sample size and a relatively low representation of participants with severe gait impairment may have affected model stability, particularly for higher WGS score categories, and may limit generalizability to broader populations of individuals with stroke and more diverse gait impairments. Independent validation across different clinical sites, devices, and participant populations is required before clinical implementation. Second, the model relied primarily on kinematic data. Additional modalities, such as plantar pressure, force-plate measurements, or video-based movement features, may improve the prediction of items related to weight shifting, limb comparison, and transverse-plane rotation. However, the use of additional equipment may reduce clinical feasibility, and future work should balance model performance with practical usability.

Conclusions

STAT-GCN demonstrated reasonable preliminary performance for automated WGS item prediction in individuals with stroke using IMU-derived kinematic data. By combining a graph-based representation of lower-limb kinematics with participant-level validation, this study provides initial evidence that data-driven models may support more standardized observational gait assessment. However, further studies using larger and more clinically diverse stroke cohorts, additional data modalities, and independent external validation are needed to determine the clinical utility and generalizability of this approach.

Abstract

Background: Plantar fasciitis causes heel pain and functional limitations; conservative treatment typically includes plantar fascia and calf stretching. High-intensity laser therapy (HILT) offers deeper photobiomodulation and potential tissue-healing benefits, but robust evidence of added clinical benefit remains limited.

Objective: This study aims to evaluate the efficacy of HILT combined with plantar fascia stretching exercises compared with a sham control for the treatment of plantar fasciitis.

Methods: This study was designed as a randomized, double-blind, sham-controlled trial conducted at the outpatient clinic of a university hospital. Participants were randomly allocated into 2 groups: the HILT group and the sham treatment group. Both groups received 9 treatment sessions over 3 weeks. The HILT group received active laser therapy, while the sham group received identical treatment without laser emission. The HILT used a wavelength of 1064 nm in continuous mode, with a power output of 12 W applied for 250 seconds, delivering an energy density of 120 J/cm² applied to a 25-cm² area for a total energy of 3000 J. In addition to the assigned interventions, all participants performed a standardized self-stretching exercise program targeting the plantar fascia and Achilles tendon throughout the study period. The primary outcome was pain intensity measured using a visual analog scale. Secondary outcomes included ultrasonographic measurement of plantar fascia thickness (PFT) and the subjective foot and ankle ability measure (FAAM) score, recorded before and immediately after the intervention.

Results: A total of 34 patients diagnosed with unilateral plantar fasciitis were enrolled in this study. Based on intragroup comparison, both groups demonstrated statistically significant improvements in all outcomes compared with baseline (P<.001). However, no significant differences were found between the 2 groups across all outcomes. The mean difference in pain reduction, measured by the visual analog scale, was –35.3 (95% CI –45.3 to –25.0) mm in the HILT group and –30.4 (95% CI –46.3 to –14.4) mm in the sham group (–5.0 mm, 95% CI –14.3 to 4.3; P=.59). Similarly, reductions in PFT and improvements in FAAM scores showed no significant differences between groups (mean difference –0.02 mm, 95% CI –0.2 to 0.1; P=.90 and 5.6 points, 95% CI –1.1 to 12.4; P=.40, respectively).

Conclusions: There was no additional clinical effectiveness of HILT on pain reduction, decreased PFT, or increased FAAM scores compared with sham laser when combined with standard stretching exercises for plantar fasciitis and the Achilles tendon.

KEYWORDS

plantar fasciitis; high-intensity laser therapy; lasers; pain measurement; ultrasonography; fascia; foot; ankle

Introduction

Plantar fasciitis is a common and often disabling condition characterized by pain at the plantar aspect of the heel, which can substantially limit daily activities [1]. Risk factors include increasing age, elevated body mass index, prolonged standing, and foot posture abnormalities that increase stress on the plantar fascia [2]. First-line management is conservative and heterogeneous, encompassing manual therapy, night splints, taping, orthoses, and exercise programs; among these, stretching of the plantar fascia and associated calf musculature is widely recommended and frequently used in clinical practice [3].

For this study, passive stretching was chosen as the standardized backbone intervention. Mechanistically, stretching directly targets gastrocnemius–soleus tightness and plantar fascia strain, two important contributors to symptom persistence, and has been shown in clinical studies to reduce pain and improve

XSL•FO
RenderX

function in the short to medium term [4]. Practically, passive stretching is easily standardized, low cost, self-administered, well tolerated, and associated with good patient adherence compared with more resource-intensive or operator-dependent modalities (eg, manual therapy or supervised exercise programs). Using a single, well-established conservative treatment as the common background therapy therefore reduces between-participant variability and more clearly isolates any incremental effect of the adjunctive intervention under study.

Adjunctive physical modalities—including extracorporeal shockwave therapy, ultrasound, and low-intensity laser therapy—are commonly used to enhance recovery [5]. Laser therapy delivers photons that may stimulate cellular processes involved in tissue repair, including increased adenosine triphosphate production, enhanced collagen synthesis, and improved microcirculation [6-8]. Systematic reviews indicate that low-intensity laser therapy can reduce pain in plantar fasciitis [5,9-12]. In theory, high-intensity laser therapy (HILT) has greater tissue penetration and may produce stronger collagen stimulation, greater blood flow effects, and more pronounced anti-inflammatory responses than low-intensity devices [13,14]. However, studies comparing HILT with low-intensity laser or sham treatment have reported conflicting results [15,16], and recent meta-analyses have not comprehensively evaluated HILT for plantar fasciitis.

Prior HILT studies have often been limited by methodological weaknesses, inconsistent control treatments, and a scarcity of objective outcomes such as ultrasound-measured plantar fascia thickness (PFT) or functionally relevant measures. To address these gaps, this randomized, sham-controlled trial evaluated the efficacy of HILT added to a standardized passive stretching program compared with sham laser plus the same conservative regimen. We hypothesized that adjunctive HILT would produce greater improvements in pain, functional capacity, and PFT compared with conservative care using sham laser.

Methods

Study Design

This study was a prospective, randomized, double-blinded (participant and assessor), sham-controlled trial conducted in an outpatient rehabilitation setting at Srinagarind Hospital, Khon Kaen University.

Ethical Considerations

The study protocol was approved by the Khon Kaen University Ethics Committee (HE621318). Written informed consent was obtained from all participants prior to enrollment. Participant privacy and confidentiality were strictly maintained. All data were deidentified prior to analysis, and personal identifiers were removed. The dataset was stored securely and was accessible only to authorized members of the research team. Participants received compensation of 900 for their participation. Based on an exchange rate of US $1 to 31, this is approximately US $29 per participant. Compensation was provided regardless of study completion.

The study adhered to the CONSORT (Consolidated Standards of Reporting Trials) guidelines.

Participants

A total of 36 participants diagnosed with unilateral plantar fasciitis were recruited between January 2020 and September 2020.

Inclusion Criteria

Participants were eligible for inclusion if they met all of the following criteria:

- Adults aged 18 years or older
- Foot pain persisting for a minimum of 6 weeks
- Diagnosis of plantar fasciitis confirmed by a rehabilitation medicine physician based on clinical history, characterized by pain primarily felt during the first steps after waking, which worsens with prolonged weight-bearing activities throughout the day [17]
- Tenderness at the medial calcaneal tubercle upon palpation [17]

Exclusion Criteria

Participants were excluded from the study if they met any of the following criteria:

- History of foot surgery
- Chronic inflammatory arthritis (eg, rheumatoid arthritis, gout, systemic lupus erythematosus)
- Conditions affecting sensory perception (eg, diabetes mellitus with peripheral neuropathy)
- History of corticosteroid injection to the plantar fascia within the preceding 6 months
- Neuropathic pain in the foot, or evidence of intrinsic foot muscle weakness
- Pregnancy

Baseline Assessment

At baseline, the following data were collected: age, gender, body mass index, side with the most severe pain, and Foot Posture Index (FPI-6) score.

Randomization and Blinding

Participants were randomly assigned to either the HILT group or the sham laser (control) group using a permuted block randomization method with a block size of 4. The randomization sequence was computer generated and concealed within sequentially numbered, opaque, sealed envelopes. Envelopes were opened by the treating therapist immediately prior to the first treatment session. Participants were blinded to their treatment allocation. The assessor performing outcome measurements was also blinded to treatment allocation.

Intervention

Overview

All participants received 9 treatment sessions administered every 3 days. Both groups received a standardized home exercise program consisting of plantar fascia and Achilles tendon stretching exercises. Participants were instructed to perform the following stretch while seated or supine: with a towel or strap around the forefoot, the knee was extended and the forefoot pulled toward the body, maintaining dorsiflexion for 30 seconds. The exercise was performed for 10 repetitions per session, once

XSL•FO
RenderX

daily. Adherence to the home exercise program was monitored using patient logs.

HILT Group

HILT was administered by a trained medical doctor using the BTL-6000 high-intensity laser device (BTL Industries) operating at a wavelength of 1064 nm. The treatment parameters were as follows: continuous mode, power output of 12 W applied for 250 seconds, energy density of 120 J/cm² delivered over a 25-cm² area, resulting in a total energy of 3000 J [15,16]. The participant was positioned prone with the foot in a neutral position. The laser was applied using a 10-mm pen applicator and swept over the calcaneal insertion and along the medial border of the plantar fascia.

Sham Laser Group

The sham treatment mimicked the HILT procedure, including the visual and auditory cues of the laser device, but without actual laser energy delivery. The same treatment protocol as the HILT group was followed in terms of positioning, applicator movement, and device sounds.

Medication and High Plantar Fascial Loading Activity

Participants were instructed to maintain their usual pain medication regimen, which was limited to 500 mg of paracetamol, and not to exceed 3000 mg per day. They were also advised to strictly refrain from strenuous exercises that involve high plantar fascial loading. Crucially, the use of anti-inflammatory drugs was strictly prohibited during the study per the protocol. The number of pain medication pills taken was recorded throughout the study period.

Outcome Measures

Outcomes were assessed at baseline and immediately postintervention by a blinded assessor. Pain intensity was measured using a 100-mm visual analog scale (VAS). Participants were asked to recall the pain experienced during the first 3 steps taken in the morning. Scores were assessed immediately preintervention and again via telephone 1 day after the final session to capture pain during participants' first steps in the morning following the treatment period.

PFT was measured by ultrasound using a LOGIQ E Premium system (GE Healthcare) with a 5 MHz linear probe at the calcaneal insertion. Participants were positioned prone with feet in a neutral position, and the feet were placed at the end of the examination bed. The ultrasound probe was placed perpendicular to the plantar fascia on the plantar surface, and the thickness of the thickest portion was measured [18]. The reported value is the mean of 3 measurements.

Foot and ankle function was assessed using the activities of daily living subscale of the Thai version of the foot and ankle ability measure (FAAM). The FAAM subjective form evaluates foot and ankle function for daily activities and sports; however, only the activities of daily living subscale was used in this study. The reliability of the FAAM was examined by Arunakul et al [19], who reported strong internal consistency.

Data Analysis

All analyses were conducted using Python (version 3.10), executed in Google Colaboratory. Continuous variables are presented as mean (SD) or as median (IQR) for nonnormally distributed data, while categorical variables are presented as frequency (percentage). Normality of continuous data was assessed using the Shapiro-Wilk test.

The primary analysis followed the intention-to-treat (ITT) principle. Missing outcome data (5%) were addressed using multiple imputation by chained equations with 20 imputations. The imputation model included baseline outcome values, treatment group, and relevant covariates. Each imputed dataset was analyzed separately, and the results were pooled using Rubin's rules.

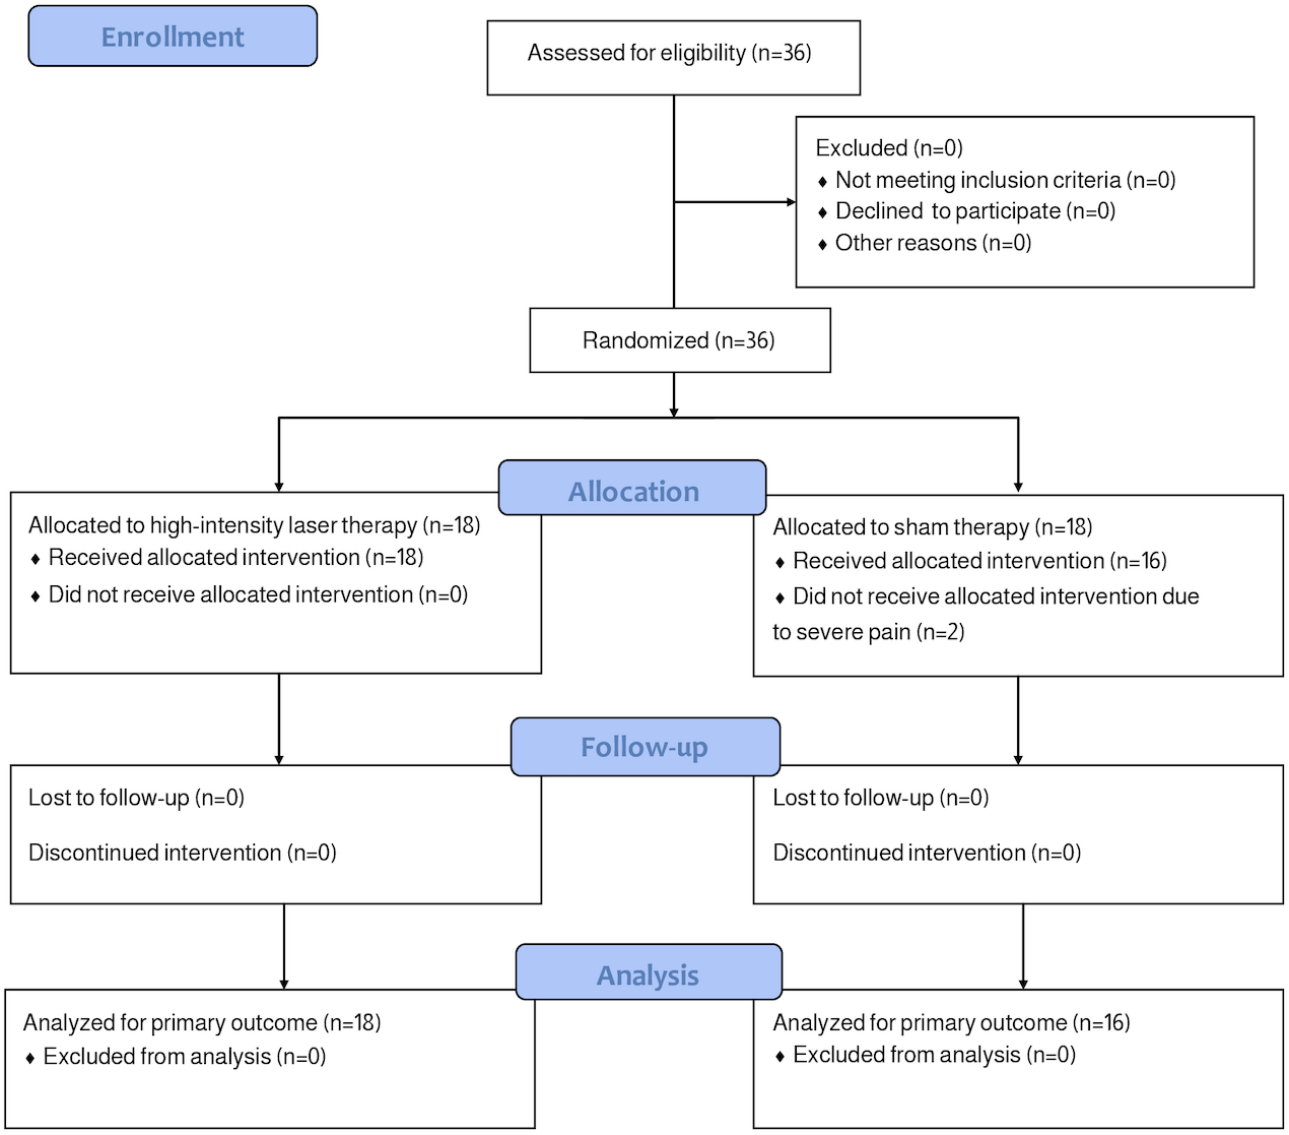
Between-group comparisons of continuous posttreatment outcomes (primary and secondary) were conducted using independent *t* tests when distributional assumptions were met. For nonnormally distributed outcomes, between-group comparisons used the Mann-Whitney *U* test on observed data, with additional sensitivity analyses performed on the imputed datasets. Within-group changes were evaluated using paired *t* tests or the Wilcoxon signed rank test, as appropriate.

A per-protocol analysis including participants who completed at least 7 treatment sessions was conducted as a sensitivity analysis. Effect sizes (Cohen *d*) and 95% CIs were reported for parametric comparisons. All statistical tests were 2-tailed, and a *P* value <.05 was considered statistically significant.

Sample Size Calculation

Based on prior studies [15], a sample size of 16 participants per group was required to detect a mean difference of 15 (SD 15) mm on the VAS, with 80% power and a 2-sided α of .05. To allow for an anticipated 10% dropout rate, 36 participants (18 per group) were recruited.

Withdrawal and Discontinuation Criteria



Participants could withdraw from the study at any time without affecting their care. Discontinuation criteria included withdrawal of consent or adverse effects (eg, burns, eye irritation).

Results

A total of 36 participants were enrolled, with 34 participants completing the study. Two participants withdrew due to severe pain and opted for alternative treatments (Figure 1).

XSL•FO
RenderX

Figure 1. CONSORT (Consolidated Standards of Reporting Trials) diagram outlining the identification, enrollment, and allocation of participants to the 2 groups: high-intensity laser therapy group and sham group.

The HILT group included 18 participants (n=2 men, n=16 women; mean age 46, SD 11.4 years), while the sham laser group included 16 participants (n=1 man, n=15 women; mean age 49, SD 13.0 years). The mean body mass index was 23.3 (SD 2.9) kg/m² in the HILT group and 26.0 (SD 2.8) kg/m² in the sham laser group (*P*=.20). The FPI-6 mean scores were –0.4 (SD 1.1) in the HILT group and –0.6 (SD 1.1) in the sham group, indicating a slightly supinated foot posture [20]. Moreover, no patients in our study had markedly supinated or pronated feet. There was no significant difference in the duration of foot pain, with a mean of 14.7 (SD 4.2) weeks in the HILT group and 14.8 (SD 4.4) weeks in the sham group (Table 1).

XSL•FO
RenderX

Table . Demographic characteristics of the 2 study groups.

Characteristics	High-intensity laser therapy group (n=18)	Sham group (n=16)	*P* value
Age (y), mean (SD)	46 (11.4)	49 (13.0)	.52
Gender, n (%)			.61
Male	2 (11.1)	1 (6.3)	
Female	16 (88.9)	15 (93.7)	
FPI-6[a] (points), mean (SD)	–0.4 (1.1)	–0.6 (1.1)	.51
BMI (kg/m²), mean (SD)	23.3 (2.9)	26.0 (2.8)	.21
Duration of foot pain (wk), mean (SD)	14.7 (4.2)	14.8 (4.4)	>.99

[a]FPI-6: Foot Posture Index.

The ITT analysis (n=36; pooled across 20 imputations) showed the following posttreatment results. For pain (VAS), the mean posttreatment score was 23.0 (SD 17.5) mm in the HILT group versus 26.8 (SD 20.7) mm in the sham group. The between-group mean difference (laser and sham groups) in posttreatment VAS was –5.0 mm (95% CI –14.3 to 4.3; *P*=.59). Cohen *d* for the between-group difference at posttreatment (pooled SD) was small (d≈–0.20).

Mean PFT decreased from 4.8 (SD 1.4) mm to 4.1 (SD 1.2) mm (mean change –0.7 mm, 95% CI –1.0 to −0.5; *P*<.001) in the HILT group. For PFT, the median decreased from 5.3 (IQR 4.5 - 5.4) mm to 4.5 (IQR 3.7 - 4.7) mm (median change –0.7 mm, 95% CI –1.0 to −0.5; *P*<.001) in the sham group. The between-group difference in change was –0.02 mm (95% CI –0.2 to 0.1; *P*=.90). Because values in the sham group were nonnormally distributed, a nonparametric test (Mann-Whitney *U* test) was used for between-group comparisons of this outcome, and Cohen *d* was not reported for this comparison.

For FAAM, the mean posttreatment scores were 82.3 (SD 12.8) in the HILT group and 82.8 (SD 17.7) in the sham group. Within-group improvements were significant in both groups. The mean change was 18.7 (95% CI 10.4 to 27.1; *P*<.001) in the HILT group and 14.5 (95% CI 3.2 to 25.8; *P*=.02) in the sham group. The between-group mean difference in change was 5.6 (95% CI –1.1 to 12.4; *P*=.40). Cohen *d* for the between-group posttreatment comparison was very small (d≈0.03; Table 2).

Table . Comparison of pain intensity measured by the 100-mm VAS, plantar fascial thickness, and FAAM score.

Outcomes	High-intensity laser therapy group (n=18)				Sham group (n=16)				High-intensity laser therapy versus sham	
	Before, mean (SD)	After, mean (SD)	Mean difference (95% CI)	*P* value	Before, mean (SD)	After, mean (SD)	Mean difference (95% CI)	*P* value	Between-group mean difference (95% CI)	*P* value
VAS[a] (mm)	58.3 (19.1)	23.0 (17.5)	–35.3[b] (–45.3 to –25.0)	<.001	57.1 (22.2)	26.8 (20.7)	–30.4[b] (–46.3 to –14.4)	.001	–5.0 (–14.3 to 4.3)[c]	.59
Plantar fascia thickness (mm)	4.8 (1.4)	4.1 (1.2)	–0.7[b] (–1.0 to –0.5)	<.001	5.3 (4.5 to 5.4)[d]	4.5 (3.7 to 4.7)[d]	–0.7[e] (–1.0 to –0.5)	<.001	–0.02 (–0.2 to 0.1)[c]	.90
FAAM[f] (point)	63.6 (13.6)	82.3 (12.8)	18.7[b] (10.4 to 27.1)	<.001	68.3 (23.8)	82.8 (17.7)	14.5[b] (3.2 to 25.8)	.02	5.62 (–1.1 to 12.4)[c]	.40

[a]VAS: visual analog scale.

[b]Paired *t* test was used.

[c]Independent *t* test was used.

[d]Median (IQR).

[e]Wilcoxon signed rank test was used.

[f]FAAM: foot and ankle ability measure.

The per-protocol analysis (n=34 completers) produced results consistent with the ITT analysis; between-group differences in change scores remained small and nonsignificant for VAS, PFT, and FAAM, supporting the robustness of the findings. Among participants with plantar fasciitis who had a history of strenuous weight-bearing exercise, 1 participant (a runner) in the HILT

XSL•FO
RenderX

group was advised to refrain from such activity during the treatment period. Furthermore, 2 participants (1 from each group) reported taking paracetamol at a dosage of 2000 mg per day for 2 days. No adverse events (eg, increased pain, skin burns) were reported in the HILT group. Two participants in the sham group withdrew owing to pain intolerance. Adherence to the exercise protocol did not differ significantly between groups: there were a mean 15.1 (SD 3.8) sessions in the HILT group versus 17.5 (SD 3.7) in the sham group (P=.06).

Discussion

This randomized controlled trial assessed the effectiveness of HILT combined with conventional therapy (stretching exercises) compared with sham laser plus conventional therapy in patients with plantar fasciitis. A key strength of our methodology, which distinguishes it from many prior trials, was the inclusion of objective structural outcomes (ultrasound) and validated quality-of-life assessment (FAAM), coupled with a rigorous sham control. Both treatment arms showed significant improvements in pain scores, a reduction in PFT, and an increase in foot and ankle function following treatment. However, HILT did not demonstrate superiority over the sham intervention.

This primary finding—that HILT offered no clear added benefit—aligns with several previous investigations. For instance, Tkocz et al [21], studying chronic heel pain (including plantar fasciitis and calcaneal spurs) using a HILT device at a lower power (7 W) and high total energy, similarly found no clear advantage of HILT over sham combined with ultrasound. Furthermore, Naruseviciute and Kubilius [16] also reported no superiority of HILT versus low-intensity laser therapy regarding either pain or fascial thickness. Conversely, Akkurt et al [22] observed improved outcomes when HILT was combined with insoles; however, the absence of a true sham laser control in that study makes it impossible to definitively exclude a significant placebo contribution.

The reasons for this consistent lack of incremental benefit are likely multifactorial. High-intensity laser protocols vary widely across trials concerning power, energy per session, mode, number of sessions, and application technique [15,16,21,22]. This substantial heterogeneity may partly explain discrepant results in the literature, as these parameters dictate whether the tissue effects are primarily photobiomodulatory or thermal. Nevertheless, the majority of trials to date do not show a consistent, clinically meaningful incremental effect of HILT over standard conservative care. Future research must prioritize robust dose-finding studies, provide complete dosimetry and application details, and include mechanistic measures to determine whether any specific parameter set reliably improves outcomes in plantar fasciitis before routine adoption.

Beyond methodological variations, anatomical considerations may temper the potential benefit of HILT. The plantar fascia lies only a few millimeters below the skin, varying by location and individual subcutaneous thickness. Consequently, the deeper penetration advantage often ascribed to HILT may be less relevant for plantar fasciitis compared with deeper targets (eg, knee osteoarthritis), where reaching intra-articular structures is more pertinent [23]. This superficial anatomical location of the target may inherently limit the potential incremental benefit of HILT in this disease.

Given that all 3 primary outcomes improved significantly in both study arms, it strongly suggests that the standardized stretching program was the major driver of clinical benefit. Plantar fascia and calf stretching target the gastrocnemius–soleus complex and the fascia because tightness increases tensile strain on the arch [4]. Mechanistically, regular stretching likely contributed to the reduction in pain and functional gains by increasing ankle dorsiflexion, lowering passive tension transmitted to the fascial insertion, and improving tissue viscoelasticity.

The consistent improvements observed in our objective and patient-centric measures validate the effectiveness of this conservative approach. The reduction in PFT, quantified objectively via ultrasound, confirms that the therapy successfully induced a positive structural change in the affected tissue, moving beyond mere symptomatic relief. PFT is considered the anatomical hallmark of chronic plantar fasciitis (reflecting chronic microtearing and disorganized collagen repair) [18]. Similarly, the significant increase in scores on the FAAM further substantiates the clinical relevance of the treatment. Since the FAAM is a validated patient-reported outcome measure focusing specifically on function and participation in daily living and sports activities [19], the documented improvements indicate that the structural and pain changes successfully translated directly into better functional capacity for participants.

An alternative explanation for the null between-group difference lies in statistics. The study was powered to detect a 15-mm VAS difference, yet the observed between-group difference was statistically small (only –5.0 mm). This small effect size combined with substantial variability reduced the power to find a statistically significant difference. Additionally, because many participants improved substantially with stretching (and some used short courses of acetaminophen), a ceiling effect is possible, leaving little room for additional measurable improvement attributable solely to HILT. Reporting responder rates, change-score distributions, and conducting larger trials or trials enrolling participants with higher baseline pain would help determine whether a clinically meaningful subgroup benefit exists.

Most participants in our sample had near-normal alignment with slight supination, and baseline alignment was balanced between the 2 groups, so imbalance in foot posture is unlikely to account for the null between-group findings. Nonetheless, because plantar fascia loading differs across foot types and many patients with plantar fasciopathy present with pes planus or overpronation [2], the sample's alignment profile may limit external validity. Future trials should objectively quantify foot posture (eg, FPI-6, navicular drop, calcaneal eversion, or dynamic pressure measures), consider stratified randomization or prespecified subgroup analyses by alignment, and, where appropriate, tailor background conservative care to alignment to test whether foot posture modifies the effect of adjunctive treatments such as HILT.

In terms of safety and adherence, a small number of participants used brief acetaminophen therapy, and 1 HILT participant was

XSL•FO
RenderX

advised to avoid strenuous running during treatment. This activity modification is an independent potential confounder. Importantly, however, no adverse events were reported among HILT recipients, supporting short-term tolerability in our sample. Although 2 participants in the sham group withdrew because of pain intolerance, both ITT and per-protocol sensitivity analyses produced similar results, supporting the robustness of our conclusions.

Finally, this study assessed outcomes only immediately postintervention, meaning the durability of effects remains unknown. Furthermore, the lack of standardized HILT protocols for plantar fasciitis complicates cross-trial comparison. Future research must prioritize longer follow-up, dose-finding studies, standardized reporting of dosimetry, and adequately powered trials (including stratified or targeted enrollment) to identify the specific patient subgroups most likely to benefit from HILT.

This study provides high-quality evidence that HILT does not offer additional benefits over standard stretching exercises in the treatment of plantar fasciitis. Given the statistically similar outcomes between the HILT and sham laser groups, our findings reinforce the effectiveness of conservative treatment approaches as the primary management strategy for plantar fasciitis.

Abstract

Background: Cervical sensorimotor control (SMC) is often disrupted in individuals with chronic neck pain, contributing to persistent symptoms and functional limitations. Traditional cervical SMC assessments are limited by complex setups, single-domain testing, and examiner dependency. Virtual reality (VR) technology offers a promising platform for multidimensional, standardized, and user-friendly assessment.

Objective: This study aimed to develop and evaluate the validity and reliability of a VR-based system for assessing cervical SMC in healthy adults.

Methods: A cross-sectional observational study was conducted in 30 healthy adults (aged 18-60 years). The custom-developed VR system (HP Reverb G2 Omnicept Edition, Unity engine) incorporated 5 SMC tests: cervical range of motion (ROM), joint position error (JPE), head-tilt response, figure of eight (FOE), and postural sway (PS). Test-retest reliability was assessed across 2 sessions, separated by 1 week, using intraclass correlation coefficients (ICCs). Concurrent validity was examined by comparing VR-based measures with gold standard optical motion capture or established clinical tools using Pearson correlation coefficients.

Results: The VR system demonstrated good to excellent test-retest reliability across most outcome measures. The ICC for cervical ROM ranged from 0.851 to 0.968 across movement directions. The ICC for JPE in each direction ranged from 0.813 to 0.827. The ICC for the FOE test's deviation frequency and task duration were 0.810 and 0.913, respectively. The ICC for the head-tilt response was 0.742 and ranged from 0.720 to 0.843 for PS under both visual conditions. The VR-based assessments for ROM, JPE, FOE, and PS showed strong correlations with reference measures (r=0.723-0.980), supporting concurrent validity.

Conclusions: This VR-based assessment system provides a valid, reliable, and user-friendly multidimensional evaluation of cervical SMC. It offers a standardized, integrated, and clinically feasible alternative to conventional assessments, with potential applications in both clinical diagnostics and rehabilitation monitoring.

Introduction

Neck pain is a common global health concern, with epidemiological studies suggesting that approximately 30% to 50% of adults experience it at least once in their lifetime [1,2]. Although many acute episodes resolve spontaneously, a considerable proportion of individuals develop chronic neck pain (CNP), typically defined as pain persisting for more than 3 months [3]. Recent estimates suggest that more than 200 million people worldwide are affected by CNP, making it one of the leading causes of musculoskeletal disability globally. The prevalence of CNP is expected to rise sharply in the coming decades due to population aging and sedentary lifestyles [2,4]. Beyond physical discomfort, CNP is associated with psychological distress, decreased work productivity, and substantial long-term health care expenditures [5,6]. Moreover, evidence suggests that individuals with CNP frequently exhibit various sensorimotor control (SMC) impairments, including impaired proprioception, delayed neuromuscular responses, reduced joint mobility, altered eye-head coordination, and increased movement variability and postural sway (PS), which may complicate rehabilitation efforts and contribute to the persistence of symptoms [7-11].

Accurate assessment of cervical SMC is important for identifying underlying deficits associated with CNP and tailoring rehabilitation strategies. Previously, assessment methods targeting distinct functional components of cervical SMC were established and used in both clinical and research settings [7,12,13]. However, they often require multiple instruments, experienced examiners, and controlled environments. For example, cervical range of motion (ROM) assessments vary in complexity, from the use of basic tools such as goniometers and inclinometers to more advanced systems including optical motion capture and inertial measurement units (IMUs) [14]. The joint position error (JPE) test for cervical proprioception typically requires a head-mounted laser pointer and a target board to quantify repositioning error [9,10,15]. PS, which reflects whole-body balance control, is usually measured using force platforms or stabilometric systems [16]. Their fragmented nature and susceptibility to human error limit their clinical scalability. Therefore, there is an increasing need for more accessible, integrated, and standardized approaches to comprehensively assess cervical SMC across its multiple dimensions.

Virtual reality (VR) technology enables immersive, interactive, and quantifiable testing environments that integrate multiple SMC domains [17-20]. Head-mounted VR systems with embedded motion sensors enable real-time tracking of head kinematics, providing standardized and automated feedback [18,21]. Recent research has increasingly explored the potential of VR as a tool for assessing cervical SMC in individuals with CNP, although the studies are still limited. Few studies have validated VR-based measures of cervical motion and proprioception, showing strong agreement with gold-standard systems [10,22-24]. The VR-based assessment of the subjective visual vertical or head-tilt response (HTR) has also been shown to be reliable for screening otolithic dysfunctions and measuring perceptual orientation [25-27]. These findings suggest that VR may offer a compelling, multidimensional platform for the precise and engaging assessment of SMC in both clinical and research settings. However, current studies still focus on a single domain of SMC and lack integrated evaluation across multiple sensorimotor components. To address this gap, this study developed a multidimensional immersive VR-based cervical SMC assessment system that integrates mobility, proprioception, coordination, verticality perception, and postural stability within a single protocol. The study aimed to (1) evaluate the test-retest reliability of the VR system and (2) examine its concurrent validity compared with established reference methods. We hypothesized that the VR-based assessments would demonstrate good to excellent reliability (intraclass correlation coefficient [ICC] ≥0.75) and strong correlations (r≥0.70) with gold-standard measures.

Methods

Study Design

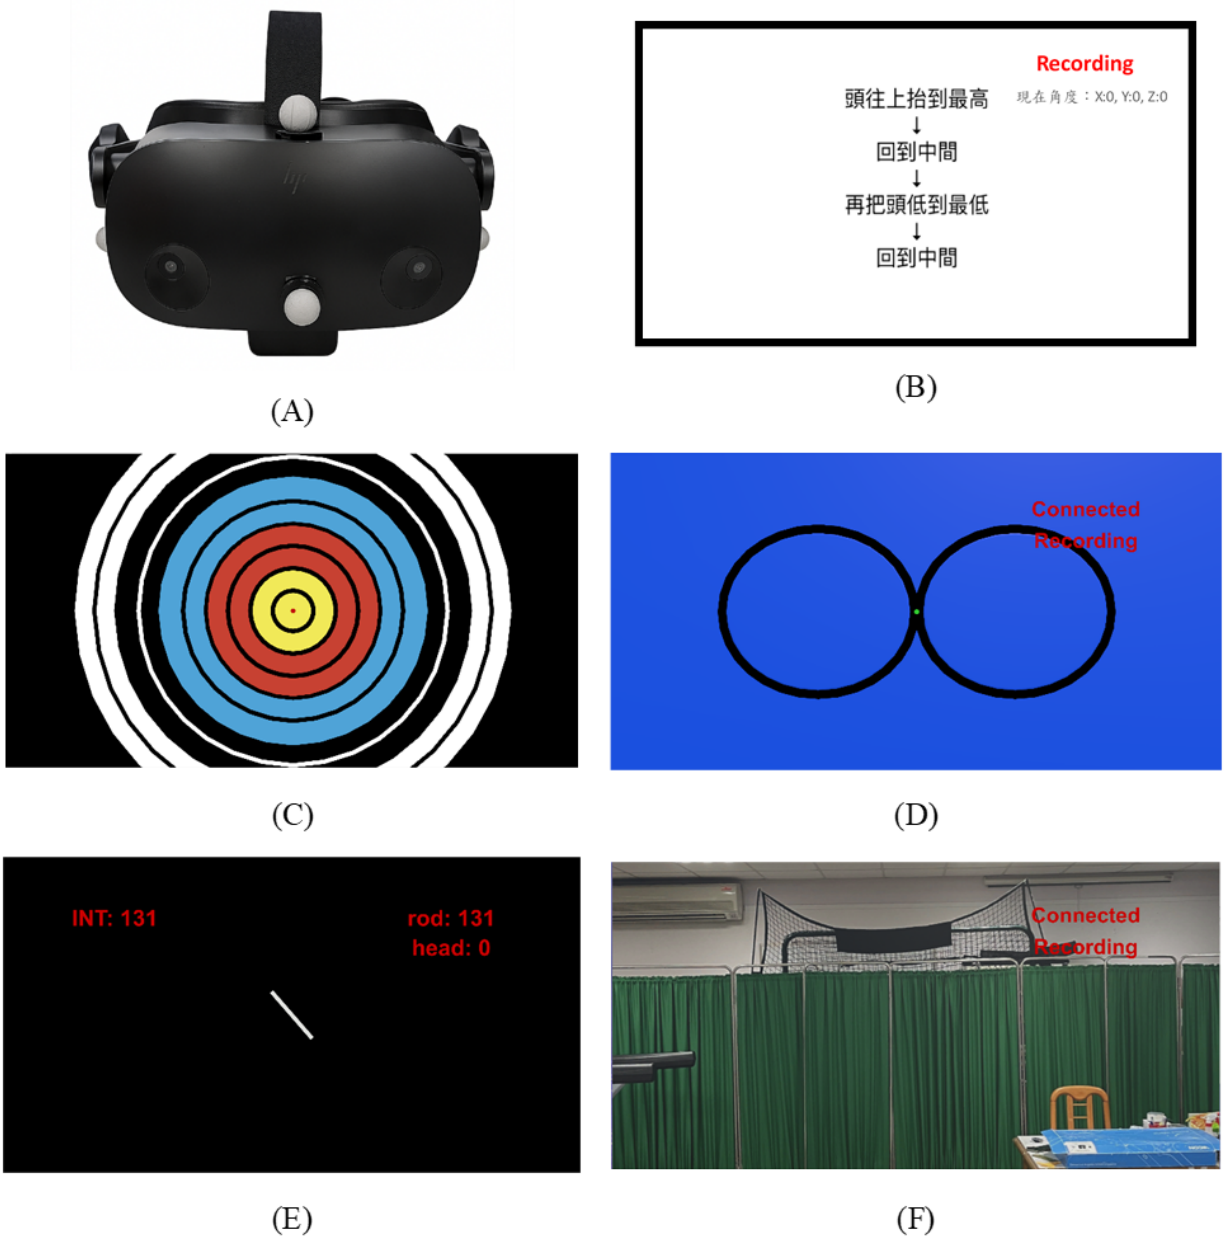
This cross-sectional observational study was conducted from October 2024 to May 2025 in a university laboratory.

Participants

A total of 30 healthy adults (15 male and 15 female; mean age 20.43, SD 1.01 years; mean height 166.08, SD 8.57 cm; mean weight 59.38, SD 12.49 kg) participated in the study. Exclusion criteria included (1) current spinal pain and spinal deformities, (2) history of spinal fracture or surgery, (3) neurological or musculoskeletal conditions that may affect performance, (4) diseases causing balance dysfunction such as central or peripheral nervous system disorders, or vestibular system dysfunction, (5) metabolic diseases, (6) psychological conditions that may affect questionnaire responses, and (7) visual impairments requiring correction, if participants were unable to wear contact lenses during VR testing.

Power analysis (α=.05; power=0.90) indicated that a minimum of 24 samples was required for reliability (expected ICC=0.75) and 14 for validity (expected r=0.70), ensuring adequate power for all analyses [28,29]. The sample size was estimated using G*power software (version 3.1.9.6; Heinrich Heine University Düsseldorf).

Instrumentation



VR-Based System

A custom VR-based cervical SMC assessment system was developed using the HP Reverb G2 Omnicept Edition headset (HP Inc; Figure 1A), integrated with a custom-built virtual environment created using Unity 3D (Unity Technologies). The VR headset is equipped with embedded IMUs (gyroscope, accelerometer, and magnetometer) operating at a sampling rate of 512 Hz, capturing 3D inertial signals to enable precise tracking of head kinematics. The system incorporated 5 virtual test modules simulating standardized SMC assessments: (1) ROM tests to determine maximal active motion range, (2) JPE test to quantify cervical proprioceptive accuracy, (3) figure of eight (FOE) test to assess visual-head dynamic coordination, (4) HTR to assess verticality perception, and (5) PS to assess postural stability in standing postures. All modules provided

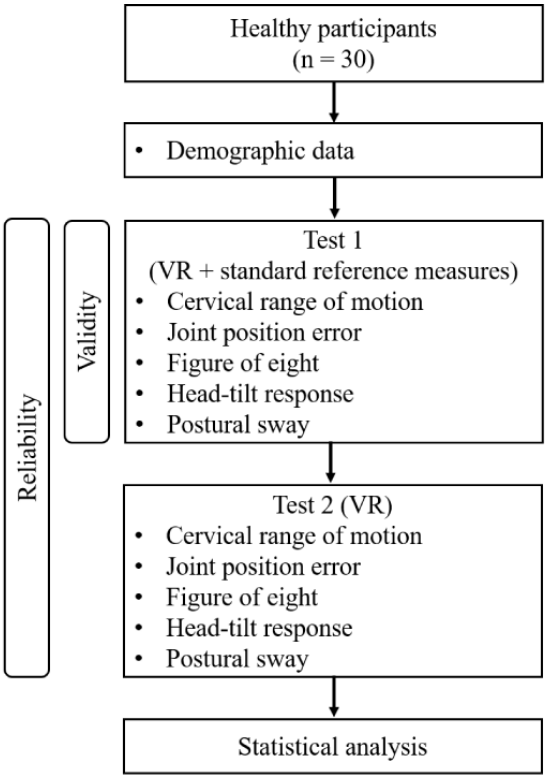
XSL•FO
RenderX

real-time visual feedback and standardized instructions. All visual targets and feedback across modules were presented as virtual images within the VR environment at a fixed virtual distance. No real-world targets or pass-through vision were used.

Figure 1. Virtual reality system used for cervical sensorimotor control assessment. (A) HP Reverb G2 Omnicept Edition head-mounted display and the reflective markers attached for the validity study. (B) Virtual environment designed for cervical range of motion assessment. (C) Virtual environment designed for joint position error assessment. (D) Virtual environment designed for figure-of-eight assessment. (E) Virtual environment designed for head-tilt response. (F) Virtual environment designed for postural sway assessment.

Reference Systems

To evaluate concurrent validity, the VR-derived outcomes were compared with those obtained from a motion analysis system or a clinical observation test. An optical motion capture system, including 10 cameras (VICON T10, Vicon Motion Systems Ltd) with a 100 Hz sampling rate, was used as the gold standard for ROM, JPE, and PS measures. A total of 4 reflective markers with 14 mm spheres were attached onto the front, top, left, and right sides of the VR headset to define a local coordinate system of the head (Figure 1A). Trajectory data were first digitized using the Nexus 2.10 software (Vicon Motion Systems Ltd) and subsequently processed using a custom MATLAB script (R2023a, MathWorks Inc).



Experimental Procedures

Participants completed 2 identical VR assessment sessions, separated by 1 week, to assess test-retest reliability. To examine validity, VR and reference measures were collected concurrently within the same first session (Figure 2). All participants wore the VR headset in a comfortable and stable position throughout the assessment. For most tests, they were seated in a

XSL•FO
RenderX

back-supported chair with their feet flat on the ground and their hips/knees at approximately 90 degrees. The only exception was the PS assessment, which was performed in a quiet standing position with feet together. During all seated tasks, participants were instructed to maintain their trunk in contact with the back support and to avoid any trunk or shoulder movement during all head motion tasks. The examiner visually monitored participant performance throughout testing, and trials were repeated if obvious compensatory trunk or upper body movements were observed.

Figure 2. Study design and overall experimental procedures. VR: virtual reality.

To ensure consistency in orientation-based measurements, a neutral head position was established through a standardized calibration procedure. Participants were instructed to adopt a comfortable, upright head posture while looking straight ahead at a fixed visual reference in the virtual environment. Head orientation data were recorded over a brief 1-second static period, and the average orientation during this period was defined as the neutral reference. This calibration procedure was repeated before each trial to minimize the influence of sensor drift or initial positioning offsets. The same standardized instructions and procedures were applied across sessions to ensure consistency between test and retest measurements.

Participants completed a standardized familiarization phase prior to formal data collection. Each participant performed one practice trial for each task. Only for the HTR task, 2 practice trials were provided due to its greater complexity and to ensure adequate understanding. No performance feedback was provided beyond standardized instructions. A 1-minute rest period was provided between tests to minimize fatigue. The same testing procedures and environmental conditions were maintained across sessions to ensure consistency. All assessments were administered by a single trained examiner who provided standardized instructions using a predefined script. The same examiner conducted both test sessions for each participant to ensure consistency across sessions. Given the automated nature of the VR system, examiner involvement was limited to task instruction and safety supervision, with no manual data recording or subjective scoring involved. The examiner was blinded to the results of the previous session.

Five Cervical SMC Assessments

ROM Assessment

Cervical ROM tests were assessed to evaluate movement capacity in 6 directions: flexion, extension, lateral bending, and rotation to both the left and right sides [30]. Participants followed visual cues in the VR headset to move their head to the maximal range in each direction and then return to neutral (Figure 1B). Each movement was performed 3 times, with rest between directions to prevent fatigue.

For VR data analysis, head orientation was continuously tracked using the headset tracking system and expressed as an Euler angle sequence relative to the calibrated neutral position. Orientation data were derived from quaternion-based signals integrated from inertial and positional tracking and converted within Unity (transform.eulerAngles). Data were then exported and processed offline using MATLAB (MathWorks), where angular discontinuities were corrected, and values were expressed relative to the initial position. No additional filtering was applied. Peak angular displacement was identified for each trial, and the mean of the 3 trials was used as the final ROM value [31,32].

For concurrent validation, cervical ROM was simultaneously captured using the Vicon optical motion system. Euler angles

XSL•FO
RenderX

were computed from the head orientation relative to the global coordinate system, and peak angular displacements in each direction were identified using the same criteria as those applied to the VR-based data.

JPE Assessment

The JPE test evaluated cervicocephalic proprioception by measuring head repositioning accuracy in the absence of visual feedback [33,34]. In the VR headset, a virtual target (50 cm in diameter with concentric rings at 5 cm intervals) was displayed 1 meter in front of the participant (Figure 1C). Participants were instructed to align a red dot representing the head orientation with the target center, memorize the starting position, close their eyes, rotate their head in 1 of 4 directions (flexion, extension, right rotation, or left rotation), and attempt to return to the starting point. Three trials were completed per direction, and mean values were used for analysis [12,14].

For VR data analysis, head orientation data were continuously tracked by the embedded IMUs. The orientation data were transformed into a forward unit vector to derive 2-dimensional coordinates of the red dot. No additional filtering was applied. The difference between the starting and repositioned coordinates was converted into an angular deviation, representing repositioning error.

For concurrent validation, head orientation during the JPE test was simultaneously recorded by the Vicon motion capture system. JPE values were calculated as the angular difference between the head's initial orientation and return orientation, following the same computational criteria used for the VR data.

FOE Assessment

The FOE test assessed sensorimotor coordination, as well as the smoothness and accuracy of head-controlled tracking [35,36]. In the VR environment, a horizontal FOE path (2 cm wide) appeared 1 meter in front of the participant, with a red dot pointed to the center of the visual field serving as the controllable cursor (Figure 1D). Participants traced the figure continuously using head movements at a self-selected comfortable speed. Each participant performed 3 trials, and mean values were used for analysis.

For VR data analysis, the system recorded the cursor trajectory in a 2-dimensional X-Y plane. Two primary metrics were derived, including the completion duration and the number of deviations. Completion duration was the total time required to complete one full tracing path. The number of deviations was the total number of instances when the red dot moved outside the designated path for at least 1 consecutive frame. Continuous frames outside the boundary were counted as a single deviation until the red dot reentered the path.

For clinical validation, participants performed an equivalent head-controlled tracing task using a laser pointer mounted on the top of the head to trace a physical FOE pattern (2 cm wide, size 85 × 38 cm) displayed on a vertical board positioned 1 meter in front, replicating the VR environment conditions. Outcome measures, including completion duration and number of deviations, were manually recorded by an assessor using a stopwatch and visual inspection of the recorded videos.

HTR Assessment

The HTR test evaluated verticality perception and cervical proprioceptive control, reflecting visual dependency in spatial alignment. In the VR environment, a 15 cm white rod was displayed against a black background and randomly tilted between 45° and 135°, in 1° increments (Figure 1E). Participants were instructed to laterally tilt their heads to align the rod to the perceived vertical, after which the system automatically recorded the final orientation. A total of 20 trials were performed, and the mean angular deviation across trials was calculated as the outcome measure.

For VR data analysis, head orientation was continuously tracked via embedded IMUs. The system calculated the angular deviation between the participant-adjusted rod and the true vertical reference to quantify perceived alignment error. Mean absolute deviation across all trials represented the final HTR score.

The HTR test was excluded from the validity analysis since it primarily measures perceptual-cognitive processing rather than biomechanical movement. It reflects verticality perception and multisensory integration based on internal psychophysical judgments, and has previously demonstrated acceptable reliability and validity in computerized or virtual platforms [25,26].

PS Assessment

The PS test assessed whole-body balance control and postural stability under eyes-open and eyes-closed conditions [16,27,37]. Participants stood upright with their feet together and arms at their sides for 20 seconds while viewing a static virtual scene that replicated their natural environment (Figure 1F). Three trials were performed per condition, and mean values were used for analysis.

For VR data analysis, head motion was continuously recorded by the IMUs of the headset, which measured linear acceleration in the anteroposterior and mediolateral directions as an indirect measure of PS [38,39]. Acceleration data were processed using standard signal processing procedures, including unit conversion, low-pass filtering (6 Hz), and smoothing to reduce high-frequency noise. Sway trajectories were reconstructed using signal vector magnitude and direction cosine transformations [39]. Based on an estimated head height [40], linear displacements in the anteroposterior and mediolateral directions were derived. Four sway parameters were obtained to quantify balance performance, including maximum anteroposterior and mediolateral displacements, total path length (TPL), and sway area (SA) [40-42].

For concurrent validation, Vicon motion capture data were used to estimate head center position from the midpoint between reflective markers, serving as a proxy for the body's center of mass. The X and Y coordinates of this midpoint represented mediolateral and anteroposterior displacements, respectively. The same sway parameters, including maximum anteroposterior and mediolateral displacement, TPL, and SA, were computed to enable cross-system comparison of postural stability performance.

Statistical Analysis

Test-retest reliability of the VR-based system was examined using the ICC with the 2-way random-effects model ($ICC_{2,1}$). Reliability was interpreted as poor (<0.50), moderate (0.50-0.75), good (0.75-0.90), and excellent (≥0.90) [43]. The standard error of measurement (SEM) was calculated to estimate score precision, and the minimal detectable change (MDC) was derived to identify the smallest change exceeding measurement error. Agreement between sessions was further evaluated using Bland-Altman plots, illustrating the mean difference and 95% limits of agreement (mean ± 1.96 × SD) [44]. Concurrent validity was assessed using Pearson correlation coefficients (*r*) between VR-based outcomes and corresponding measures from clinical tests or the Vicon motion capture system. Correlation strength was interpreted as poor (<0.30), fair (0.30-0.49), moderate (0.50-0.69), strong (0.70-0.89), or excellent (≥0.90) [45]. All statistical analyses were performed using IBM SPSS Statistics 25 (IBM Corp). In line with recommendations for measurement studies, ICC and Pearson correlation coefficients were interpreted as measures of effect size, and emphasis was placed on the magnitude and precision of estimates (eg, 95% CI, SEM, and MDC) rather than statistical significance testing.

Ethical Considerations

The study was prospectively registered on ClinicalTrials.gov (NCT06474130). Ethics approval has been received from the institutional review board of the National Cheng Kung University Hospital (B-ER-113-126). Written informed consents were obtained from all participants before the experiment. Participant data were handled with strict confidentiality. All identifiable information was removed prior to analysis, and the data were stored securely with access limited to members of the research team. No financial compensation was provided to participants for their involvement in this study.

Results

Test-Retest Reliability

The VR-based assessment system demonstrated good to excellent test-retest reliability across most measures (Table 1). Cervical ROM showed good to excellent reliability for all 6 directions (ICC=0.851-0.967), with low SEMs and narrow CIs, indicating stable and precise measurements. The results of JPE showed good reliability (ICC=0.813-0.827) and small MDC values (around 1.11°-1.27°), confirming the system's ability to detect meaningful changes in repositioning accuracy. The results of FOE demonstrated good to excellent reliability, with ICCs of 0.81 for deviation frequency and 0.91 for completion duration, reflecting consistent performance across sessions. The HTR demonstrated reliability approaching the good range, with an ICC of 0.742. For PS, reliability varied by visual condition. Under eyes-open conditions, the ICC values ranged from 0.720 to 0.772, while eyes-closed conditions produced higher consistency (ICC=0.759-0.843). Overall, the VR-based system provided stable, repeatable measurements across all tests, particularly for dynamic and proprioceptive tasks.

[f]AP: anteroposterior direction displacement.

[g]ML: mediolateral direction displacement.

[h]TPL: total path length.

[i]SA: sway area.

Bland-Altman plots were generated for each sensorimotor domain to visualize agreement between sessions. The plots revealed acceptable limits of agreement across all tests, further confirming the consistency of the VR-based assessments (Multimedia Appendix 1).

Concurrent Validity

Table 2 summarizes the concurrent validity results comparing VR-based cervical SMC assessments with reference measures from the motion analysis system or established clinical tests. Overall, VR outcomes showed strong to excellent correlations with their gold-standard counterparts, confirming concurrent validity across the domains for ROM, JPE, FOE, and PS. For cervical ROM, excellent correlations were observed between VR and Vicon data across 6 movement directions (r=0.892-0.980), indicating highly comparable ROM outputs. The results of JPE demonstrated strong to excellent correlations with Vicon-based angular deviations (r=0.869-0.953),

XSL•FO
RenderX

confirming accurate detection of proprioceptive errors. The FOE test demonstrated an excellent correlation for deviation frequency (r=0.923) and a strong correlation for task completion duration (r=0.723) compared with corresponding clinical reference measures, supporting its validity in assessing dynamic head coordination. For PS, VR-derived sway metrics showed strong correlations with Vicon-based measures under both visual conditions, with the highest agreement observed for TPL (r=0.895-0.917) and SA (r=0.908-0.962). These findings collectively demonstrate that the VR-based system provides accurate and valid measures of cervical motion, proprioception, coordination, and postural stability.

Discussion

Principal Findings

This study demonstrated that a custom-developed VR-based system provided reliable assessments of cervical SMC across all domains (ROM, JPE, FOE, HTR, and PS) and valid measurements for ROM, JPE, FOE, HTR, and PS. The shows that this VR-based system exhibited good to excellent test-retest reliability. The consistency of repeated measurements was further supported by Bland-Altman plot analyses. Concurrent validity revealed strong correlations with gold-standard measures for ROM, JPE, FOE, and PS, confirming the measurement accuracy of this system in assessing cervical SMC.

XSL•FO
RenderX

These results are consistent with previous studies supporting the reliability and validity of VR-based approaches for assessing cervical ROM and proprioception [24,46-50]. Prior work has demonstrated strong agreement between VR-derived and optical or goniometric measurements, as well as good to excellent reliability using IMU-based or VR-based systems [24,46-52]. A recent systematic review also confirmed that VR-based ROM assessments effectively differentiate between individuals with and without CNP [24,46,49]. In this study, the neutral head position was standardized using a calibration procedure; however, slight variations in self-selected posture may still influence absolute ROM values. Repeated calibration before each trial and consistent procedures across sessions likely minimized systematic bias and contributed to the high test-retest reliability observed.

Compared with previous VR-based cervical assessment systems, this study offers several methodological and conceptual advancements. Most previous studies have focused on single-domain assessments [53], whereas the current system integrates multiple domains of cervical SMC, including mobility, proprioception, coordination, verticality perception, and postural stability, within a single immersive platform. In addition, several tasks were specifically designed for VR-based interaction and automated data capture, enabling continuous kinematic tracking without reliance on manual scoring. Furthermore, this study systematically evaluated both test-retest reliability and concurrent validity across all domains within the same cohort, providing a more comprehensive validation framework.

This study also presents an immersive VR adaptation of the FOE head-tracing task, enabling quantitative assessment of coordination through metrics, such as completion time and deviation frequency. Compared with traditional head-mounted laser-pointer methods [36,47], the VR implementation allows standardized visual presentation, continuous trajectory tracking, and automated outcome computation, thereby reducing examiner dependency and improving measurement precision. Furthermore, the VR-based format allows controlled manipulation of visual feedback and task complexity, offering new opportunities to quantify SMC across varying sensory conditions. Similarly, the HTR task demonstrated acceptable reliability, consistent with previous studies on VR-based assessments of verticality perception [7,14,25,54-56].

The VR-based PS assessment exhibited good reliability and strong correlations with reference measures under both visual conditions, consistent with previous findings [57,58]. Previous studies have also reported moderate to strong agreement between VR-based and force plate-based PS measures, supporting the use of VR systems as portable and cost-effective tools for clinical balance assessment [59]. In addition, VR-based sway metrics have been shown to differentiate between healthy individuals and clinical populations across various applications [60-62]. However, systematic differences in absolute magnitude were observed, with VR values consistently higher than those obtained from the reference system. These discrepancies may be attributed to fundamental differences in measurement principles, as the VR-based sway metrics were reconstructed from head-mounted IMU signals, whereas the reference system directly quantified head displacement using marker-based motion capture. In addition, IMU-based approaches are inherently more sensitive to high-frequency motion components and may accumulate small fluctuations in orientation signals, leading to overestimation of trajectory-based metrics such as TPL and SA. Similar patterns have been reported in previous studies, where strong correlations were observed despite differences in absolute values [39,40]. These findings suggest that a VR-based system is suitable for relative comparisons and longitudinal monitoring, although direct interchangeability with reference systems should be interpreted with caution.

Slightly lower reliability observed in the HTR and certain PS parameters is consistent with previous studies and likely reflects the intrinsic variability of perceptual, proprioceptive, and balance-related tasks rather than limitations of the VR system itself [47,49]. Such variability, influenced by sensory integration, attentional demand, and postural control strategies across sessions, may reduce test-retest stability even under standardized conditions. Nevertheless, the observed reliability levels remain within acceptable ranges for complex sensorimotor assessments.

From a clinical measurement perspective, the relatively small SEM and MDC values observed across most parameters indicate good measurement precision and support the ability to detect meaningful changes at the individual level. MDC values provide a practical threshold for distinguishing true change from measurement error, suggesting that relatively small improvements can be confidently interpreted as real changes rather than measurement variability. These findings support the use of the VR-based system for monitoring rehabilitation progress and evaluating intervention outcomes. Taken together, the present findings support the notion that the proposed VR system provides an integrated and clinically feasible platform for the multidimensional assessment of cervical SMC. Furthermore, the high repeatability observed in healthy participants may also serve as a normative reference for cervical SMC performance. Such baseline data could facilitate future comparisons with individuals presenting with cervical symptoms or pathologies, thereby supporting the clinical applicability of the VR-based system for assessment and rehabilitation.

Limitations

Despite the valuable contributions of this study, several limitations should be acknowledged. The participants in this study were healthy young adults; therefore, the results may not generalize to older populations or those with CNP. Future research should validate the system in diverse age groups and clinical populations, and further examine its predictive validity and responsiveness to intervention-induced changes. Although participants were instructed to minimize trunk movement and were visually monitored during testing, compensatory cervicothoracic or trunk motion cannot be completely excluded, particularly during lateral bending tasks. As the current system relies on head-mounted tracking without additional trunk sensors, the measured angles may partially reflect combined head and trunk motion. Future studies incorporating objective trunk motion monitoring (eg, thoracic IMUs, motion capture markers, or head-to-trunk relative angle calculations) are warranted to further isolate cervical motion and improve measurement specificity. Despite this limitation, the high

XSL•FO
RenderX

test-retest reliability observed in this study suggests that the measurement approach was consistent across sessions. Visual requirements may pose a practical constraint during the VR-based assessment. Participants who usually wore glasses were required to use contact lenses to ensure compatibility with the VR headset, which may have excluded individuals with visual impairments or low tolerance for immersive VR environments. This limitation may introduce potential bias and affect both the accessibility and ecological validity of the system in real-world clinical applications. Although familiarization trials were provided prior to formal testing, the novelty of the VR environment may have introduced learning effects or interindividual variability in task adaptation, potentially influencing performance consistency across trials and participants. Moreover, factors such as headset fit, visual delay, or cybersickness could affect measurements, though none were reported in this study. Continued optimization of head-tracking accuracy and algorithm calibration may further enhance the system's sensitivity to low-amplitude motion and subtle postural adjustments.

Conclusion

This study established the reliability and validity of a novel VR-based assessment system for the multidimensional assessment of cervical SMC. A single session provides data across 4 major SMC domains and the immersive environment sustains participant motivation. The system demonstrated good to excellent reliability across all domains and strong concurrent validity for ROM, JPE, FOE coordination, and PS. Its standardized, immersive, and user-friendly design supports efficient and objective evaluation of cervical sensorimotor function with reduced operator bias and higher reproducibility. Future studies should extend validation to clinical populations and evaluate responsiveness to therapeutic interventions. This VR-based platform uses commercially available hardware and portable software that is adaptable for both clinical and tele-assessment contexts and provides a robust foundation for establishing normative reference values and advancing digital assessment and management of CNP in both clinical and telehealth settings.

Abstract

Background: The Michigan Hand Outcomes Questionnaire (MHQ) is a key instrument for assessing hand and wrist conditions, but a validated version for European Portuguese speakers is unavailable. Furthermore, the potential of an electronic format to improve data collection and clinical workflows has not been formally evaluated.

Objective: This study aimed to translate and culturally adapt the MHQ for European Portuguese and to evaluate the measurement properties and comparability of its paper and electronic formats.

Methods: An observational study was conducted in three phases: (1) translation and expert review, (2) content validation through cognitive interviews, and (3) psychometric evaluation in a cohort of 81 adult patients with hand or wrist conditions. Exploratory known-groups analyses were performed according to clinical, sociodemographic, and digital-access variables. Analysis also included internal consistency (Cronbach α and McDonald ω), measurement error (standard error of measurement [SEM]), relative and absolute reliability (intraclass correlation coefficient [ICC], Spearman correlation coefficient [ρ], and Bland-Altman analysis). The electronic format's usability was assessed with the System Usability Scale (SUS).

Results: The translation and cognitive interviews confirmed the content validity and conceptual equivalence of the European Portuguese MHQ. The instrument demonstrated excellent internal consistency (Cronbach α=0.85-0.98; McDonald ω=0.88-0.99). Exploratory known-groups analyses showed significant gender-related differences and suggested side-specific clinical discrimination in fracture cases. While group-level relative reliability between formats was strong (ρ=0.68-0.91; ICC=0.76-0.95), individual-level absolute reliability was poor, with wide 95% limits of agreement spanning a 32.83-point interval. Format-related score discrepancies were most pronounced among older participants, those with lower educational attainment, and those with low digital literacy. The electronic MHQ was the preferred format (43 out of 74, 58%), showed acceptable usability (median SUS score 70, IQR 66-88), and had lower SEM in pain and function domains.

Conclusions: The European Portuguese MHQ is a relevant and reliable instrument with adequate measurement properties for both clinical practice and research. The electronic version demonstrated superior precision and user preference. However, maintaining the paper format as a viable alternative is essential to ensure equitable access for patients with digital barriers. Due

XSL•FO
RenderX

to the overall low absolute reliability between formats, once a patient-preferred format is adopted, it should be used consistently for longitudinal patient monitoring.

(JMIR Rehabil Assist Technol 2026;13:e83563) doi:10.2196/83563

KEYWORDS

Michigan Hand Outcomes Questionnaire; patient-reported outcome measures; digital technology; rehabilitation; psychometrics

Introduction

Hand conditions, whether acute or chronic, are impactful due to the essential role of the hand in activities of daily living (ADL) and skilled tasks [1]. Acute hand injuries account for approximately 30% of emergency department visits, with common injuries including tendon damage, fractures, degloving injuries, and amputations [2]. The global incidence rate of hand and wrist fractures is 179 per 100,000 people, and, in Portugal, it is significantly higher at 271.2 per 100,000 inhabitants [3]. In addition, a burn center study revealed that 41.5% of burn victims had hand injuries, often resulting in long-term functional limitations [4].

Beyond acute trauma, the hand is also a primary site for manifestations of systemic and chronic conditions. For instance, rheumatoid arthritis may affect the hand and wrist, with a reported impairment prevalence of 94% [5,6]. Other prevalent hand conditions include osteoarthritis, DeQuervain's tenosynovitis, carpal tunnel syndrome, trigger finger, and Dupuytren's contracture, each of which can also significantly impair hand function [7]. Given the hand's essential role in ADL and its high susceptibility to injury, clinical assessment must integrate physical examination findings with patient-reported outcomes. This dual approach prioritizes patient-centered functional goals and guides treatment strategies [4,8].

There is a growing emphasis on value-based, patient-centered care, where patient-reported outcome measures (PROMs) complement physical assessments. By capturing patients' functional abilities, symptoms, and quality of life, PROMs enhance shared clinical decision-making, treatment monitoring, patient adherence, and overall care effectiveness and experience [9-13]. The Michigan Hand Outcomes Questionnaire (MHQ) is a widely recognized PROM for its comprehensive evaluation of hand and wrist conditions, assessing function, pain, ADL, work performance, hand appearance, and patient satisfaction. Notably, it is the only hand assessment PROM that effectively integrates components of the International Classification of Functioning, Disability, and Health framework, making it a valuable resource for complete patient evaluation [14,15]. The MHQ has also robust measurement properties, including minimal clinically important difference (MCID) values, which range from 8 to 13, with subscale-specific values varying depending on the diagnosis and treatment strategy [16,17]. It is often used in clinical research and included in standardized outcome sets, having received provisional endorsement from Outcome Measures in Rheumatology (OMERACT) and adoption by the International Consortium for Health Outcomes Measurement (ICHOM) for hand and wrist conditions [18,19]. Despite being validated in multiple languages, a European Portuguese version is still needed. Such an adaptation would ensure cultural and linguistic accuracy for the Portuguese population, enable comprehensive assessment of hand outcomes following conservative or surgical treatment in health settings, and support participation in international multicenter research [14,20,21].

With the increasing integration of digital technology into daily life and clinical practice, there is an opportunity for the implementation of electronic PROMs [22,23]. To the best of our knowledge, an electronic format of MHQ has not yet been published in peer-reviewed literature. This format could overcome the limitations of a paper version [20,24], support MHQ integration into clinical workflows, and improve patient engagement.

Thus, our study aimed to translate, culturally adapt, and validate the MHQ for European Portuguese, comparing its paper and electronic formats while evaluating its measurement properties and comparability.

Methods

Study Design

An observational study was conducted between February and December 2024 at the Physical Medicine and Rehabilitation (PMR) Department of the Unidade Local de Saúde de Gaia e Espinho. The study was divided into three phases: phase 1 – translation and expert panel review, phase 2 – content validity through cognitive debriefing, and phase 3 – measurement properties and comparability between formats. The study design followed the research principles outlined in the Declaration of Helsinki, with detailed procedures described in the Ethical Considerations section [25]. The study was reported according to the STROBE (Strengthening the Reporting of Observational Studies in Epidemiology) guidelines [26].

Participants

Patients were enrolled only in phases 2 and 3 and were recruited by convenience sampling at our department. Eligible patients were aged 18 years or older, proficient in European Portuguese, and diagnosed with any hand and wrist conditions with functional impairment. We excluded participants who presented with hand conditions secondary to central nervous system disorders, as well as those with severe cognitive or visual impairments.

Phase 1: MHQ Translation and Expert Panel Review

The MHQ is a comprehensive PROM assessing each hand using 37 core items across six subscales, I to VI, respectively: I - overall hand function (5 items per hand; eg, "Overall, how well

XSL•FO
RenderX

did your right hand work?"), II - ADL (5 items per hand and 7 for two-handed activities; eg, "Carry grocery bags"), III - work performance (5 items; eg, "How often were you unable to do your work because of problems with your hand(s)/wrist(s)?"), IV - pain (5 items per hand; eg, "How often did the pain in your right hand/wrist interfere with your sleep?"), V - appearance (4 items per hand; eg, "I am satisfied with the appearance (look) of my right hand"), and VI - patient satisfaction with hand function (6 items per hand; eg, "Motion of the fingers in your right hand") [27]. Except for work performance, all subscales are evaluated separately for each hand [14,15]. Items are scored on a 1-5 Likert scale, summed, and converted to a 0-100 scale. Higher subscale scores indicate better outcomes, except for pain.

For unilateral conditions, the score of the affected hand is used. For bilateral conditions (eg, rheumatoid arthritis), the right- and left-hand scores are averaged. The total score is the average of all subscales, with the pain score reversed. At the end of the MHQ, a set of questions proposed by the original authors collects demographic information, including dominant hand, ethnicity, job-related details, gender, education level, and annual family income. The questionnaire takes approximately 15 minutes to complete and can be self-administered by patients or aided by health care professionals [20].

A license for academic research was obtained from the MHQ copyright holders to translate the questionnaire into European Portuguese and to develop an electronic format. Following international guidelines, the translation and cross-cultural adaptation process began with two independent translations conducted by native Portuguese-speaking PMR residents fluent in English (EMG and MA) [28,29]. The socioeconomic questions of the sociodemographic section were also adapted to ensure cultural relevance. The 2 translations were merged and disagreements identified. Both translations were reviewed item by item during an online meeting with a panel of experts. The expert panel included the 2 translators, a PMR physician (PC), a rheumatologist (MB), and a PROM expert (CJ). A synthesis of the discussion produced a preliminary Portuguese version. In accordance with the Beaton et al [28] methodology, the preliminary version was back-translated into English by two translators: a native Canadian English speaker and a native Portuguese speaker with professional fluency in English from over 25 years of living and working in English-speaking countries. Both back-translators were non–health care professionals and were unaware of the original MHQ. The expert panel reviewed and resolved discrepancies between the two back-translated versions. The final European Portuguese MHQ and the back-translated version were approved by the original authors.

Phase 2: Content Validity Through Cognitive Debriefing

Cognitive debriefing interviews were conducted with patients with hand conditions, following established qualitative research guidelines and the Consensus-based Standards for the selection of health Measurement Instruments (COSMIN) recommendations [30,31]. A structured interview guide was used, incorporating think-aloud techniques and probing questions to assess the MHQ relevance, comprehensiveness, and comprehensibility.

The interviews were conducted by two trained PMR residents (EMG or BF); both received specific training in cognitive debriefing techniques prior to the study to ensure procedural consistency. Participants were encouraged to clarify and confirm their interpretations, ensuring accurate data collection. The interviews were audio-recorded, and field notes were taken to capture nonverbal cues. Verbatim transcriptions were thematically analyzed by two researchers (EMG, male, and CS, female) to identify ambiguities and key issues [31]. An initial sample size of 8 to 10 patients was planned, but data collection continued until thematic saturation was reached. This was defined as the point at which no new themes or insights emerged in 2 subsequent interviews, and responses became redundant, occurring at the 10th interview [32].

Participants also reported their clinical diagnosis and provided sociodemographic information, including age, ethnicity, gender, educational level, annual family income, and dominant hand.

Following cognitive debriefing, patient feedback was reviewed by the expert panel to determine whether revisions were required. Suggested changes were considered only when they improved clarity without compromising the original construct. Final decisions were made by consensus after reviewing the interview findings and the corresponding original item content.

Phase 3: Measurement Properties and Comparability Between Formats

In line with COSMIN recommendations, at least 50 participants were recruited and randomly assigned to complete either the paper or electronic format first [29,33]. To mitigate recall bias, participants completed the alternate format within one week of the initial MHQ administration to ensure consistency in their reported clinical and functional status [34].

The electronic format was developed in accordance with the International Society for Pharmacoeconomics and Outcomes Research (ISPOR) best practices [33,35]. The migration from the paper format involved specific design choices to optimize user experience while adhering to specific migration principles. The visual layout was modified from the paper grid layout to a vertical list in the electronic format, where each item was followed by its corresponding radio-button response options. All items belonging to a single subscale were presented together on one screen, a design intended to maintain context for the participant. The instrument's skip logic for the pain subscale was preserved using conditional logic; if a participant selected "Never" (*Nunca*) in response to the initial pain frequency question, the subsequent branched questions about pain characteristics were automatically hidden and could not be answered. The format is hosted on a secure, web-based platform (Jotform) compliant with the European General Data Protection Regulation (GDPR). It was designed to ensure accessibility, provide real-time scoring for each MHQ domain and the total score, and enable efficient data analysis. Indeed, upon completing the electronic format on an 11-inch tablet device, patients were redirected to an interface that uses OpenAI's ChatGPT-4o, an AI tool, to deliver personalized MHQ results

XSL•FO
RenderX

with a report. This report includes comparisons to normative data from US patients with and without hand conditions [36-38]. A demonstration video is available in Multimedia Appendix 1.

After completing the electronic format, participants assessed its usability using the European Portuguese version of the System Usability Scale (SUS) [39]. The SUS is a standard 10-item questionnaire that uses alternating positive and negative statements to avoid response bias. Examples of positive items include "I think that I would like to use this system frequently" and "I thought the system was easy to use," while negative items include statements such as "I found the system unnecessarily complex." SUS scores range from 0 to 100, with scores of 68 or above indicating acceptable [39]. Participants also indicated their format preference: paper, electronic, or no preference.

Participants also provided clinical and sociodemographic data, as described in phase 2, and reported their digital literacy. Digital literacy was evaluated using the text messaging and smartphone usage subscales from the validated European Portuguese version of the Media and Technology Usage and Attitudes Scale (MTUAS) [40,41]. This assessment consisted of 11 questions assessing activities such as sending and receiving text messages, browsing the web, and using mobile apps. Each item is rated on a 10-point Likert scale (1=never to 10=all the time), reflecting the frequency of use. The digital literacy score was determined by calculating the average of all item scores, yielding a final score ranging from 1 to 10.

Data Analysis

Participants' characteristics in phases 2 and 3, as well as MHQ scores, were described using descriptive statistics. Normality was assessed through the Kolmogorov-Smirnov test and histogram inspection. Normally distributed data were presented as mean (SD), while nonnormally distributed data were summarized using median and quartiles (Q1 and Q3).

Missing data were handled according to their type. Structural missing data, which arose from the MHQ's intended skip-pattern logic in the pain subscale (IV-A and IV-B), were preserved as valid nonresponses. Little's test indicated that sporadic missing data were not missing completely at random. Therefore, multiple imputation using the predictive mean matching method was performed [42].

Exploratory known-groups analyses were conducted to examine whether affected-hand MHQ scores differed across clinical (dominant-hand involvement), sociodemographic (age group, income level, educational attainment, and gender), and digital-access (digital literacy and usability) subgroups. Between-group comparisons were performed using Mann-Whitney *U* tests. To further assess comparability between administration formats, paired comparisons between paper and electronic scores were performed within each subgroup using Wilcoxon signed-rank tests.

Internal consistency was assessed using Cronbach (α>0.70 considered acceptable), and McDonald ω as a more robust measure [34,43].

Comparability between formats was evaluated using several methods. At the group level, relative reliability was assessed using the intraclass correlation coefficient (ICC) based on a 2-way random-effects, single-rater, absolute agreement model, with values interpreted as poor (<0.50), moderate (0.50-0.74), good (0.75-0.89), or excellent (≥0.90); and Spearman rank correlation coefficient (ρ) for association between format scores [44]. For individual-level agreement, the analysis of absolute reliability was conducted to visualize systematic bias and quantify random error, using the Bland-Altman method by calculating the mean difference and 95% limits of agreement (LoA) and through standard error of measurement (SEM), calculated separately for each format to estimate the margin of error for an individual's score. Participants who completed only one format were excluded from these analyses.

Format preferences were explored according to gender, age group, educational attainment, and digital literacy using Mann-Whitney *U* tests.

Statistical analyses were performed using IBM SPSS Statistics (version 29.0) and R (version 4.2.0), with a *P* value less than .05 considered statistically significant.

Ethical Considerations

This study was conducted in accordance with the principles of the Declaration of Helsinki [25]. Ethical approval was granted by the Health Ethics Committee of the Unidade Local de Saúde de Gaia e Espinho (reference number 62/2023, addendum numbers 64/2024-1 and 187/2024). All participants received clear explanations of the study objectives and provided written informed consent prior to any data collection. To protect participant privacy and confidentiality, all collected data were strictly deidentified and stored securely. Participants did not receive any financial compensation for their involvement in this study.

Results

Phase 1: Translation and Expert Panel Review

The proposed adaptation maintains the original MHQ context while incorporating linguistic and cultural refinements to ensure clarity and accessibility. These modifications, informed by expert panel discussions, enhanced the questionnaire's relevance for Portuguese-speaking users, regardless of their educational background. For example, "gestures" (*gestos*) was chosen over "activities" (*atividades*) to better capture the nature of hand movements required for the tasks described in the questionnaire items related to the left and right hand, respectively. Similarly, a few response options were modified to reflect expressions commonly used in Portuguese, for instance, "very poor" (*muito pobre*) to "very bad" (*muito mal*). Additionally, the term "normal work" (*trabalho normal*) was translated as "usual work" (*trabalho habitual*), as it more accurately conveys the concept of routine professional and daily tasks in Portuguese. Some English terms also lacked a direct Portuguese equivalent that would be appropriate in the given context. For instance, "sensation (feeling)" was translated as "sensitivity to touch" (*sensibilidade [ao toque]*), since the literal Portuguese equivalent of "feeling" (*sentimento*) is primarily associated with emotions rather than tactile perception. Similarly, "look" was translated as "aspect" (*aspecto*), as the word "look" (*olhar*) in

XSL•FO
RenderX

Portuguese refers to the act of looking rather than physical appearance. Additionally, "pain level" (*nível de dor*) was translated as "pain intensity" (*intensidade da dor*), which is a more commonly known term among Portuguese-speaking patients. Adjustments were also made in the demographic section. Demographic categories, including ethnicity, gender, job-related questions, education, and income, were adapted to align with Portuguese cultural and statistical standards, using terms adopted from the Portuguese National Institute of Statistics.

Phase 2: Content Validity Through Cognitive Debriefing

A total of 12 patients participated in the cognitive debriefing phase (Table 1 and Figure 1), and interviews lasted between 20 and 40 minutes. Participants had a median age of 54, IQR 49-57 years, were predominantly female (8 out of 12, 67%), and mostly non-Hispanic White (11 out of 12, 92%). Most patients demonstrated a clear understanding of the questionnaire's content. However, adjustments were needed based on participants' suggestions. As highlighted in Table 2, some expressions raised doubts regarding interpretation. Regarding finger movement (subscales I and VI), 2 patients asked for help before answering, as not all fingers were equally affected by stiffness and immobility. The same issue applied to the term "sensibility," where patients were unsure which specific finger they should base their answer on, given that sensory perception varies across different digits. In subscale V, several patients noted that the response system was not as intuitive as in previous subscales, considering that the items in these tables were in the affirmative form and not in the interrogative form.

All findings were discussed with the expert panel. Because these are common challenges when completing standardized questionnaires, and a primary goal was to preserve the structural integrity of the original instrument as much as possible to ensure comparability, modifications were kept subtle and limited to minor wording adjustments, with no changes made to the original MHQ structure.

Figure 1. Flowchart outlines patient enrollment and retention across phase 2 (content validity) and phase 3 (psychometric evaluation). Phase 2 included all 12 approached patients. In phase 3, 81 of 87 approached patients participated, with reasons provided for the 6 nonparticipants. The final phase 3 sample (n=81) details Michigan Hand Outcomes Questionnaire format completion rates: 75 completed both formats, 79 completed the paper format, and 77 completed the electronic format. Additionally, the flowchart notes the exclusion of 3 participants from specific subscale analyses due to missing data.

XSL•FO
RenderX

Table 2. Examples of controversial expressions identified by patients during cognitive interviews.

MHQ[a] subscale	Original expression	Rationale	Revised expression
Activities of Daily Living Item II[b]-C4	"Carry a grocery bag"	Although there is a direct translation in Portuguese for "carry a grocery bag" (*carregar um saco de mercearia*), this expression does not reflect the need to use both hands as it was intended by the original item. Since most patients usually carry a grocery bag in one hand only, we considered more appropriate to replace it with "carry grocery bags" (*carregar sacos de mercearia*) to translate a bilateral activity.	"Carry grocery bags" (*Carregar sacos de mercearia*)
Activities of Daily Living Item II-C5	"Wash dishes"	It was not considered a common chore. The alternative "loading the dishwasher" (*colocar a loiça na máquina*) was suggested to be added. The expert panel considered that would involve a different hand activity and could alter the construct assessed by the original item.	No revision was made
Work Performance Subscale III	—[c]	Items 3, 4 and 5 were perceived as identical. However, no patient suggested a more suitable alternative.	No revision was made
Pain Items IV-A2 and IV-B2	"Please describe the pain you had in your hand/wrist" (*Por favor, descreva a dor que teve na sua mão/punho*)	There were doubts about whether the statement referred to the maximum pain the patient felt or the average. Furthermore, it was not understandable if these items were related to the pain while at rest or during activity. As the identified ambiguity is also present in the original instrument, the item was intentionally left unchanged.	No revision was made
Pain Items IV-A5 and IV-B5	"Unhappy"	As this word carries a substantial meaning, some patients suggested the alternative "sad" (*triste*).	"Sad" (*triste*)
Satisfaction Items VI-A1 and VI-B1	"Overall function"	The translated expression "overall function" (*função global*) was unclear to some participants, particularly older patients, who did not understand its meaning. The alternative "general function" (*função geral*) was suggested by one participant, but the participant also understood the wording "*função global*."	No revision was made

Phase 3: Measurement Properties and Comparability Between Formats

Participants' Characteristics

A total of 81 participants were included in this study phase. Their demographic and clinical characteristics are summarized in Table 3. The median age was 55 (45-67) years, with most participants being women (51 out of 81, 63%). Median digital literacy score was 5.45 (3-6.6), and almost half (39 out of 81, 48%) completed primary education. Right-hand dominance was high (76 out of 81, 94%), with disability affecting mostly the right (36 out of 81, 44%). Fractures and dislocations (42 out of 81, 52%), especially distal radius fractures (29 out of 81, 36%), were the most frequent conditions.

[a]Values shown as n (%) unless otherwise indicated; n: absolute frequency; %: relative frequency; Q1-Q3: IQR.

[b]Digital literacy was calculated using the Media and Technology Usage and Attitudes Scale (MTUAS), with scores ranging from 1 to 10 points.

[c]The average exchange rate at the time of data collection was 1 EUR=US $1.08.

[d]Total percentage exceeds 100% as participants could have more than one diagnosis.

Three participants' paper questionnaires exhibited more than 50% of missing items in the pain (2) and satisfaction (1) subscales, which were excluded from specific subscale analysis. Isolated missing values were present in two paper questionnaires related to items II-B2 ("pick up a coin") and VI-A5 ("pain level of your right hand"). No missing values were observed in the electronic MHQ, as fields were mandatory by design.

MHQ Scores and Known-Group Analyses

The distribution of scores for the paper and electronic formats was highly similar across nearly all subscales, with comparable median scores and IQRs, although subgroup analyses showed selected format-related differences (Table 4).

Table 4. Descriptive statistics of European Portuguese Michigan Hand Outcomes Questionnaire (MHQ) scores in both formats.

MHQ subscales	Paper format, median (IQR)	Electronic format, median (IQR)
Overall hand function of the right hand	70 (50-90)	70 (50-90)
Overall hand function of the left hand	75 (45-100)	70 (50-95)
ADL[a] with the right hand	75 (50-100)	75 (55-100)
ADL with the left hand	75 (40-100)	75 (50-100)
ADL with both hands	60.7 (35.7-82.1)	57.1 (35.7-75)
Work performance	50 (35-70)	50 (25-67.5)
Pain in the right hand	22.5 (0-51.3)	25 (0-50)
Pain in the left hand	17.5 (0-45)	10 (0-45)
Appearance of the right hand	68.8 (37.5-100)	81.3 (50-96.9)
Appearance of the left hand	75 (31.3-100)	75 (43.8-100)
Satisfaction with the right hand	75 (45.8-92.7)	75 (39.6-100)
Satisfaction with the left hand	75 (36.5-100)	75 (39.6-100)
Total score of the right hand	68.9 (47.3-83.1)	69.8 (47.1-83.3)
Total score of the left hand	68.5 (48.6-80.9)	69.7 (49.5-84.1)
Total score of both hands	63.90 (53.7-77.4)	64 (54.4-76.1)

[a]ADL: activities of daily living.

Exploratory known-groups analyses showed a clinically interpretable pattern in the distal radius fracture subgroup. Dominant-hand involvement alone did not consistently differentiate MHQ scores. However, hand-specific analyses by

XSL•FO
RenderX

fracture side indicated side-specific clinical discrimination, particularly in the paper format, where total scores were significantly lower for the fractured hand than for the contralateral hand in both right- and left-sided fractures. This pattern was only partially reproduced in the electronic format, where the left-hand total score remained significantly lower among participants with left-sided fractures. Contralateral, uninjured-hand scores remained below the maximum possible value at the group level in both formats.

Among sociodemographic subgroups, gender showed the most consistent differences across formats, with men reporting higher scores in several MHQ domains, including function, ADL, work performance, satisfaction, and total score. Education-related differences were observed mainly in the paper format, where participants with lower educational attainment reported lower work performance, appearance, and total scores. Format-related differences were more frequent among older participants, those with lower educational attainment, lower digital literacy, and lower perceived usability, particularly for appearance and total scores.

Internal Consistency

As shown in Table 5, internal consistency was good to excellent across all subscales as demonstrated by Cronbach α values ranging from 0.85 to 0.98, while McDonald ω values ranged from .88 to .99. The highest internal consistency was observed in the "Satisfaction with the left hand" subscale for both coefficients.

Table 5. Internal consistency of the European Portuguese Michigan Hand Outcomes Questionnaire (MHQ) and reliability between formats.

MHQ subscales	Cronbach α	McDonald ω	ρ [a]	ICC[b] (95% CI)	SEM[c]	
					Paper format	Electronic format
Overall hand function of the right hand	0.95	0.97	0.68	0.80 (0.68-0.87)	2.29	1.28
Overall hand function of the left hand	0.96	0.97	0.89	0.93 (0.90-0.96)	2.31	1.12
ADL with the right hand	0.95	0.96	0.76	0.85 (0.76-0.90)	1.72	1.75
ADL with the left hand	0.96	0.98	0.91	0.95 (0.93-0.97)	2.71	2.97
ADL with both hands	0.95	0.97	0.87	0.92 (0.87-0.95)	4.05	2.95
Work performance	0.95	0.96	0.82	0.89 (0.83-0.93)	2.41	2.13
Pain in the right hand	0.94	0.99	0.72	0.85 (0.76-0.90)	3.88	2.21
Pain in the left hand	0.94	0.99	0.88	0.80 (0.69-0.88)	3.44	1.97
Appearance of the right hand	0.86	0.89	0.76	0.80 (0.66-0.88)	1.35	1.39
Appearance of the left hand	0.85	0.88	0.74	0.86 (0.78-0.91)	2.04	2.16
Satisfaction with the right hand	0.95	0.98	0.71	0.76 (0.62-0.85)	3.45	2.76
Satisfaction with the left hand	0.98	0.99	0.75	0.86 (0.78-0.91)	3.95	2.91
Total score of the right hand	__[d]	—	0.85	0.81 (0.71-0.88)	—	—
Total score of the left hand	—	—	0.89	0.91 (0.86-0.94)	—	—
Total score of both hands	—	—	0.83	0.88 (0.82-0.93)	—	—

[a]All Spearman rank correlation coefficients (ρ) were statistically significant (*P*<.01).

[b]ICC: intraclass correlation coefficient.

[c]SEM: standard error of measurement.

[d]Not applicable.

Reliability and Comparability Between Formats

The analysis of relative reliability between the paper and electronic formats revealed a good to excellent reliability, with ICC ranging from 0.76 to 0.95 (Table 5). These findings were supported by strong and statistically significant Spearman coefficients (ρ=0.68 to 0.91; *P*<.01).

In contrast, the absolute reliability analysis demonstrated slight measurement error at the individual level. While Bland-Altman analysis (Figures 2-4) confirmed negligible systematic bias, it revealed wide 95% LoA. For the total score of both hands, this interval spanned a substantial 32.83 points (from –18.26 to 14.57). Reinforcing the differences in measurement error, the analysis of the SEM showed the electronic version to be metrically superior. For instance, the SEM for pain in the right hand was 3.88 for the paper format compared to a much lower 2.21 for the electronic format (Table 5).

XSL•FO

RenderX

Figure 4. Bland-Altman plot comparing paper and electronic Michigan Hand Outcomes Questionnaire total score for both hands. The mean difference is shown with 95% limits of agreement calculated as mean (SD 1.96).

Administration Preference and Usability

Most participants (43 out of 74, 58%) preferred the electronic format, whereas 15 (20%) preferred the paper version, and 16 (22%) were indifferent. This preference was more pronounced among individuals with higher digital literacy (24 out of 36, 67%) and higher education background (13 out of 18, 72%). It was also favored by less frequent technology users (19 out of 38, 50%) and those with less formal education (30 out of 56, 54%). Notably, more than half (12 out of 22, 55%) of participants aged 65 and older also favored the electronic format, closely tracking the preference seen in younger participants (31 out of 52, 60%). Similarly, gender did not significantly influence preference, with the electronic format being the top choice for both male (18 out of 27, 67%) and female (25 out of 47, 53%) participants. Regarding usability, this format scored a median of 70 (66-88) on the SUS.

Discussion

Principal Findings

This study translated and culturally adapted the MHQ for European Portuguese and conducted an evaluation of its measurement properties in both paper and electronic formats. The adaptation process, informed by expert review and patient cognitive interviews, yielded an instrument that was well-understood and relevant. Exploratory known-groups analyses provided partial evidence of clinical relevance. The subsequent psychometric evaluation revealed high internal consistency across all subscales in both formats and an overall adequate relative and absolute reliability between the paper and electronic formats supporting their use in clinical practice and research.

Content Validity and Clinical Relevance

The translation and cultural adaptation process confirmed the relevance and comprehensibility of the European Portuguese MHQ. Cognitive interviews showed that most participants understood the questionnaire, although some items generated uncertainty, particularly those involving abstract concepts such as “overall function,” hand appearance, and satisfaction. These findings are clinically important because they show that even when a PROM is linguistically accurate, some concepts may still be interpreted differently by patients depending on their condition, education, and lived experiences. Importantly, no structural changes were made to the original MHQ, preserving comparability with other validated versions [31].

Exploratory known-groups analyses provided evidence of clinical relevance. Gender showed consistent sociodemographic discrimination across both administration formats, with men generally reporting better function and lower pain burden than women. However, these findings should not be interpreted as reflecting a direct effect of gender alone, as they may also reflect differences in diagnosis, disease severity, occupational exposure, pain perception, treatment stage, or other unmeasured clinical factors [45].

In the distal-radius-fracture subgroup, affected-hand MHQ scores did not differ consistently according to dominance status, suggesting that dominance alone was not a major determinant of perceived disability. More clinically relevant was the observation that contralateral, uninjured-hand scores remained below the maximum possible score. This supports previous MHQ normative findings indicating that unilateral hand or wrist problems may also reduce perceived function of the unaffected hand, likely because many daily tasks require bilateral hand use or because impairment in one hand can increase demand on the other [46].

Therefore, contralateral scores after unilateral distal radius fracture should not necessarily be interpreted as fully “normal” and bilateral summary scores may dilute side-specific impairment. The absence of clear work-performance differences between right- and left-sided fracture groups further suggests that occupational impact may depend on factors beyond injury side or dominance alone, including task demands, compensatory strategies, pain, rehabilitation stage, and postinjury adaptation.

XSL•FO
RenderX

Reliability and Comparability Between Formats

This study provides evidence for the comparability between paper and electronic formats. The high Spearman correlations (ρ up to 0.91) and excellent ICC values (up to 0.95) indicate that, on average, the two formats produce highly comparable scores. This finding supports data collection via either format within a single study. While the formats are equivalent for groups, the Bland-Altman analysis showed they might not be interchangeable for individuals. The 95% LoA for the total score of both hands spanned a 32.83-point interval. This is a substantial degree of random error when compared to the MHQ's established MCID, which is 8 to 13 points [16]. For a patient, a score difference generated simply by switching from paper to electronic format could be 2 to 3 times larger than a genuine, clinically meaningful change. This finding strongly cautions against using the two formats interchangeably to monitor a single patient's progress. Format-related differences were more likely to appear among participants with lower educational attainment, lower digital literacy, lower perceived usability, older age, and female gender. The inherently subjective appearance domain was the most consistently affected by administration format, and total score differed between formats in selected subgroups [47].

Furthermore, the analysis of measurement precision via SEM suggests that the electronic version is not merely an alternative but, in some respects, a metrically superior instrument. The electronic format demonstrated a significantly lower SEM for the crucial domains of hand function and pain, meaning it has less inherent measurement "noise" and can therefore detect smaller true changes more reliably than the paper format.

Given its precision, lack of missing data, and patient preference, the electronic format appears suitable as the preferred administration format in many settings. Nevertheless, maintaining a paper alternative remains advisable to ensure access for patients with lower digital familiarity, lower perceived usability, or specific technological barriers. For clinical care involving longitudinal assessments, the two formats should never be used interchangeably for the same patient.

Strengths, Limitations, and Contribution to Practice

This study's strengths include its adherence to COSMIN and ISPOR guidelines, the direct comparison between paper and electronic formats, and a mixed methods approach that allowed qualitative findings to explain quantitative results. The development of a preferred electronic version with acceptable usability is a step toward modernizing data collection in Portuguese rehabilitation settings [35,48]. Patient preference for electronic MHQ was strongly influenced by age, education, and digital literacy. While younger, highly educated patients showed the most preference, acceptance among older individuals points to a shrinking digital divide. These findings highlight the need for user-friendly electronic tools alongside traditional paper forms to guarantee accessibility [37].

Nonetheless, limitations must be acknowledged. The use of a convenience sample from a single center may limit generalizability. Structural validity was not examined because of the modest sample size and multidimensional structure of the MHQ. Convergent and divergent validity were also not formally assessed because no external comparator instrument was administered. Both paper and electronic formats were completed in the presence of a health care professional, allowing clarification when needed. However, assistance during completion was not systematically recorded. Based on clinical observation, assistance appeared more frequent with the paper format, possibly because writing, turning pages, and handling the questionnaire may be challenging for patients with hand or wrist functional impairment [49]. Therefore, the frequency and potential influence of assistance on responses could not be quantified. The electronic format was tested only on an 11-inch tablet in a controlled clinical setting, and usability may differ in unsupervised or device-diverse contexts. Although mandatory response fields prevented missing data, they may have introduced response bias by forcing uncertain participants to select an answer. Digital literacy was assessed using selected MTUAS subscales as a proxy. While it is practical to reduce respondent burden, this approach primarily measures technology use frequency rather than directly evaluating digital skills, confidence, or the independent ability to complete an electronic platform [40]. High internal consistency coefficients in several subscales may indicate item redundancy, supporting future validation of a shorter European Portuguese MHQ [43,50,51].

Finally, in the Portuguese context, this work provides a valuable tool for patient-reported outcomes in hand and wrist conditions. While other instruments are available, the MHQ offers a more comprehensive evaluation, uniquely assessing each hand separately and including domains like appearance and satisfaction [52,53]. The European Portuguese MHQ is a relevant and reliable instrument with adequate measurement properties for both clinical practice and research. The electronic version demonstrated superior precision and user preference. However, maintaining the paper format as a viable alternative is essential to ensure equitable access for patients with digital barriers. Due to the overall low absolute reliability between formats, once a patient-preferred format is adopted, it should be used consistently for longitudinal patient monitoring. Future research should assess the instrument in larger and more diverse samples, particularly regarding structural validity, external validity, and the performance of the electronic format in routine clinical and remote-care settings.

Acknowledgments

The authors would like to thank Dr. Lilibeth Campos for her valuable support and contributions to this work.

Multimedia Appendix 1
This video file is a demonstration of the electronic version of the European Portuguese Michigan Hand Outcomes Questionnaire (MHQ). It shows the entire user process, from entering an ID and providing consent to answering the questions on the web-based platform. After completion, the video demonstrates the system's ability to provide instant, real-time scoring and an automatically generated, personalized report. This report, created with the assistance of an AI tool (ChatGPT-4o), summarizes the patient's results and compares them to normative data.

Abstract

Background: Drowning is a leading cause of unintentional injury-related mortality worldwide, particularly in swimming pool environments, where rapid detection is critical to prevent fatalities. Traditional monitoring approaches rely on lifeguards and rule-based systems, which are often limited by human error, delayed response, and environmental challenges such as occlusion, glare, and multiple swimmers. Machine learning (ML) and computer vision methods have emerged as promising alternatives for automated drowning detection; however, their methodological rigor, real-world applicability, and reliability remain unclear.

Objective: This study aimed to systematically review advancements in ML-based drowning detection systems over the past 15 years. The review focused on detection methods, sensing modalities, evaluation metrics, and validation practices. It also examined how studies addressed real-world challenges such as occlusion, lighting variability, and multiswimmer environments, and identified key gaps related to generalizability, reliability, and privacy.

Methods: A systematic literature review was conducted using major electronic databases, including IEEE Xplore, Scopus, PubMed, Web of Science, ACM Digital Library, and Google Scholar. A total of 4927 records were initially identified and screened by 2 independent reviewers using predefined inclusion and exclusion criteria. A final set of 30 studies was included for data extraction and synthesis. The methodological quality and risk of bias were assessed using the Prediction Model Risk of Bias Assessment Tool (PROBAST), while reporting transparency was evaluated using the TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) guidelines. Data analysis was conducted in R.

Results: The findings indicate that drowning detection research is dominated by supervised, vision-based approaches (23/30, 76.7%), with convolutional neural networks (5/30, 16.7%) and You Only Look Once–based architectures (7/30, 23.3%) being the most commonly used methods. While reported performance is generally high, with mean accuracy exceeding 90.9%, evaluation practices are heavily centered on accuracy, with limited reporting of precision, recall, false alarm rate, and latency. One of 30 (3.3%) studies reported validation under real-world operational conditions, with an additional 5 (16.7%) studies using real-world data without formal real-world validation, and no studies conducted cross-dataset evaluation. In addition, critical real-world challenges such as occlusion, glare, and crowding were rarely addressed (<10% of studies), and all studies relied on private datasets. The PROBAST assessment further indicated a high risk of bias in 96.7% (29/30) of studies, primarily due to limited validation and nonrepresentative data sources.

Conclusions: ML-based drowning detection systems have demonstrated substantial progress in algorithm development, particularly in vision-based models. However, this progress is not matched by equivalent advances in validation, robustness, and real-world applicability. The field is characterized by a significant gap between experimental performance and deployment readiness. Future research should prioritize standardized evaluation frameworks, external validation, comprehensive performance reporting, and the integration of multimodal and privacy-preserving approaches to enable reliable real-world implementation.

Introduction

Drowning remains a major global public health concern and a leading cause of unintentional injury-related mortality worldwide. Drowning is a major but preventable public health problem worldwide [1]. Each year, about 300,000 people die from unintentional drowning [2]. It is a leading cause of injury-related deaths. Young people are most affected. Over half of victims are under 25 years. Children aged 1 to 4 years are at the highest risk [3]. Most deaths, about 90%, occur in low- and middle-income countries due to limited safety measures and supervision.

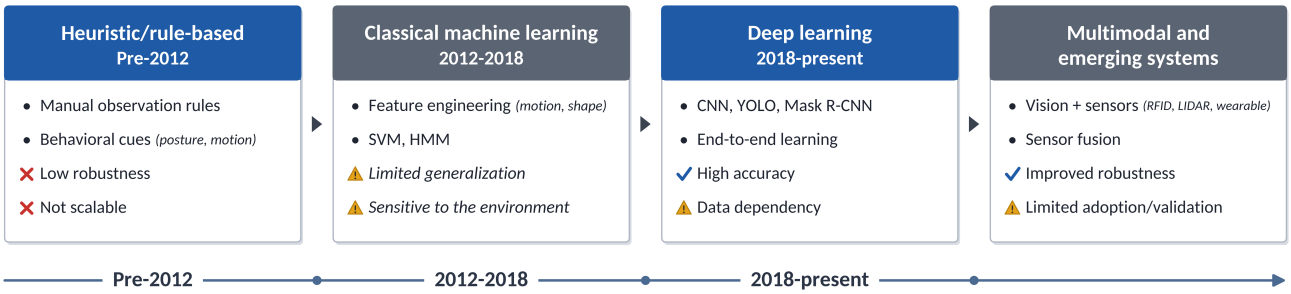
Drowning is difficult to prevent because it is rapid and often silent, and victims show the instinctive drowning response. This includes vertical positioning and little movement. They are often unable to call for help. The time to intervene is very short, often seconds to minutes. Lifeguards play an important role but face limitations. Their performance is affected by fatigue, attention limits, and crowded environments [4]. Occlusion and high swimmer-to-lifeguard ratios make detection harder. These challenges highlight the need for automated, real-time monitoring systems to support human supervision.

Early technological approaches relied on rule-based systems and handcrafted features derived from visual observations. These methods attempted to detect distress through predefined patterns such as vertical body positioning and irregular motion. However, they lacked robustness and performed poorly in dynamic and real-world environments.

The emergence of machine learning (ML) and computer vision significantly advanced drowning detection research [5]. Convolutional neural networks (CNNs) were widely used for feature extraction from visual data [6]. Object detection models such as YOLO (You Only Look Once) and region-based approaches like Faster region-based CNN (R-CNN) improved real-time detection capabilities [7-10]. Recurrent neural networks and long short-term memory networks were applied to capture temporal patterns in swimmer behavior [11]. More recent studies explored spatiotemporal architectures and transformer-based models to model complex motion dynamics. Hybrid approaches combining multiple models further improved detection performance.

Despite substantial methodological progress, the field lacks a comprehensive and rigorous synthesis of existing evidence. Current studies are highly heterogeneous, with inconsistent reporting of evaluation metrics, limited use of operational performance indicators such as false alarm rates and latency, and minimal external validation. Most systems are evaluated in controlled environments using simulated scenarios, with little evidence of real-world deployment or cross-dataset generalization. These limitations make it difficult to assess the true effectiveness and readiness of existing systems for practical use.

This study therefore aimed to systematically review advancements in ML-based drowning detection methods published over the past 15 years. This time period was selected to capture the period during which modern ML, particularly deep learning and computer vision, emerged and rapidly evolved. The review examined detection models, data modalities, evaluation metrics, and deployment strategies. It also assessed how studies addressed real-world challenges and evaluated their methodological rigor.



Building on this trajectory, the remainder of this section traces the field's technical evolution in greater depth. Automated drowning detection has evolved from heuristic observation models to data-driven ML systems. Early approaches identified drowning based on observable behavioral cues such as vertical body posture, limited forward motion, and irregular limb activity [12]. While these rule-based systems provided initial insights into drowning behavior, they were constrained by predefined thresholds and lacked robustness to environmental variability, including reflections, occlusion, and crowding. The introduction of classical ML methods improved automation by leveraging engineered features derived from motion and appearance. However, these approaches remained dependent on feature design and exhibited limited generalizability in complex aquatic environments [5].

The adoption of deep learning marked a significant shift in the field, enabling end-to-end learning of spatial and temporal representations directly from visual data. CNNs became widely used for feature extraction, while object detection frameworks such as YOLO have been extensively applied for real-time swimmer localization and monitoring [13,14]. More advanced architectures, including feature pyramid networks, Mask R-CNN, and pose estimation models, have further improved detection performance under varying conditions [11]. Despite these advances, most systems rely on supervised learning, which requires labeled datasets that are scarce for rare events such as drowning [11,15]. Research in this domain remains dominated by frame-based detection approaches, with comparatively limited exploration of temporal modeling or anomaly detection strategies.

Recent work has also explored alternative sensing modalities, including underwater cameras, wearable devices, radio-frequency identification (RFID) systems, and depth-based approaches. While these modalities aim to improve robustness under challenging conditions, vision-based systems remain dominant due to their practicality and scalability [16]. Across the literature, key challenges persist, including sensitivity to environmental factors such as glare and occlusion, limited validation in real-world settings, and the absence of standardized datasets. These limitations highlight the need for a systematic synthesis of existing approaches, particularly in relation to methodological trends, evaluation practices, and deployment readiness. The evolution practices have been illustrated in Figure 1.

Methods

Goal and Review Questions

Goal of the Study

The main goal of this study was to systematically map, review, and synthesize studies that focused on ML-based drowning detection. This included an in-depth examination of detection models, data modalities, deployment strategies, and practical applications of these systems. The study also examined how different approaches addressed real-world challenges such as occlusion, glare, and the presence of multiple swimmers.

This study aimed to identify recent trends, coverage, and directions in drowning detection research. It also aimed to highlight key limitations related to generalizability, reliability, and privacy. These insights were intended to inform future research and support the development of robust and deployable detection systems. The protocol was defined before data collection, thereby minimizing the risk of bias in study selection and reporting. The protocol has been registered with the Open Science Framework before data collection. Details of the registered protocol may be found in [17]. This ensured absolute transparency, reproducibility, and minimized risk of bias in study selection and reporting.

Based on established guidelines for conducting systematic literature reviews and reporting findings, the selection and review process was carefully designed and documented. Based on this goal, the following review questions (RQs) were formulated and adopted.

Category 1: General RQs for the Systematic Review

The following research questions were general to all systematic literature review studies:

1. RQ 1.1. Contributions presented in the studies: What were the main contributions of the reviewed studies? This question focused on identifying whether the studies contributed through the development of models, algorithms, systems, datasets, or practical applications for drowning detection.
2. RQ 1.2. Research methods used in the studies: How were the studies categorized based on research methods? This question aimed to classify the studies based on whether they employed empirical, experimental, or hybrid approaches, given the multidisciplinary nature of drowning detection systems.

Category 2: RQs Specific to the Topic of Systematic Review

The following RQs were specific to the topic of advances in ML-based drowning detection:

1. RQ 2.1. Methods and models employed for drowning detection: What methods and models were employed for detecting drowning incidents? This question aimed to identify whether studies used classical approaches, ML models, deep learning architectures, or hybrid methods. It also examined the use of specific models such as CNNs, object detection frameworks, pose estimation, and spatiotemporal models.
2. RQ 2.2. Data modalities and feature representation: What types of data and feature representations were used in the studies? This question focused on whether studies used vision-based data, sensor-based data, or multimodal approaches. It also examined how spatial, temporal, and motion-related features were represented and used for detection.
3. RQ 2.3. Types and sources of datasets: What datasets were used in the studies? Were they primary datasets collected by researchers or secondary datasets obtained from existing sources?
4. RQ 2.4. Evaluation metrics and reported performance: What evaluation metrics and performance measures were reported? This question examined metrics such as accuracy, precision, recall, F_1-score, false alarm rate, and latency. It aimed to compare the effectiveness of different models and assess consistency in reporting.
5. RQ 2.5. Real-time capability and deployment: Were the proposed models capable of real-time detection, and were they deployed in practical settings? This question evaluated whether systems were implemented in real-world environments such as swimming pools, surveillance systems, or embedded devices, and how they handled operational constraints.
6. RQ 2.6. Handling of real-world challenges: How did the studies address real-world challenges such as occlusion, glare, lighting variability, and multiple swimmers? This question examined whether the models were robust under complex and dynamic conditions.
7. RQ 2.7. Generalizability and external validation: To what extent did the studies evaluate generalizability? This question assessed whether models were tested across different datasets, environments, or populations, and whether external validation was performed.

XSL•FO
RenderX

8. RQ 2.8. Privacy and data security considerations: How did the studies address privacy and data security? This question examined whether privacy-preserving approaches, such as federated learning, were used or discussed.
9. RQ 2.9. Limitations and risk of bias: What limitations and risks of bias were identified in the studies? This question focused on issues related to data quality, study design, lack of validation, and incomplete reporting, as observed in the risk of bias assessment.

Search Strategy

To ensure transparency and completeness in our systematic review, we followed PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines for conducting systematic literature reviews as outlined by relevant studies. Our search spanned 6 databases, covering literature from 2012 to 2025, with the aim of identifying relevant articles on the methodologies, deployment strategies, and practical applications in drowning detection. Records published between 2012 and 2018 were identified during the search but did not meet the study's inclusion criteria at the full-text screening stage, primarily because they described rule-based or handcrafted-feature detection approaches rather than ML-based systems, and were therefore excluded under the exclusion criterion. All 30 included studies fall within the 2019 to 2025 period, consistent with the rapid emergence of deep learning–based approaches in this field during that time.

The databases used for this review include IEEE Xplore, Web of Science Core Collection, Scopus, PubMed, ACM Digital Library, and Google Scholar. The databases and full search terms are provided in Multimedia Appendix 1. The search strings were developed and structured using the PICO framework, which considers the Problem, Intervention, Comparison, and Outcome components (Multimedia Appendix 2) [18]. It was designed to address the overarching question: "Can advanced ML methodologies enhance drowning detection and improve real-time response in water environments?" We tailored the PICO structure as follows:

1. Comparison: Due to the specificity of our research objectives, direct comparison studies were not applicable in this context.
2. Outcome: We sought outcomes related to accuracy, deployment, and practical applications of drowning detection methodologies, incorporating terms such as "accuracy" OR "precision" OR "recall" OR "F_1-score" OR "false alarm rate" OR "real-time" OR "deployment" OR "latency."

By employing "AND" and "OR" operators, we formulated a general search phrase:

- ("drowning detection" OR "drowning recognition" OR "swimmer distress" OR "near-drowning" OR "water safety monitoring") AND ("machine learning" OR "deep learning" OR "computer vision" OR "neural networks" OR "YOLO" OR "CNN" OR "LSTM" OR "pose estimation") AND ("accuracy" OR "precision" OR "recall" OR "F_1-score" OR "false alarm rate" OR "real-time" OR "deployment" OR "latency")

Eligibility Criteria

The eligibility criteria for inclusion were established to comprehensively evaluate studies that focused on ML-based drowning detection. The criteria considered a wide range of methodologies, data modalities, and application contexts. They were carefully designed to ensure the inclusion of studies aligned with the objectives of this review.

The studies were evaluated to determine whether they addressed key aspects of drowning detection, including detection methods, deployment strategies, real-time capabilities, and practical applications. Emphasis was placed on studies that examined challenges such as occlusion, lighting variability, and multiswimmer environments. The criteria also ensured the inclusion of studies that contributed to understanding trends, limitations, and future research directions in drowning detection.

Initial Screening

During this preliminary phase, articles identified through database searches and manual exploration underwent early screening based on titles and abstracts. The aim was to ensure that the screened studies aligned with the goal of systematically reviewing ML-based drowning detection.

Emphasis was placed on filtering out irrelevant studies and identifying those contributing to the analysis of detection methods, data modalities, deployment strategies, performance evaluation, and practical applications. Studies not related to drowning detection or not involving computational or ML approaches were excluded at this stage.

Adherence to established systematic review practices ensured comprehensive documentation of the selection process. This supported the formulation of the research questions and the synthesis of findings.

Inclusion and Exclusion

Out of 4927 search results, a total of 30 studies were included for review. Studies that were included had to fulfill the following criteria: (1) studies that focused on ML-based drowning or swimmer distress detection, (2) studies that detailed the methodologies or models used for detection, and (3) studies that clearly defined evaluation metrics, deployment strategies, or practical applications of drowning detection techniques.

To ensure precise and robust findings, this study used exclusion criteria guided by specific thematic considerations. (1) Irrelevant topics: literature investigating other aspects of aquatic monitoring not related to drowning or distress detection. (2) Incomplete focus: studies focused solely on other processing tasks, such as preprocessing or noise reduction, without subsequent detection or classification. (3) Lack of technological interventions: literature that did not apply ML, computer vision, or related computational approaches, such as studies focusing purely on theoretical or descriptive aspects without implemented detection systems. (4) Insufficient application: literature that only described swimmer behavior, features, or observations without using them in detection models. (5) Limited scope: studies that focused solely on general surveillance, swimmer tracking, or water safety without addressing drowning or distress detection. (6) Non-English publications: studies that were not

XSL•FO
RenderX

available in English due to language proficiency constraints of the review team.

A 2-stage screening process was used to ensure thoroughness and reduce the bias arising. Two reviewers independently screened all titles and the corresponding abstracts in the first step to assess relevance based on the inclusion criteria. Afterward, the papers were advanced to the next stage if and when at least 1 reviewer deemed them relevant. In cases where consensus at the title and abstract level could not be achieved between the 2 reviewers, an adjudication by a third person was sought on a consultation basis and on the purpose. During the second stage, 2 independent reviewers performed a full-text blind review. Consensus was obtained through deliberation between reviewers when required. Consensus meetings were held to resolve any disagreements and uncertainties. The objectivity of the criteria was assessed through reviewer agreement during the screening stages. The study selection process is presented in Figure 1.

Data Synthesis and Comprehensive Analytical Approach

In alignment with the RQs, the following information points were recorded and analyzed: (1) year of publication, (2) contribution of each study, (3) categorization of each study based on research approach, (4) ML methods and model architectures, (5) data modalities employed (eg, red, green, and blue [RGB] video, underwater video, sensor-based, or multimodal data), (6) deployment characteristics including real-time capability and hardware requirements, (7) practical application settings (eg, swimming pools, open water environments, surveillance systems), (8) reported performance metrics such as accuracy, precision, recall, F_1-score, false alarm rate, and latency, and (9) challenges addressed, including occlusion, lighting variability, multiswimmer environments, and viewpoint variation.

Tables and graphical summaries were developed to synthesize these information points, providing a comprehensive overview of advancements in drowning detection methods, system design, and real-world applicability. The temporal distribution of publications indicated a growing research interest in recent years, reflecting the increasing importance of automated drowning detection systems and the advancement of ML techniques in safety-critical environments. Meta-analysis was not undertaken because the included studies were heterogeneous in model, evaluation metrics reported, dataset type, and study design. This degree of methodological and outcome heterogeneity precluded meaningful statistical pooling, consistent with PRISMA guidance favoring narrative and tabular synthesis under such conditions [19].

Quality Assessment

The objective of this quality assessment was to evaluate the significance and validity of each selected document in the context of ML-based drowning detection. Although the quality rating did not significantly influence the selection of the primary studies, the assessment aimed to reflect the overall validity and reliability of the included studies.

The TRIPOD (Transparent Reporting of a Multivariable Prediction Model for Individual Prognosis or Diagnosis) [20] standard was employed as a measure of reporting quality. Each article was scored based on adherence to the TRIPOD checklist, with binary scores assigned as either 1 (compliant) or 0 (noncompliant). Moreover, all reviewed studies were expected to meet a minimum threshold of reporting quality to ensure clarity and reproducibility. A detailed checklist of the TRIPOD assessment is provided in .

The TRIPOD checklist was used to evaluate the reporting clarity and comprehensiveness across all selected studies. Each study was assessed based on key TRIPOD components, including data description, model development, validation procedures, and reporting of results. The assessment highlighted variability in reporting practices across studies, particularly in relation to external validation, dataset transparency, and performance metric reporting. Overall, the application of TRIPOD ensured a structured evaluation of reporting quality and supported the reproducibility of the findings.

The study additionally employed the PROBAST (Prediction Model Risk of Bias Assessment Tool) to assess the risk of bias in the included studies [20]. Each study was scored across 5 core TRIPOD reporting domains: Title/Abstract, Introduction, Methods, Results, and Discussion, rather than scoring each of the checklist's individual items separately. Each domain was scored as 1 (adequately reported) or 0 (not adequately reported), yielding a total domain-level score out of 5 per study; this approach was adopted to provide a tractable, reproducible summary measure of reporting quality across a heterogeneous set of study designs, while a detailed item-level checklist is provided in Checklist 1 [21]. The PROBAST framework was considered appropriate given the predictive modeling nature of drowning detection systems. It is acknowledged that PROBAST and TRIPOD were originally developed for clinical multivariable prediction models used for individual prognosis or diagnosis, and that applying them to computer vision object detectors, including YOLO variants, Mask R-CNN, and wearable sensor systems, represents an extension beyond their original scope. This extension was considered justified because the included studies, despite differing in architecture, share the core structure of a prediction model. They take input data such as images, video frames, or sensor signals and output a binary or probabilistic prediction (drowning vs nondrowning), which is the fundamental unit of analysis PROBAST and TRIPOD were designed to appraise. Domain-specific tools for AI/ML diagnostic studies, such as Quality Assessment of Diagnostic Accuracy Studies 2 (QUADAS-2), Checklist for Artificial Intelligence in Medical Imaging (CLAIM), and CLEAR, were considered as alternatives; however, PROBAST and TRIPOD were retained because they offer the most established, validated domain structure for systematically assessing risk of bias and reporting transparency across heterogeneous prediction-model designs, and because comparable systematic reviews in adjacent safety-critical ML domains have applied the same tools. The risk of bias assessment covered 4 key domains: (1) bias related to participants and datasets, (2) bias in predictor selection and feature representation, (3) bias in outcome definition and measurement, and (4) bias in model development and analysis.

XSL•FO
RenderX

The results of the quality and risk of bias assessments were summarized in Table 1, with detailed individual evaluations provided in Multimedia Appendix 3.

Table . Risk of bias assessment (N=30).

Domain	Low risk, n (%)	Some concerns, n (%)	High risk, n (%)
Data source bias	4 (13.3)	10 (33.3)	16 (53.3)
Prediction bias	27 (90)	3 (10)	0 (0.0)
Outcome assessment bias	1 (3.3)	28 (93.3)	1 (3.3)
Analysis bias	11 (36.7)	10 (33.3)	9 (30)
Overall risk	0 (0.0)	1 (3.3)	29 (96.7)

The assessment of data source bias indicated that a substantial proportion of studies, 53.3% (16/30)**,** were considered to have a high risk of bias, largely due to reliance on limited, nonrepresentative, or synthetic datasets. A further 33.3% (10/30) of studies raised some concerns, while only 13.3% (4/30) were assessed as low risk. These findings suggest that data-related limitations remain a major challenge, potentially affecting the generalizability and robustness of the reported results.

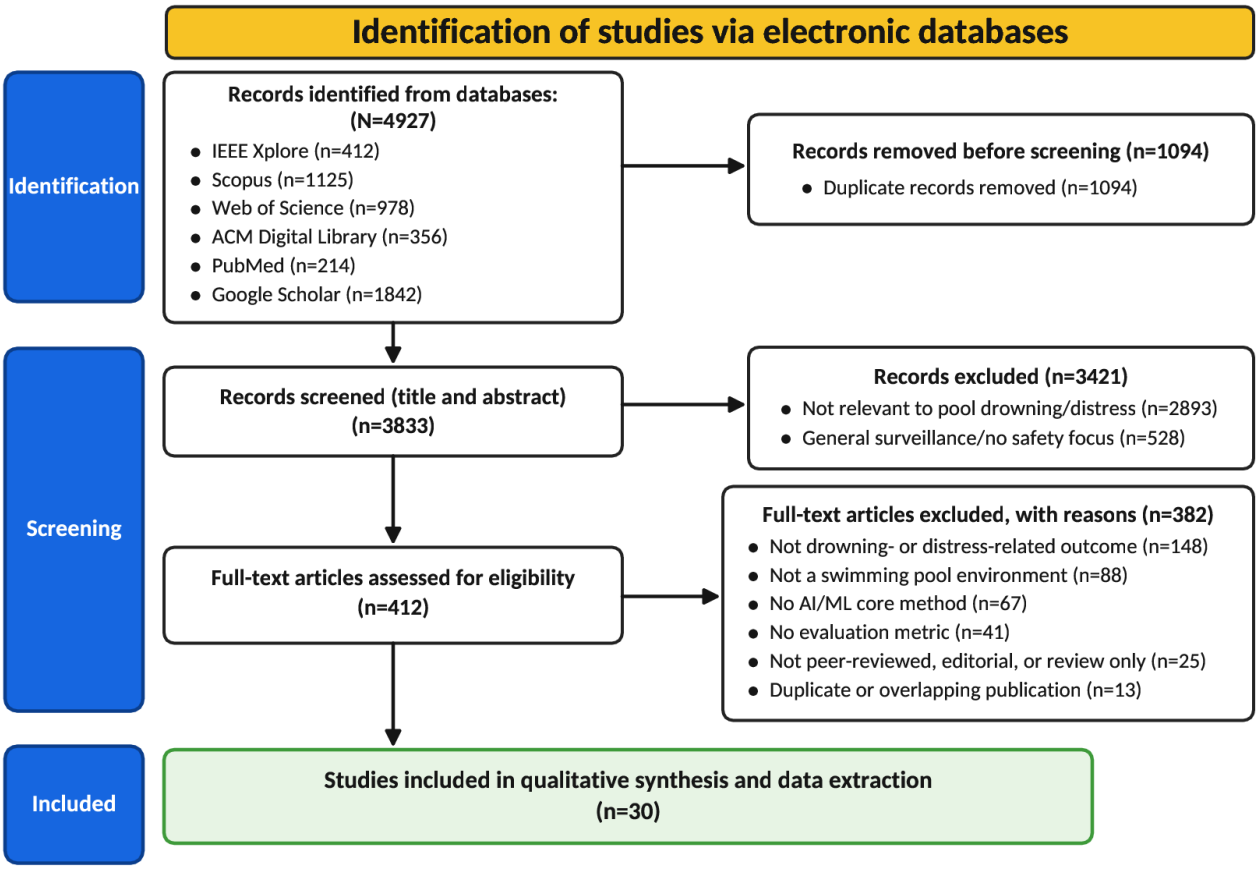
The assessment of prediction bias showed that 90% (27/30) of studies had a low risk of bias, indicating that most studies employed appropriate modeling techniques and prediction strategies. Only 10% (3/30) of studies presented some concerns, suggesting that predictive modeling approaches were generally well implemented across the reviewed literature.

The assessment of outcome assessment bias revealed a significant area of concern, with 93.3% (28/30) of studies classified as having some concerns, primarily due to inconsistencies in evaluation protocols and lack of standardized performance metrics. Only 3.3% (1/30) of studies were considered low risk, while 3.3% (1/30) were categorized as high risk. These findings indicate that outcome evaluation remains insufficiently standardized, limiting comparability across studies.

The assessment of analysis bias indicated a relatively balanced distribution, with 36.7% (11/30) of studies categorized as low risk, 33.3% (10/30) showing some concerns, and 30% (9/30) identified as high risk. This variability reflects differences in validation strategies, with several studies lacking external validation or relying on limited experimental setups, which may introduce overfitting and reduce reliability.

The overall assessment of risk of bias indicated that 96.7% (29/30) of the studies posed a high risk, while only 3.3% (1/30) showed some concerns. No studies were classified as low overall risk. These findings highlight substantial methodological limitations across the literature, particularly related to dataset quality, evaluation consistency, and real-world validation.

The TRIPOD assessment indicates generally strong reporting practices, with an average score of 4.07 (81%) out of a maximum of 5 (one point per reporting domain: Title/Abstract, Introduction, Methods, Results, and Discussion). Domain-level compliance varied substantially: Title/Abstract and Introduction were adequately reported in 100% (30/30) of studies, Discussion in 86.7% (26/30), Results in 70.0% (21/30), and Methods in only 50% (15/30), the weakest-performing domain, consistent with this review's broader finding of limited methodological transparency. Overall**,** 24 studies were classified as having high reporting quality (domain score of 4/5 or 5/5), 5 studies as having moderate reporting quality (3/5), and 1 study as having low reporting quality (2/5 or below). This suggests that most studies provided clear descriptions of model development and reported performance metrics adequately. However, important gaps remained, particularly in relation to external validation, dataset transparency, and reproducibility details. These limitations affect the interpretability and generalizability of the findings despite strong reporting compliance.



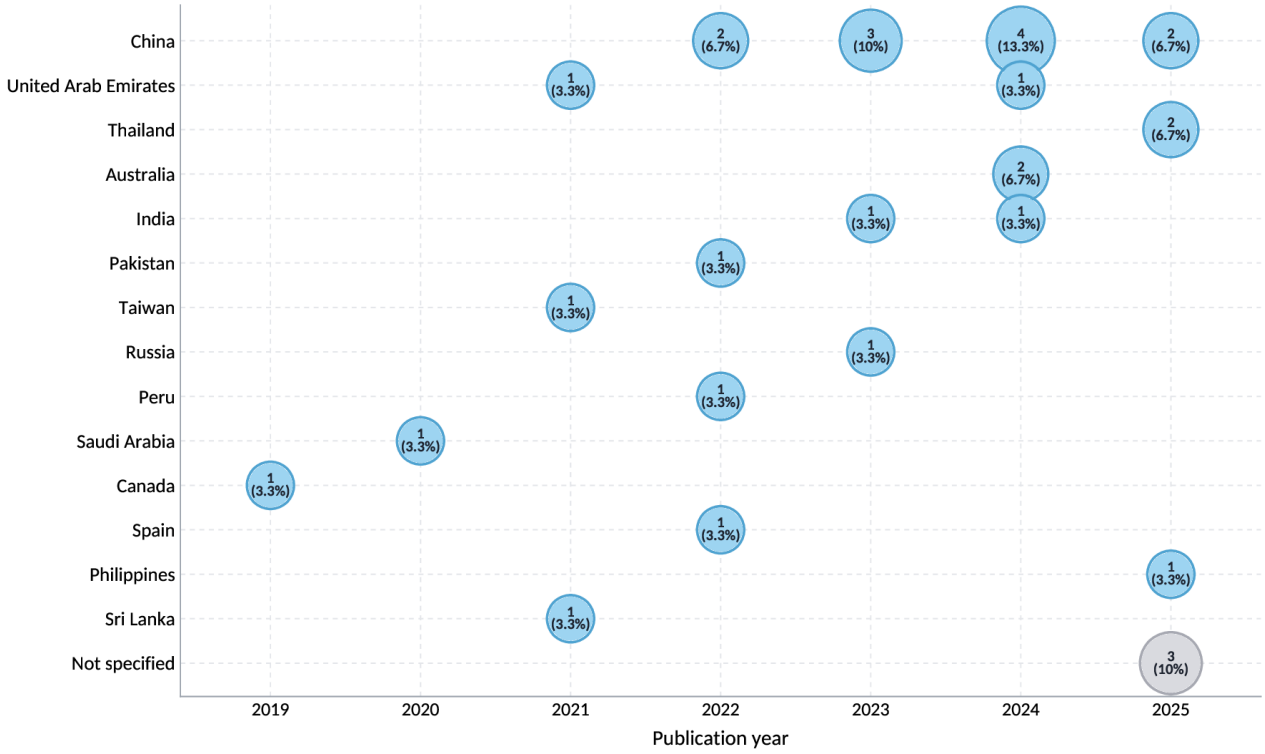
The combined risk of bias and reporting quality assessments indicate that, while the field demonstrates strong methodological progress in model development and reporting clarity, there are significant gaps in data quality, evaluation standardization, and real-world validation.

Results

The findings in this section are structured according to the classification of the reviewed studies and the key technical considerations relevant to contextualizing drowning detection systems (Figure 2).

XSL•FO
RenderX

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart. ML: machine learning.



Overview of Included Studies

A total of 30 studies published between 2019 and 2025 were included in this review. The temporal distribution demonstrates a clear and rapid increase in research activity over time. Publication output remained minimal in the early years, with 3.3% (n=1) of studies published in both 2019 and 2020, followed by a sharp increase in subsequent years and peaking in 2024. This trend reflects the accelerating interest in ML-based drowning detection systems, particularly in recent years.

Geographically, research output was highly concentrated. China accounted for 36.7% (11/30) of the included studies, emerging as the dominant contributor. This was followed by the United Arab Emirates, Thailand, Australia, and India, each contributing 6.7% (2/30). Nine additional countries, Saudi Arabia, Canada, Spain, Sri Lanka, Pakistan, Taiwan, Russia, Peru, and the Philippines, each contributed a single study (3.3%). The dataset's country of origin could not be determined for 3 (10%) studies, and one additional study was a China and Pakistan collaboration counted toward both countries, which is why the percentages sum to slightly more than 100%. As illustrated in Figure 3, the recent surge in publications is largely driven by contributions from China across 2023 to 2025.

XSL•FO
RenderX

Figure 3. Distribution of included studies by country and publication year. Bubble size represents number of studies; labels show study count and percentage of total studies (N=30).

These findings indicate that while the field is rapidly expanding, it remains geographically concentrated. This concentration suggests that current advancements are shaped by regions with greater access to technological infrastructure and data resources. The diversity of environmental contexts represented in the literature remains limited, raising concerns about the generalizability and real-world applicability of existing drowning detection systems.

Methodological Approaches

The methodological landscape of the included studies was heavily dominated by detection-oriented approaches, which accounted for 70% (21/30) of all studies. Systems combining detection with early warning mechanisms represented 10% (3/30), while classification or recognition-based approaches constituted only 6.7% (2/30). Other methodological paradigms, including pose-based detection, anomaly-assisted detection, multimodal systems, and dataset-focused studies, were each represented by 3.3% (1/30) of the included studies. This distribution highlights a strong emphasis within the literature on direct event detection and real-time alert generation, reflecting the practical importance of timely intervention in drowning scenarios [10,22,23]. However, it also reveals a relative underrepresentation of approaches focused on behavioral modeling, temporal dynamics, and probabilistic inference, which are critical for capturing the progressive and often subtle nature of drowning events.

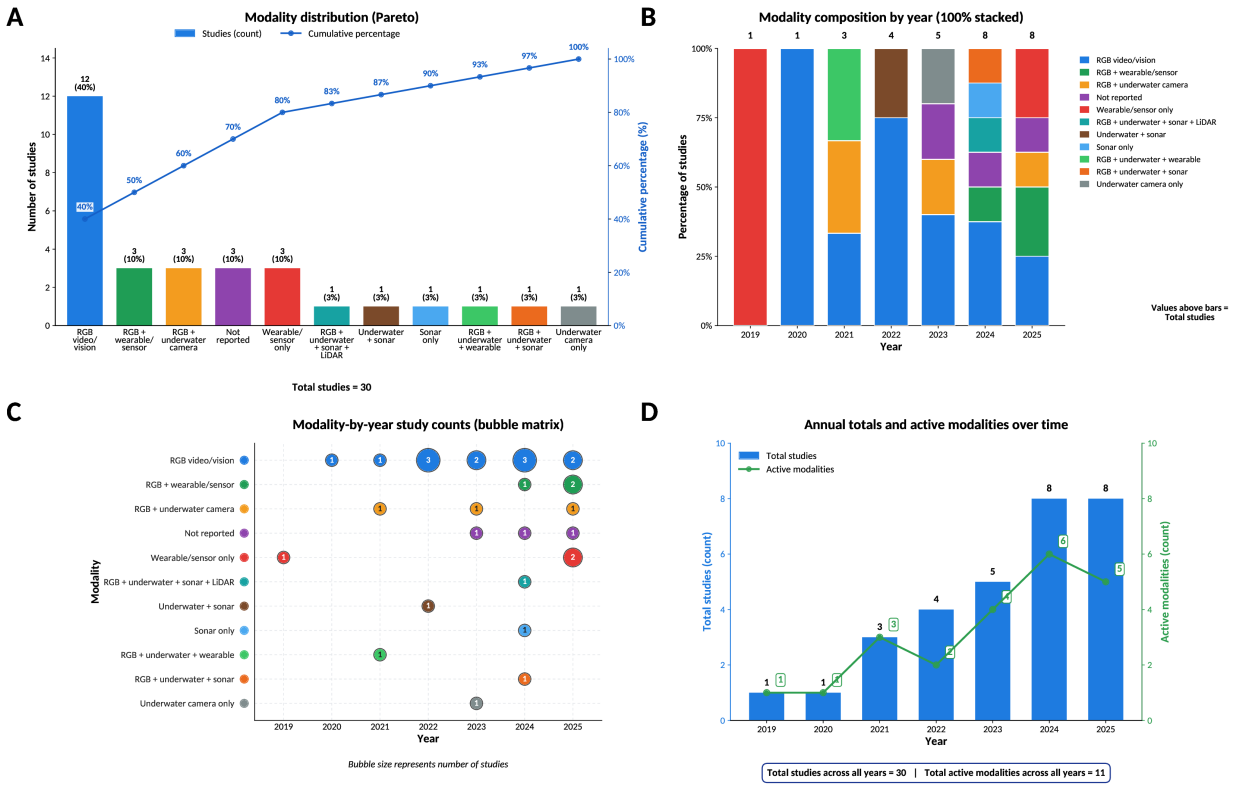
Despite the predominance of detection-based methods, most studies addressed only a limited subset of real-world operational challenges. In particular, key issues such as crowd density and multiswimmer interactions, as well as class imbalance arising from the rarity of true drowning events, were rarely incorporated into model design or evaluation frameworks [24]. Additionally, environmental distortions, including underwater visibility challenges, were predominantly handled in studies specifically tailored to underwater settings [15,25]. This suggests that robustness in current systems is often context-specific rather than generalizable across diverse aquatic environments.

Learning Paradigms and Model Architecture

Supervised learning overwhelmingly dominated the methodological landscape, accounting for 96.7% (29/30) of the included studies. Only a single study (1/30, 3.3%) employed a semisupervised anomaly detection framework, highlighting the limited exploration of alternative learning paradigms such as unsupervised or self-supervised approaches [26].

In terms of model architecture, the YOLO family of object detection models emerged as the most frequently utilized, appearing in 23.3% (7/30) of studies. This included variants such as YOLOv5, YOLOv7, YOLOv8, and YOLOv5n, reflecting the field's strong preference for real-time, detection-oriented pipelines. Generic CNN architectures were also widely used, accounting for 16.7% (5/30) of studies. Similarly, 16.7% (5/30) of studies reported the use of deep learning approaches without clearly specifying the underlying architecture, indicating a lack of transparency in model reporting.

Other architectures were less frequently represented and included Mask R-CNN, feature pyramid networks, transfer learning–based systems, neural network–based classifiers, YOLOv8-Pose, and YPMNet, each contributing 3.3% (1/30) of the total studies [7,27]. Notably, 20% (6/30) of studies did not provide sufficient detail regarding their model architecture.



XSL•FO
RenderX

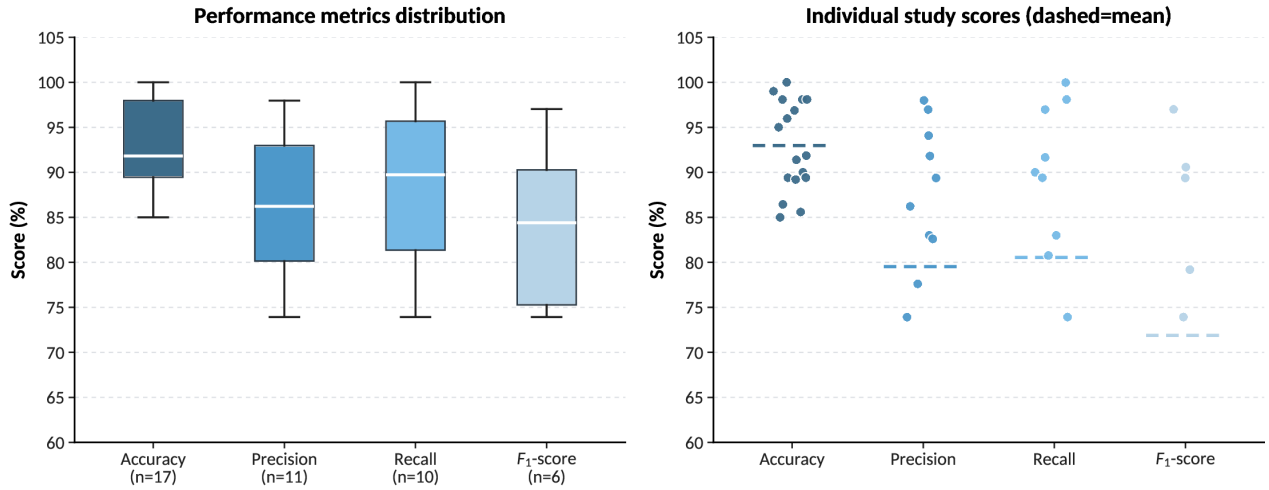
Sensing Modalities

RGB video was the most prevalent sensing modality, used either alone in 40% (12/30) of the included studies or in combination with one or more additional modalities in a further 30% (9/30) of studies (6 studies paired RGB video with either wearable/sensor data or underwater camera footage; 3 studies combined RGB video with two further modalities, underwater camera plus wearable sensing, sonar, or sonar and light detection and ranging).

Non-RGB sensing modalities were used in a further 20% (6/30) of studies: wearable or smartphone-based sensing alone (n=3), underwater camera alone (n=1), sonar alone (n=1), and underwater camera combined with sonar (n=1). The sensing modality could not be determined for the remaining 10% (n=3), as shown in Figure 4.

Figure 4. Distribution of sensing modality over time. LiDAR: light detection and ranging; RGB: red, green, and blue.

These findings indicate that the field is heavily dominated by vision-based modalities, particularly RGB and underwater imaging [13,28]. In contrast, multimodal and sensor-fusion approaches remain underexplored [29]. Notably, robustness to underwater distortion appears largely confined to systems explicitly designed for underwater environments, reinforcing the modality-specific nature of current solutions and highlighting a gap in generalizable, cross-modal detection frameworks [16].



Performance Metrics

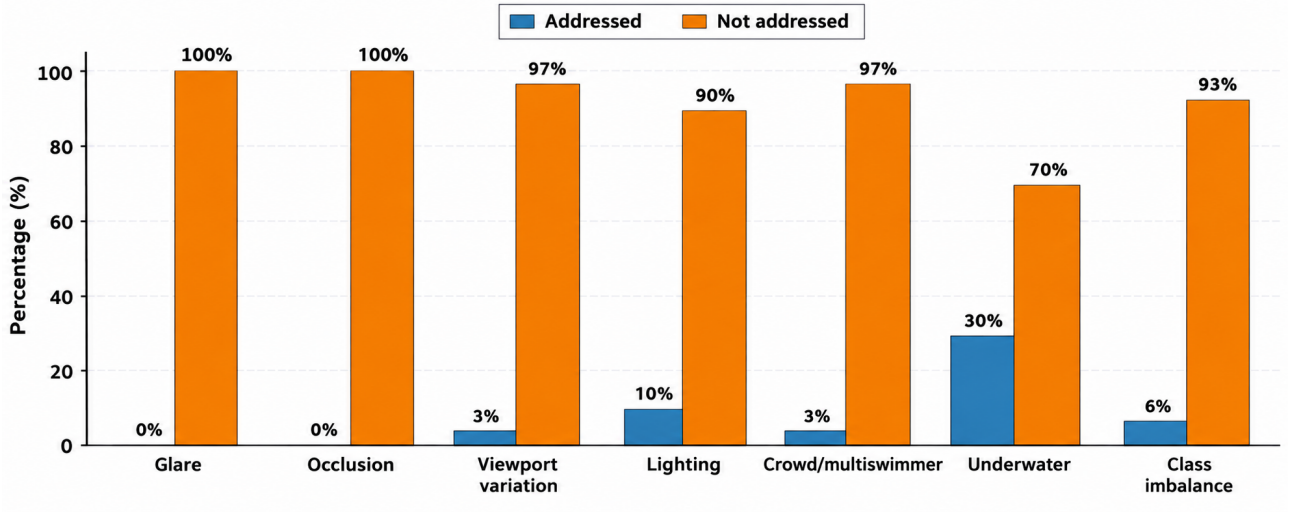
Accuracy was the most frequently reported evaluation metric, appearing in 56.7% (17/30) of the included studies. Among these studies, the mean reported accuracy was 90.9%, with a median of 90%, and values ranging from 72.17% to 100%. The highest reported accuracies included 100%, 99.4%, and 99%, indicating generally strong classification performance across studies.

Precision was reported in 36.7% (11/30) of studies, with values ranging from 73.91% to 98%**,** while recall was reported in 33.3% (10/30). In contrast, F_1-score and related classification metric negative trade-offs were reported inconsistently, limiting direct comparability across studies as shown in Figure 5.

XSL•FO
RenderX

Figure 5. Reported performance metrics distribution.

Overall, the metric profile of the field is heavily centered on accuracy, despite drowning being a rare event relative to normal swimming activity. This imbalance raises concerns about the adequacy of accuracy as a standalone metric. The limited and inconsistent reporting of precision, recall, and F_1-score constrains the ability to evaluate false positive and false negative trade-offs, which are critical factors for real-world deployment.



Operational performance metrics were notably scarce. Latency was reported in only 3.3% (1/30) of studies, while frame rate was reported in 20% (6/30), with values including 118.6 FPS, 31 FPS, 30 FPS, 22.9 FPS, and 5 FPS. This suggests that the literature remains largely focused on classification performance, with limited emphasis on real-time feasibility and deployment constraints.

Real-Time Capability and Validation

A total of 46.7% (14/30) of the included studies reported real-time capability. However, only 3.3% (1/30) provided empirical validation demonstrating both real-time performance and evaluation under real-world operational conditions.

The remaining 43.3% (13/30) of studies claimed or implied real-time operation without providing sufficient validation evidence, while 53.3% (16/30) made no reference to real-time capability, as shown in Figure 6.

Figure 6. Real-world challenges addressed by studies.

This gap between reported capability and validated performance is further reflected in the limited reporting of operational metrics. Latency and frame rate (FPS) were inconsistently documented across studies, restricting the ability to assess whether proposed systems meet real-time deployment requirements. These findings indicate that while real-time detection is frequently presented as a core objective, it remains largely unverified in practice.

Dataset Description and Reporting Practices

The reporting of dataset characteristics across the included studies was limited and inconsistent, raising concerns about transparency and reproducibility. A substantial majority of studies, 80% (24/30), did not clearly specify whether their datasets were real, simulated, or synthetic. Only 16.7% (5/30) explicitly reported the use of real-world data, while 3.3% (1/30) used simulated data.

XSL•FO
RenderX

This lack of clarity limits the ability to assess the ecological validity of reported performance outcomes and undermines confidence in how well these systems would generalize to real-world settings [25].

In addition, all studies reviewed relied exclusively on private datasets, with no use of publicly available benchmark datasets. The absence of shared datasets restricts comparability across studies and significantly limits reproducibility, both of which are critical for advancing the field.

Sample size reporting was also inconsistent. A total of 43.3% (13/30) of studies did not report sample size. Among those that did, there was substantial variability, ranging from as few as 17 samples to as many as 8572 images, indicating a lack of standardization in dataset scale and evaluation practice (Table 2).

XSL•FO
RenderX

Table . Summary table.

Method category	Representative approaches	Key achievements	Key limitations (as reported in studies)
Object detection (YOLO[a]-based)	YOLOv5, YOLOv7, YOLOv8, YOLOv8-Pose [23,27,29-32]	Achieved high detection performance, for example, accuracy up to 98%, high mean average precision values, demonstrated suitability for real-time detection; strong object localization capabilities	Several studies explicitly reported reliance on self-collected datasets and lack of external validation; key limitations include absence of false alarm rate reporting, limited real-world evaluation, and generalizability concerns
CNN[b]-based	CNN, Mask R-CNN[c], ResNet-based models [22,33-40]	Demonstrated strong classification performance (85%-96% accuracy); effective spatial feature learning; widely adopted for drowning recognition tasks	Studies reported lack of real-world deployment, small or simulated datasets, and absence of comprehensive evaluation metrics (eg, AUC[d], latency); limitations also include restricted generalizability across environments
Pose-based detection	YOLOv8-Pose, pose estimation methods [31,41,42]	Improved representation of human posture and motion; enhanced interpretability of drowning-related behaviors	Reported limitations include sensitivity to occlusion, difficulty handling multiple swimmers, and lack of real-world testing scenarios; studies also note limited evaluation datasets
Underwater computer vision	Underwater CNNs, YOLO-based underwater models [16,42-44]	Achieved high accuracy in underwater datasets (up to ~96%); effective handling of underwater distortion and visibility conditions	Studies reported limited applicability outside underwater settings, lack of cross-environment validation, and restricted dataset diversity; also noted absence of real-time validation in practical settings
Temporal/spatiotemporal models	Temporal anomaly detection, motion-based models [25,33]	Capture temporal dynamics of drowning behavior; suitable for detecting abnormal motion patterns over time	Reported limitations include computational complexity, lack of standardized evaluation metrics, and limited validation on real-world continuous video streams; also insufficient reporting of latency and deployment feasibility
Multimodal systems	Vision+LiDAR[e]/multimodal fusion [29]	Improved robustness through sensor fusion; enhanced contextual understanding; potential to reduce false positives	Study explicitly reported system complexity, lack of large-scale evaluation, and absence of real-world deployment validation; also noted limited benchmarking against standard vision-based approaches
Sensor-based/wearable systems	RFID[f], wearable devices, embedded sensing [33,41,45-48]	Robust to visual challenges such as glare and occlusion; enables continuous monitoring independent of camera systems	Studies reported very small sample sizes, limited scalability, and dependency on user compliance; also lack of comprehensive performance evaluation metrics and absence of real-world deployment validation
Anomaly detection/semisupervised learning	Semisupervised and anomaly-based models [13,49]	Suitable for rare-event detection; reduces reliance on labeled drowning data; captures deviations from normal swimming patterns	Reported limitations include lack of interpretability, absence of standardized evaluation benchmarks, and limited comparative analysis with supervised methods; also minimal real-world validation

Table 3 summarizes the reported accuracy across the ML architecture categories included in this review. Mean reported accuracy ranged from 85.7% for YOLO-based approaches to 100% for the RFID-based approach. However, the latter was based on a single study with a small sample size. Similarly, the R-CNN–based and underwater computer vision categories each comprised only one study. Overall, the findings indicate that a range of ML approaches have achieved high reported accuracies, although direct comparisons should be interpreted with caution because the studies were conducted using different datasets and evaluation settings. The studies differed in ML architectures, sensing modalities (vision, sonar, RFID, and multimodal systems), datasets, evaluation protocols, and reported performance metrics. In addition, accuracy was the only performance metric reported consistently across a sufficient number of studies, whereas precision, recall, F_1-score, and inference latency were reported inconsistently. Consequently, a descriptive synthesis was considered more appropriate than a statistical meta-analysis.

Table . Summary of reported accuracy by machine learning architecture.

Method category	Studies, n	Studies reporting accuracy, n	Accuracy range, %	Mean reported accuracy, %
YOLO[a]-based	7	4	72.2 - 98.1	85.7
CNN[b]-based	5	3	85.6 - 96	93.5
Pose-based	2	2	89.4 - 95	92.2
Sonar-based	2	2	82 - 99.4	90.7
Multimodal (vision+sensor)	2	2	85 - 90	87.5
R-CNN–based	1	1	94.1	94.1
RFID[c]-based	1	1	100	100
Underwater computer vision (device-based)	1	0	Not reported	—[d]
Architecture not clearly specified	9	2	89.4 - 99	94.2

[b]CNN: convolutional neural network.

[c]RFID: radio-frequency identification.

[d]Not applicable.

Discussion

Overview of Key Findings

This review synthesizes current evidence on ML-based drowning detection and highlights both methodological progress and critical limitations. The findings show that the field is dominated by detection-based systems using supervised learning, with CNN and YOLO-based visual architectures being the most commonly adopted approaches [8,11,22]. Reported performance is generally high, particularly in terms of accuracy; however, evaluation practices are heavily skewed toward this single metric, with limited reporting of precision, recall, latency, and false alarm rates.

In addition, most systems are developed and evaluated using private datasets under controlled conditions, with minimal real-world validation and no evidence of external or cross-dataset testing [24,28]. Real-world challenges such as glare, occlusion, and crowding are rarely incorporated into evaluation frameworks, and multimodal approaches remain limited [25,33]. Together, these findings indicate that while methodological development is advancing, evidence of real-world reliability remains insufficient.

Methodological Patterns and Evaluation Limitations

The dominance of detection-oriented, supervised learning systems suggests that the field has converged around a relatively narrow set of approaches. While these methods have demonstrated strong performance, this convergence may limit innovation and reduce the ability of systems to capture the complexity of drowning behavior, which is inherently subtle and temporally dynamic [13,49,50].

Only one of the 30 included studies evaluated vision-language models (VLMs), specifically contrastive language-image pretraining and bootstrapping language-image pretraining for swimmer-behavior question answering with light detection and ranging depth data, while the remaining studies used CNN- and YOLO-based architectures. This suggests that VLMs are still underrepresented in the current literature and warrant further investigation for real-time drowning detection.

At the same time, evaluation practices reveal a critical limitation. Accuracy remains the most frequently reported metric, despite drowning detection being a rare-event problem where false positives and false negatives have serious consequences [43]. Other key metrics, including precision, recall, F_1-score, latency, and frame rate, are inconsistently reported. As a result, many systems demonstrate strong classification performance without

XSL•FO
RenderX

providing sufficient evidence of operational effectiveness, particularly in terms of timely detection and false alarm control.

Research-to-Deployment Gap and Real-World Robustness

A central finding of this review is the persistent gap between laboratory performance and real-world readiness. Although many studies claim real-time capability, only a very small number provide validation under real-world conditions, and none report external or cross-dataset evaluation. This discrepancy arises because real-time performance is typically assessed using inference speed (eg, frames per second or latency) on offline video datasets rather than end-to-end system performance, which includes alert generation, communication, and rescue response under operational conditions [13,33,45,49,51]. As a result, high inference speed alone does not guarantee effective real-world deployment. Similar challenges have been observed in other safety-critical domains, where staged validation frameworks have been adopted to bridge the gap between laboratory performance and operational use. For example, autonomous vehicle perception systems undergo progressive evaluation through simulation, controlled environments, and supervised real-world testing before deployment, while AI-based medical devices require prospective real-world validation before regulatory approval. In contrast, drowning detection research lacks an equivalent validation framework. Establishing standardized deployment-oriented evaluation protocols, such as supervised pilot studies with lifeguard oversight, would improve the translation of laboratory findings into reliable real-world systems.

This gap is further reinforced by the limited consideration of real-world challenges in model development and testing. Key disturbances such as glare, occlusion, crowding, and viewpoint variation are rarely addressed, despite being common in operational environments. Even when specific challenges are considered, they are often handled in isolation rather than as part of a comprehensive robustness framework.

In addition, the dominance of RGB and underwater vision systems reflects practical advantages but also highlights limitations in robustness, particularly when modalities are evaluated independently [24,28,33,34]. The limited adoption of multimodal approaches suggests that the field has not yet fully leveraged strategies that could improve detection across diverse and challenging conditions. One potential barrier is the lack of a standardized, publicly available multimodal benchmark dataset. Collecting synchronized RGB video, underwater imagery, sonar, and sensor data requires considerably more infrastructure and resources than single-camera studies, forcing individual research groups to develop their own datasets. Similar challenges were observed in autonomous driving before the release of synchronized multimodal benchmarks, such as the Waymo Open Dataset [52], which substantially accelerated multimodal perception research by providing shared, standardized datasets. Developing a comparable benchmark for drowning detection, even in a controlled swimming pool environment with synchronized RGB, underwater, and sensor data, could lower barriers to research, improve comparability across studies, and accelerate the development of robust multimodal detection systems.

Reproducibility, Ethics, and Future Research Directions

The review also identifies significant challenges related to reproducibility and data transparency. All included studies relied on private datasets, and many did not clearly report dataset characteristics such as sample size or data type [28,49,51]. This lack of standardization limits comparability across studies and hinders independent validation, indicating that advances in model development have not been matched by progress in evaluation infrastructure.

Privacy and ethical considerations also remain underaddressed, despite their importance for real-world deployment. Only a minority of studies explicitly discussed privacy concerns, even though many systems rely on continuous visual monitoring in sensitive environments [25]. Nonvisual sensing approaches may offer more privacy-preserving alternatives and should be explored further.

Future research should prioritize the development of standardized evaluation frameworks, public benchmark datasets, and external validation protocols. In addition, greater emphasis is needed on comprehensive performance reporting, incorporation of real-world challenges, multimodal system design, and privacy-aware methodologies. Addressing these gaps will be essential for translating current advances into reliable and deployable drowning detection systems. Beyond the single VLM-based study identified, general-purpose VLMs such as Gemini, MiniCPM-V, and the Qwen-VL series remain largely unexplored for drowning detection. Given their strong zero- and few-shot capabilities, they represent a promising direction for future research. However, their suitability for real-time, safety-critical deployment remains unverified due to their high computational demands and the lack of benchmarking on inference latency and false alarm rates.

Conclusion

This review demonstrates that while ML has achieved remarkable progress in drowning detection, current systems remain largely experimental and fall short of real-world reliability. The widespread reliance on curated datasets, limited external validation, and inconsistent evaluation practices exposes a critical gap between reported performance and practical deployment. Bridging this gap demands a shift toward rigorous validation, standardized evaluation frameworks, and robust, privacy-aware, real-time systems. Advancing in this direction is not merely a technical necessity but a public health imperative, essential for translating promising innovations into scalable, life-saving drowning prevention solutions.

Abstract

Background: Digital technologies have become common in postoperative orthopedic rehabilitation. The tendency toward this adoption appeared in the past decade. However, no standard method exists to classify their functional capabilities. This absence hinders practical implementation. Clinicians currently lack a structured framework to distinguish between the functional capabilities of different digital rehabilitation technologies effectively.

Objective: This scoping review aims to map digital interventions used in postsurgical orthopedic rehabilitation to a proposed Coordination, Alignment, Motivation, and Strength (CAMS) framework and to identify research trends, functional coverage, and gaps in current evidence.

Methods: A systematic search was conducted across 5 databases: MEDLINE (via PubMed), Scopus, IEEE Xplore, Cochrane Central Register of Controlled Trials (CENTRAL), and the Physiotherapy Evidence Database (PEDro), following PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews) guidelines. Studies were mapped to the proposed CAMS framework pillars. Multiple validated appraisal tools were applied descriptively according to study design: version 2 of the Cochrane risk-of-bias tool for randomized trials (RoB 2; n=32), the Newcastle-Ottawa Scale (NOS) for observational studies (n=2), and the Methodological Index for Non-Randomized Studies (MINORS) for nonrandomized designs (n=1).

Results: A total of 35 studies met the inclusion criteria. Coordination was the most frequently addressed pillar (29/35, 83%), followed by Motivation (26/35, 74%). Alignment was addressed in 37% (13/35) of studies, while Strength was the least represented pillar (12/35, 34%). Overall, 49% (17/35) of studies were rated “low risk” overall on the primary appraisal tool, 46% (16/35) demonstrated “some concerns,” and 6% (2/35) were rated “high risk,” with performance bias identified as a consistent methodological characteristic across the corpus. Delivery models were predominantly hybrid (14/35, 40%) or home-based (13/35, 37%), with 8 studies (8/35, 23%) using an exclusively clinical model.

Conclusions: Digital health has shown a notable increase in the kinematic monitoring feature, offering effective solutions to movement quality (Coordination and Alignment) and psychological engagement (Motivation). Nevertheless, there is a consistent gap in strength-related studies, as current decentralized tools lack the capability to quantify physiological load. The next phase of innovations should be a shift to integrated 4-pillar solutions that would coordinate resistance-based training with high-precision biomechanical monitoring. The CAMS framework is proposed as an exploratory classification tool to guide future research design and technology evaluation in postsurgical digital rehabilitation.

Introduction

The Paradigm Shift Toward Decentralized Care

Traditionally, musculoskeletal rehabilitation has been localized in traditional ambulatory clinics, where it is hand-supervised and facilitated by a clinician. Nevertheless, the increasing clinical expenses, geographic access limitations, and the need for customized care have dictated a shift toward decentralized telerehabilitation. Digital health interventions have ceased to be alternative solutions, but they have already become a part of the continuum of care, helping to transform hospital-based acute recovery into independent, home-based maintenance [1]. Although this type of therapy has been rapidly adopted, there is still no standard approach to assessing the functional breadth of these tools.

Immersive Technologies: The Coordination-Motivation Axis

Gamification has transformed the engagement of patients by integrating virtual reality (VR) and augmented reality (AR). Immersive VR environments have been associated with reduced pain perception and perceived exertion during physical activity in the included literature [2], though this review's descriptive design does not establish a causal or clinical analgesic effect. AR systems, on the contrary, improve the rehabilitation experience through superimposing digital instructions directly onto the physical surroundings of the patient [3]. These technologies guide users through accurate movement paths by giving spatial-sensitive and real-time instructions. The tools are particularly efficient in the Coordination and Motivation pillars of the Coordination, Alignment, Motivation, and Strength (CAMS) structure, providing instant visual feedback required when learning a neuromuscular motor skill [4].

Markerless AI and Computer Vision: Ensuring Alignment

The invention of the markerless pose estimation using cameras has transformed alignment tracking. Contrary to wearable sensors, whose use can be affected by sensor drift or even being moved around during intense activity, AI-based computer vision measures the angles of joints and postural balance through normal smartphone cameras [5]. The technology plays a vital role in detecting compensatory movements, that is, patients use secondary muscular groups to avoid pain or weakness, thus providing the clinical quality of the rehabilitation setting in home-based unsupervised environments [6].

Robotics and the "Strength Gap"

The Strength pillar uses robotics and haptics to monitor movement quality via computer vision. Assist-as-needed strategies are used by the robotic devices to facilitate adaptive plasticity and functional recovery [7]. The high price and mechanical nature of these tools, however, tend to limit their application to the clinical environment and introduce a major technological gap in the realm of home-based strength training [8].

The CAMS Framework: A Proposed Taxonomy

Although there are numerous digital tools that provide generic activity tracking, they tend to overlook the subtle issues of clinical recovery. The CAMS framework is proposed in this review as an exploratory conceptual taxonomy to classify digital rehabilitation technologies according to the primary functional domains they address. The framework is not presented as a validated or standardized clinical tool; rather, it serves as a structured lens to support evidence mapping and gap identification. The classification of interventions based on these pillars helps us to understand whether the device just measures the quantity (eg, the number of repetitions) or the quality of recovery by means of biomechanical alignment and neuromuscular coordination. The framework positions motivation as the primary driver for adherence, ensuring that digital movement is viewed as a holistic clinical event rather than an isolated mechanical task. The rationale for selecting these 4 pillars reflects the authors' analysis of the digital rehabilitation literature: CAMS represent the functional domains most commonly and directly targetable by current digital health technologies. Other clinically relevant domains, including pain, range of motion, balance, gait function, and return to sport, are treated as downstream composite outcomes that emerge from the interplay of these 4 primary domains, rather than being directly addressed by a single technology class. This framing is the authors' conceptual contribution and is subject to empirical validation.

Methods

Study Design and Protocol Registration

This scoping review aimed to address the following question:

1. What types of digital technologies are used in postsurgical orthopedic rehabilitation?
2. How can they be classified across functional domains using the CAMS framework?
3. What research gaps exist in the functional coverage of current digital rehabilitation tools?

This study was conducted as a scoping review following the PRISMA-ScR (Preferred Reporting Items for Systematic Reviews and Meta-Analyses Extension for Scoping Reviews) guidelines [9]. A scoping review methodology was selected due to the heterogeneity of intervention types, outcome measures, and study designs, and the aim to map the breadth and characteristics of existing digital rehabilitation technologies rather than to evaluate their clinical effectiveness or synthesize outcome data. The protocol in the review was prospectively registered in the International Prospective Register of Systematic Reviews (PROSPERO) with a registration number of CRD420251062131.

Search Strategy and Information Sources

A comprehensive systematic search was conducted across 5 electronic databases, namely MEDLINE (via PubMed), Scopus, IEEE Xplore, Cochrane Central Register of Controlled Trials (CENTRAL) and Physiotherapy Evidence Database (PEDro). Web of Science was not accessible through the authors'

XSL•FO
RenderX

institutional subscriptions and was therefore not included in the search; this is acknowledged as a limitation.

The initial systematic search, conducted on December 15, 2025, identified 1078 records across the 5 databases, supplemented by 55 additional records identified through bidirectional citation tracking (Google Scholar snowballing), yielding 1133 records in total. Duplicate records were identified and removed using EndNote (Clarivate), supplemented by manual verification, reducing the total to an estimated 818 records for title and abstract screening. Searches covered literature published between January 2020 and December 2025, restricted to English-language publications. The search strategy used MeSH and free-text terms related to digital rehabilitation, orthopedic surgery, and postoperative care. The complete search strings for all 5 databases were as follows.

1. MEDLINE (via PubMed): ("telerehabilitation"[MeSH Terms] OR "Telemedicine"[MeSH Terms] OR "Mobile Applications"[MeSH Terms] OR "virtual reality"[MeSH Terms] OR "virtual rehabilitation"[tiab] OR "wearable electronic devices"[MeSH Terms] OR "augmented reality"[tiab] OR "mHealth"[tiab] OR "mobile health"[tiab] OR "digital rehabilitation"[tiab] OR "digital health"[tiab] OR "smartphone"[tiab]) AND ("orthopedic procedures"[MeSH Terms] OR "Orthopedics"[MeSH Terms] OR "arthroplasty, replacement, knee"[MeSH Terms] OR "arthroplasty, replacement, hip"[MeSH Terms] OR "anterior cruciate ligament reconstruction"[MeSH Terms] OR "rotator cuff"[MeSH Terms] OR "orthopedic rehabilitation"[tiab] OR "post-surgical rehabilitation"[tiab] OR "orthopedic surgery"[tiab]) AND ("postoperative care"[MeSH Terms] OR "rehabilitation"[MeSH Terms] OR "recovery of function"[MeSH Terms]). Filters: 2020 - 2025, English language, Human subjects.
2. Scopus: TITLE-ABS-KEY(("telerehabilitation" OR "mobile health" OR "virtual reality" OR "wearable electronic device*" OR "augmented reality" OR "mHealth" OR "digital rehabilitation") AND ("orthopedic procedure*" OR "knee arthroplasty" OR "hip arthroplasty" OR "anterior cruciate ligament reconstruction" OR "rotator cuff" OR "orthopedic rehabilitation" OR "post-surgical rehabilitation") AND ("postoperative care" OR "rehabilitation" OR "recovery of function")) AND PUBYEAR>2019 AND PUBYEAR<2026 AND LANGUAGE(english).
3. IEEE Xplore: ("telerehabilitation" OR "mobile health" OR "virtual reality" OR "wearable device" OR "augmented reality" OR "mHealth" OR "digital rehabilitation") AND ("orthopedic" OR "knee arthroplasty" OR "hip arthroplasty" OR "ACL reconstruction" OR "rotator cuff" OR "orthopedic rehabilitation") AND ("postoperative" OR "rehabilitation" OR "recovery of function"), limited to 2020 - 2025.
4. Cochrane CENTRAL: #1 telerehabilitation OR "mobile health" OR "virtual reality" OR "wearable electronic devices" OR "augmented reality" OR mHealth OR "digital rehabilitation"; #2 "orthopedic procedures" OR "knee arthroplasty" OR "hip arthroplasty" OR "anterior cruciate ligament reconstruction" OR "rotator cuff" OR "orthopedic rehabilitation"; #3 "postoperative care" OR rehabilitation OR "recovery of function"; #1 AND #2 AND #3, limited to 2020 - 2025.
5. PEDro: Advanced search conducted using the following filters: Body part=knee, hip, shoulder; Subdiscipline=orthopedics; Method=clinical trial; combined with free-text terms "telerehabilitation," "digital rehabilitation," "wearable," and "virtual reality" in the title or abstract field, limited to 2020 - 2025.

The search string provided above represents a reconstruction of the search logic applied, developed to document the conceptual scope of the original search (technology type AND orthopedic procedure AND rehabilitation or recovery outcome) for reproducibility purposes. Minor variation in exact result counts between the original search and this reconstruction may reflect index growth in MEDLINE (via PubMed) since the original search date, as well as evolving MeSH term indexing.

The CAMS framework was not used as a search term, as it is a novel taxonomy proposed in this review; rather, CAMS domain concepts informed post hoc mapping of retrieved studies. Google Scholar was used to perform bidirectional citation tracking (forward and backward snowballing), yielding 55 additional records (40 backward and 15 forward), which are documented as a separate identification source in the PRISMA-ScR flow diagram ().

Eligibility Criteria

Studies were included based on the population-concept-context (PCC) framework recommended for scoping reviews:

- Population: Adults undergoing postsurgical orthopedic rehabilitation following procedures such as anterior cruciate ligament (ACL) reconstruction, total knee or hip arthroplasty, or rotator cuff repair.
- Concept: Digital health technologies used as primary or adjunct rehabilitation tools, including VR, AR, AI-based computer vision, wearable sensors, or mobile health (mHealth) applications, and their functional classification across the CAMS domains.
- Context: Primary peer-reviewed experimental studies, including randomized controlled trials (RCTs), feasibility RCTs, prospective cohort studies, and nonrandomized controlled trials with an active comparator (which may include usual or standard care), published in English between January 2020 and December 2025, conducted in clinical, hybrid, or home-based settings. The full inclusion and exclusion criteria are presented in Textbox 1.

Studies were excluded if they involved nonsurgical populations, healthy participants, neurorehabilitation (eg, stroke), purely observational designs without an active digital intervention, or secondary research (reviews and meta-analyses). Only peer-reviewed articles published in English were included. A total of 3 studies identified during full-text review were subsequently excluded: 1 published in a nonindexed journal, 1 available only as an unpublished preprint, and 1 identified as a duplicate publication of an already-included trial. These exclusions are documented in the PRISMA-ScR flow diagram.

XSL•FO

Textbox 1. Inclusion and exclusion criteria for a scoping review of digital technologies in postsurgical orthopedic rehabilitation, covering studies published between January 2020 and December 2025. (Population-concept-context framework applied per Preferred Reporting Items for Systematic Reviews and Meta-Analyses extension for Scoping Reviews guidance.)

Inclusion Criteria

- Adults (≥18 years) undergoing postsurgical orthopedic rehabilitation following anterior cruciate ligament (ACL) reconstruction, total knee or hip arthroplasty, or rotator cuff repair
- Active digital health technology as primary or adjunct intervention (virtual reality, augmented reality, AI computer vision, wearable sensors, or mHealth application)
- Peer-reviewed experimental studies: randomized controlled trials (RCTs), feasibility RCTs, prospective cohort studies, or nonrandomized controlled trials with an active comparator (which may include usual or standard care)
- Published in English, January 2020 to December 2025
- Conducted in clinical, hybrid, or home-based settings
- Reported ≥1 functional rehabilitation outcome measurable by the digital intervention

Exclusion Criteria

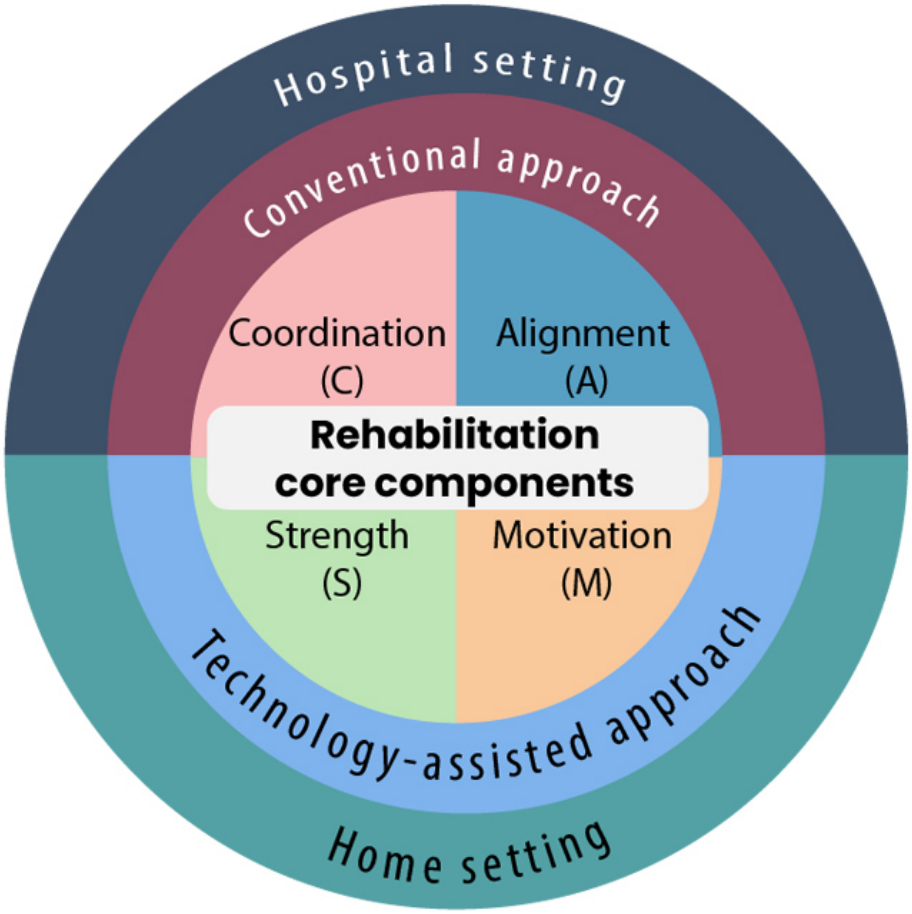
- Nonsurgical or healthy participant populations
- Neurorehabilitation populations (eg, stroke and traumatic brain injury)
- Passive or diagnostic-only technologies without an active rehabilitation component
- Secondary research (systematic reviews, meta-analyses, and narrative reviews)
- Conference abstracts, editorials, or nonpeer-reviewed grey literature
- Unpublished preprints
- Non-English language publications

Study Selection and Data Charting

Titles and abstracts were independently screened by 2 reviewers (WYC and YSL), followed by full-text assessment of potentially eligible studies. Discrepancies were resolved through discussion and consensus.

Data charting was conducted using a standardized form developed and pilot-tested by the research team prior to full extraction. Charting was performed independently by 2 reviewers (WYC and YSL), with discrepancies resolved through consensus.

The following variables were extracted: study design, patient population, type of digital intervention, rehabilitation phase, rehabilitation setting (clinical, home-based, or hybrid), anatomical focus (upper limb, lower limb, or full body), and reported outcome measures. Interventions were subsequently categorized according to the proposed CAMS framework for structured analysis.



CAMS Framework Classification

To characterize the clinical focal point of each technology, interventions were mapped to the 4 pillars of the CAMS framework (Figure 1):

- Coordination: focus on neuromuscular control, movement sequencing, and timing.
- Alignment: focus on postural integrity and the mitigation of compensatory movement patterns.
- Motivation: focus on patient engagement, adherence, and psychological involvement.
- Strength: focus on mechanical loading, resistance training, and force production.

XSL•FO
RenderX

Figure 1. The Coordination-Alignment-Motivation-Strength (CAMS) framework was applied to classify digital rehabilitation technologies in postsurgical orthopedic rehabilitation, based on 35 studies [1,3,10-42] published between 2020 and 2025.

Interventions were permitted to map to multiple CAMS domains where the digital tool addressed more than 1 functional construct (eg, an AR system providing joint angle biofeedback [Alignment] while tracking repetition speed [Coordination]). CAMS domain classification followed the same independent dual-reviewer process described above, using predefined operational coding criteria. Each reviewer (WYC and YSL) independently assigned binary codes (present or absent) to each of the 4 CAMS pillars for every included study. Overall percentage agreement across all pillar-study combinations (n=140 binary decisions: 35 studies × 4 pillars) was 94.3%, with discrepancies resolved through discussion and adjudicated by a third senior reviewer (NKL). Given the high prevalence of the Coordination pillar (29/35, 83%), Cohen kappa was not reported due to the well-documented prevalence-bias paradox [43]. The CAMS framework was applied post hoc after study selection was complete and was not used as an eligibility criterion at any stage of screening or selection. Coding in Table 1 is based on the primary intervention design and reported functional outcomes of each study; an X indicates the digital tool explicitly addressed that CAMS domain as a primary functional target.

The CAMS framework is proposed as an initial conceptual classification model to organize and interpret the functional domains targeted by digital rehabilitation technologies. As a newly proposed framework, CAMS has not yet undergone formal validation and is presented here as an exploratory tool for structured analysis. The CAMS pillars were selected because they represent key modifiable domains commonly targeted by digital rehabilitation technologies. Other clinically relevant outcomes such as pain, balance, and quality of life were intentionally treated as downstream or composite outcomes influenced by these 4 primary domains rather than independent intervention targets. It is not intended as a validated evaluative tool but rather as a structured lens to support synthesis and identify gaps in this research. Future work should focus on empirical validation of the framework across clinical and technological contexts.

Methodological Quality Appraisal

Methodological quality appraisal is optional in scoping reviews and was conducted here to characterize the methodological profile of the included studies, not as a basis for exclusion. Given the heterogeneity of study designs in the final corpus, multiple appraisal tools were applied according to study design: the Cochrane Risk of Bias 2 (RoB 2) tool was applied to all randomized controlled trials (n=32) [1,3,10-22,24-30,32-38,40-42] including feasibility RCTs across 5 domains (randomization process, deviations from intended interventions, missing outcome data, outcome measurement, and selection of reported results); the Newcastle-Ottawa Scale (NOS) was applied to prospective cohort and retrospective observational studies (n=2) [23,31]; and the Methodological Index for Non-Randomized Studies (MINORS) was applied to quasi-experimental and nonrandomized controlled trials (n=1)

XSL•FO
RenderX

[39]. PEDro scale scores were additionally reported to enable comparability with prior physiotherapy rehabilitation literature. Two reviewers (WYC and YSL) independently appraised each study, with discrepancies resolved by the same third senior (NKL) reviewer noted above. Appraisal results are summarized descriptively in Table 2 and were not used to weight or exclude studies.

Data Synthesis and Analysis

A narrative synthesis was conducted because of a high level of heterogeneity in digital modalities, intervention protocols, and outcome measures. The synthesis of findings was based on a thematic mapping approach that is congruent with the CAMS framework. Descriptive statistics were used to summarize the use of digital tools in terms of setting and anatomical targets. Temporal trends and heatmaps were used to depict how the digital orthopedic environment would evolve and identify some technological gaps in the time frame from 2020 to 2025.

Results

Overview

The initial systematic search identified 1078 records across the 5 databases, supplemented by 55 additional records identified through citation tracking, yielding 1133 records in total. The total number of records after the elimination of duplicates was an estimated 818 to be subjected to screening in relation to title and abstract. After this step, an estimated 692 records were eliminated because they failed to meet the main inclusion criteria. Among the estimated 126 reports that had been requested to be retrieved, 5 were unavailable in full text. As a result, an estimated 121 reports were mapped as being eligible.

After a rigorous full-text review, an estimated 86 studies were excluded: 32 involved nonsurgical cohorts, 26 used only diagnostic or passive technologies, 25 did not report any active functional rehabilitation outcome measurable by the digital intervention (eg, range of motion, gait parameters, adherence, strength, or patient-reported functional outcomes), and 3 were excluded following post hoc eligibility verification (1 published in a nonindexed journal; 1 an unpublished preprint; 1 duplicate publication). In total, 35 studies [1,3,10-42] met all inclusion criteria and were included in the final synthesis, representing an inclusion rate of 3.1% (35/1133). This rate is consistent with and higher than comparable reviews in the digital rehabilitation field: a systematic review of digital home rehabilitation for stroke survivors reported 0.13% (13/9873) [44], and a scoping review of AI-driven virtual rehabilitation reported 0.38% (13/3458) [45]. The CAMS framework was applied post hoc after study selection was complete and was not used as an eligibility criterion at any stage of the screening or selection process. The PRISMA-ScR flow diagram (Figure 2) describes the full selection process.

[a]C: coordination.

[b]A: alignment.

[c]M: motivation.

[d]S: strength.

[e]Not applicable.

[f]ACL: anterior cruciate ligament.

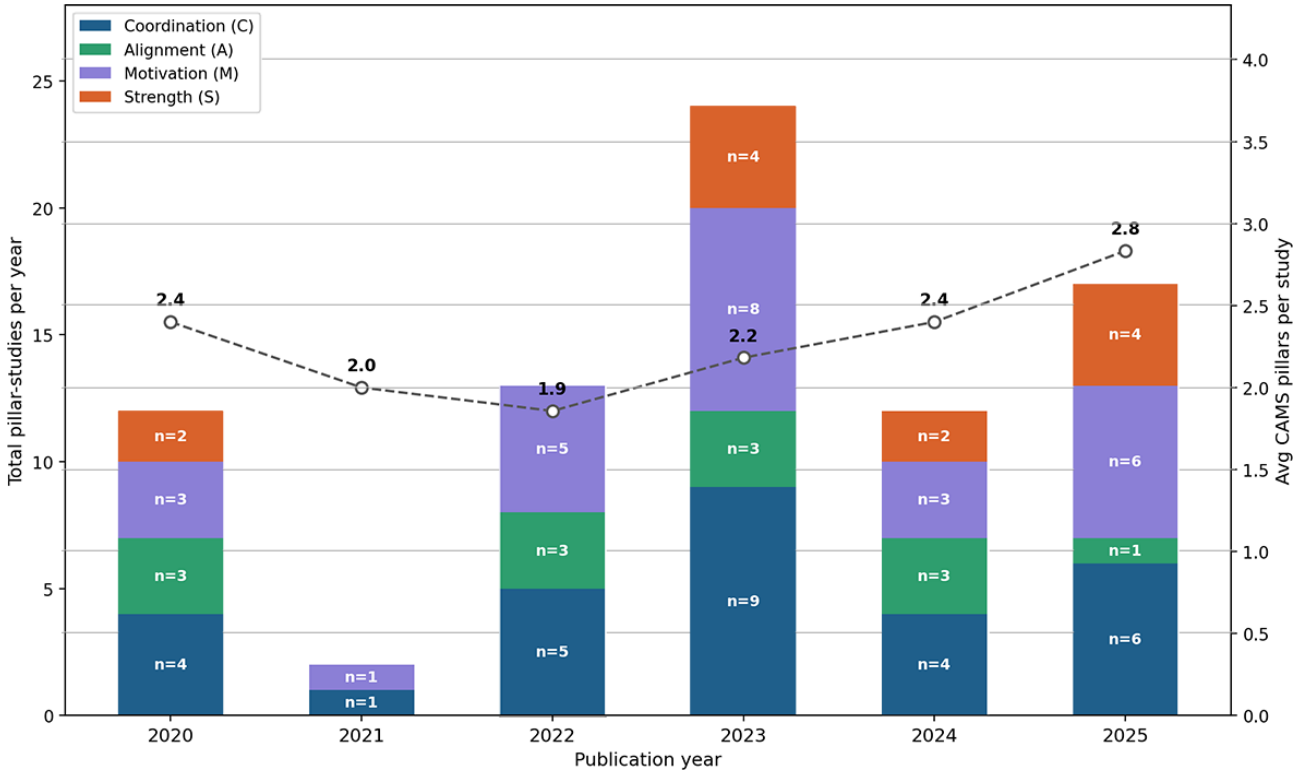
[g]AR: augmented reality

[h]VR: virtual reality.

[i]mHealth: mobile health.

[j]IMU: inertial measurement unit.

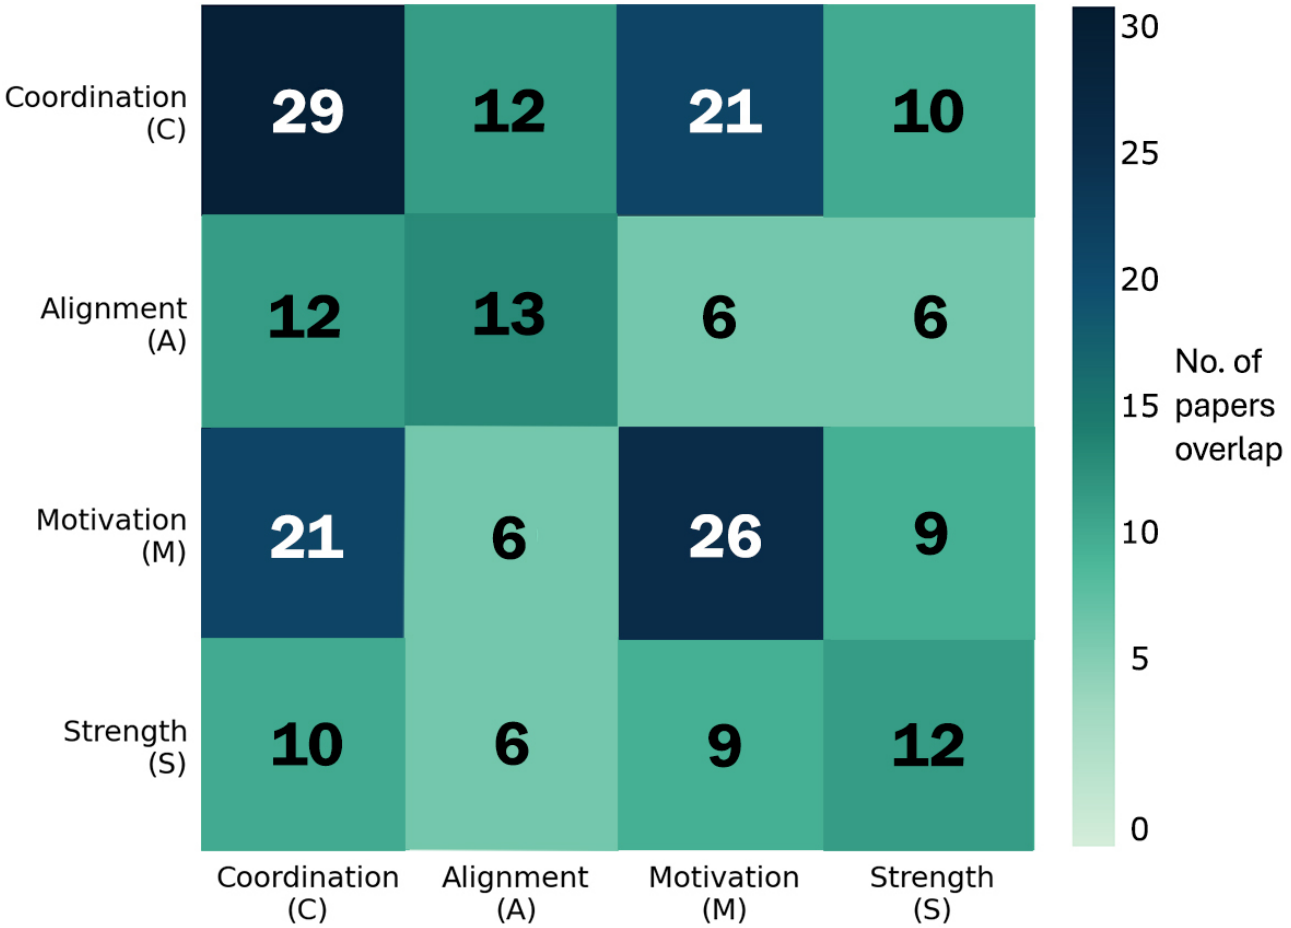
[k]TRAK: Taxonomy for the Rehabilitation of Knee Conditions.



The included studies represent a diverse geographical distribution, with significant contributions from Asia (eg, [24,25,31]), Europe (eg, [1,32,38]), and North America (eg, [10,39]). The participant cohorts were predominantly postarthroplasty (total knee arthroplasty [TKA] and total hip arthroplasty [THA]) patients (eg, [15,20,21]), with sample sizes ranging from small-scale pilot feasibility trials to large-scale multicenter randomized controlled trials (n=300, [1]). In terms of technological deployment, wearable inertial measurement units (IMUs) and mobile health (mHealth) applications were the most frequently used modalities, reflecting a clinical priority for portable and scalable solutions.

The temporal distribution of included studies shows a gradual increase in publication volume across the review period (Figures 3 and 4): 5 studies [1,39-42] in 2020, 1 in 2021, 7 in 2022, 11 in 2023, 5 in 2024, and 6 in 2025, with 2023 - 2025 collectively accounting for 63% (22/35) of the corpus. This pattern suggests growing research activity in the postpandemic period, though

XSL•FO
RenderX



the limited number of studies per year precludes formal trend analysis.

Figure 3. Longitudinal evolution and thematic density of Coordination-Alignment-Motivation-Strength (CAMS) pillars among 35 studies [1,3,10-42] of digital postsurgical orthopedic rehabilitation technologies published between 2020 and 2025. Avg: average.

XSL•FO
RenderX

Figure 4. Heatmap of synergy and overlap between Coordination-Alignment-Motivation-Strength (CAMS) pillars among 35 studies [1,3,10-42] of digital postsurgical orthopedic rehabilitation technologies published between 2020 and 2025.

Methodological Quality and RoB

The methodological profile of the included studies was characterized using design-appropriate appraisal tools (RoB 2 for RCTs, NOS for observational studies, MINORS for nonrandomized designs). As detailed in Table 2, 49% (17/35) of the studies were rated low risk overall on their respective primary appraisal tool, 46% (16/35) demonstrated some concerns, and 6% (2/35) were rated high risk. The temporal distribution of RoB 2 ratings (Table 3) shows that studies published between 2024 and 2025 (eg, [12,16]) more commonly achieved low risk overall ratings compared to earlier pilot studies, though the small number of studies per year means this observation is descriptive rather than inferential.

Table . Longitudinal evolution of methodological rigor among 35 [1,3,10-42] studies of digital postsurgical orthopedic rehabilitation technologies published between 2020 and 2025, based on overall risk of bias ratings by publication year.

Year	Low risk, n (%)	Some concerns, n (%)	High risk, n (%)	Total studies, n
2020	2 (40)	3 (60)	0 (0)	5
2021	1 (100)	0 (0)	0 (0)	1
2022	1 (14)	5 (71)	1 (14)	7
2023	5 (45)	5 (45)	1 (9)	11
2024	3 (60)	2 (40)	0 (0)	5
2025	5 (83)	1 (17)	0 (0)	6
Total	17(49)	16 (46)	2 (6)	35

Domain-based analysis (Figure 5) shows that selection and reporting biases were minimal; albeit performance bias (Domain 2) is an intrinsic issue with digital health trials because blinding participants and the therapists is technically impossible (eg, [32]). However, the large mean of PEDro (7.7) indicates that there is a serious focus on objective outcome measurement and high-statistic reporting throughout the corpus. It is important to note that most of the “some concern” ratings were signaled by the use of patient-reported outcome measures (PROMs) in unblinded designs, as opposed to inherent weaknesses in randomization or data integrity.

Figure 5. Risk of bias 2 domain-level ratings among the 32 randomized controlled trials [1,3,10-22,24-30,32-38,40-42] of digital postsurgical orthopedic rehabilitation technologies; the remaining 3 nonrandomized studies were appraised using different tools with noncomparable domain structures (Table 2). RoB2: Risk of Bias 2

Each included study contributed an independent patient cohort—no studies shared participants. Patient cohorts were predominantly postarthroplasty (total knee or hip arthroplasty; n=26 studies; Table 1) or post-ACL reconstruction (n=5 studies), with the remaining studies covering rotator cuff repair, meniscectomy, hip fracture, or mixed lower limb populations (n=4 studies). The range of digital interventions was broad: wearable sensor or IMU systems and VR or AR platforms were most common (n=10 each), followed by mHealth applications (n=9) and other telerehabilitation platforms (n=6). Several studies used multimodal combinations of these modalities. Rehabilitation duration across studies ranged from single inpatient sessions (2 - 4 days postoperatively) to 24 weeks, with home- and hybrid-based interventions spanning a wide range of postoperative timeframes, from brief early interventions to extended multiweek programs. Intervention dosing varied considerably—from predominantly unsupervised home sessions (eg, [3,15]) to more clinician-supported telehealth models (eg, [11,20])—reflecting the absence of standardized digital rehabilitation protocols in this literature. These characteristics are summarized in Table 1.

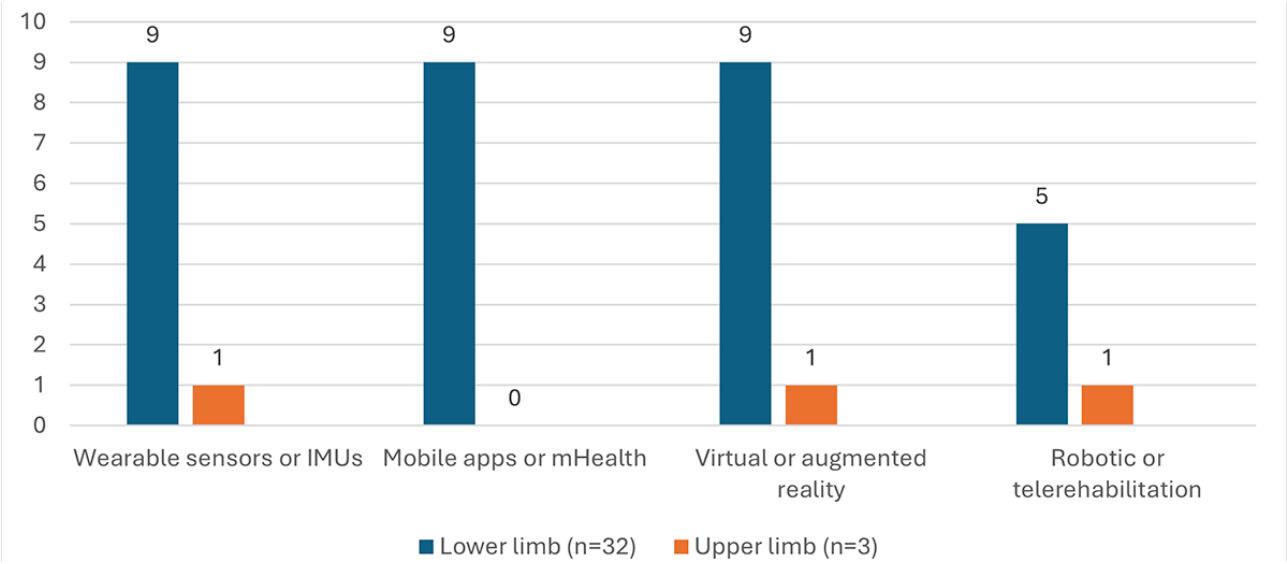
The Lower Limb Dominance: Biomechanical and Economic Drivers

The anatomy of the covered studies focused on the lower limb (32/35, 91%) and targeted the recovery interventions for total knee and hip arthroplasty. This distribution may reflect 2 convergent factors, though causal inference is beyond the scope of this review. First, from a biomechanical perspective, lower limb rehabilitation often prioritizes repetitive, sagittal-plane movements (eg, knee flexion or extension) and gait metrics, which are more easily quantified by current IMUs and markerless vision systems than the complex, multiplanar kinematics of the upper limb (eg, shoulder circumduction). Second, health economic pressures play a significant role; the high volume of lower limb arthroplasty procedures globally has created an urgent clinical need for scalable, automated solutions to reduce hospital length of stay and postoperative physiotherapy costs.

The Shift Toward Decentralized Care: From Supervision to Autonomy

Regarding the clinical delivery environment, a decisive shift from hospital-centric to decentralized care is evident. The hybrid model was the most frequently used approach (14/35, 40%). This model reflects a “safety-first” innovation strategy, where initial in-clinic supervision ensures patient safety and device calibration, followed by a transitioned digital home program to promote long-term autonomy.

The emergence of protocols that are purely home-based and remote (13/35, 37%) is the second wave of digital orthopedics, which can be enabled through the enhancements in user interface design and the reliability of remote monitoring. This pattern coincides with the accelerated adoption of telerehabilitation during the COVID-19 pandemic, during which remote-only pathways demonstrated clinical feasibility across multiple orthopedic contexts [31,38]. On the other hand, 8 studies used an exclusively clinical delivery model (8/35, 23%), suggesting that digital tools are increasingly deployed to extend rather than replace in-person care but as force multipliers that can be deployed in the domestic setting of the patient to close the critical continuity-of-care gap after discharge.



Technological Modalities and System Architecture

The technological modalities analysis (Figure 6) indicates that there is a hierarchical deployment of hardware. Wearable IMUs are widely used for objective monitoring and are used in the

XSL•FO
RenderX

majority of studies of the lower limbs to measure the angle of joints and gait parameters. Nonetheless, one of the major trends is the use of these sensors with mHealth ecosystems.

Figure 6. Distribution of technological modalities across anatomical targets among 35 studies of digital postsurgical orthopedic rehabilitation technologies published between 2020 and 2025. IMU: inertial measurement unit; mHealth: mobile health.

The most innovative change that was observed in the collected studies, for the time frame of 2024 - 2025, is the emergence of markerless computer vision and AR. These systems (eg, [3]) can reduce the patient's physical load, that is, by substituting physical sensors with camera-based pose estimation. The more recent studies (2023 - 2025) showed increasing architectural diversity, ranging from cloud-based asynchronous monitoring platforms to immersive VR or AR systems and synchronous telehealth models, reflecting the field's ongoing exploration of different digital delivery paradigms rather than convergence on a single dominant architecture.

Longitudinal Evolution of the CAMS Pillars

Figure 3 illustrates the distribution of CAMS pillars addressed by publication year. Between 2020 and 2022, when annual study counts ranged from 1 to 7 per year, interventions most frequently addressed Coordination (10/13, 77%) and Motivation (9/13, 69%), while Alignment (6/13, 46%) and, in particular, Strength (2/13, 15%) were less commonly addressed. Between 2023 and 2025, Coordination (19/22, 86%), Motivation (17/22, 77%), and Strength (10/22, 45%) coding were more frequent than in the earlier period, whereas Alignment coding was less frequent (7/22, 32%); however, given the small number of studies per year, these patterns are reported descriptively and should not be interpreted as a defined developmental sequence. The average number of CAMS pillars addressed per study ranged from 1.9 (SD 0.7) in 2022 to 2.8 (SD 0.8) in 2025, with no clear monotonic trend across the review period (Figure 3). This variability reflects heterogeneity in study scope and intervention type, though the data are consistent with a modest shift toward more multidimensional digital interventions in recent years.

Thematic Synthesis of CAMS Pillars

This section synthesizes the functional outcomes and technological architecture across the n=35 corpus. The results reveal that the current digital landscape is defined by multimodal integration. As illustrated in the synergy heatmap (Figure 4), Coordination and Motivation were the most frequently coaddressed pillars, appearing together in 60% (21/35) of included studies, suggesting this pairing functions as the functional baseline for current digital rehabilitation tools.

Motivation: The Digital Anchor

The most widespread pillar (26/35, 74%) was motivation, which became the main factor in influencing longitudinal adherence in the unsupervised domestic environment. The synthesis reveals an evolution from extrinsic motivators (eg, automated SMS reminders and adherence logs) to intrinsic engagement through immersive gamification.

VR and high-engagement digital interventions (eg, [2]) have been associated with reduced pain perception and perceived exertion during physical activity in the included literature, though this review's descriptive design does not establish a causal or clinical analgesic effect. Leveraging the "distraction effect," digital interventions may redirect emphasis on the postsurgical mechanical discomfort of movement toward goal-oriented play; these digital health technologies (DHTs) may thereby help address psychological obstacles to rehabilitation. This engagement set the basis of the high-frequency repetition volume needed to stimulate effective tissue remodeling and functional recovery.

Coordination-Motivation Axis: The Engagement-Precision Loop

Coordination and Motivation are identified as the dominant synergy. The clinical importance of this relationship is high, as high-frequency repetition is an element of the precision-based motor learning (Coordination) that could be retained only with the help of psychological engagement (Motivation). By integrating real-time biofeedback, such as AR-based movement guidance (eg, [3]), with gamified reward structures, DHTs support precise motor execution within an engaging framework. This process may reduce the cognitive load on the patient,

XSL•FO
RenderX

transitioning exercise from a monitored chore to a goal-oriented task, which is a prerequisite for achieving the high dose of training required for neural plasticity.

Alignment as a Gatekeeper for Coordination

While Coordination tracks the path of movement, Alignment is intended to assess the integrity of that path. The 17% (6/35) overlap between these pillars (eg, [3,13,25]) indicates an emerging trend toward "Gait-Aware" systems. Without Alignment, Coordination tracking is at risk of validating "compensatory movements"—where a patient achieves a coordinate goal by using maladaptive postures. AI-driven markerless vision may function as a monitoring tool for postural alignment, flagging compensatory movement patterns before Coordination metrics are recorded; whether this translates to reduced risk of abnormal loading at the surgical site was not assessed by the included studies.

The "Strength Isolation": A Technological Bottleneck

According to the heatmap, the Strength pillar had the lowest co-occurrence with Alignment (6/35, 17%), indicating that studies addressing strength rarely also addressed postural alignment. This isolation may point to a technological bottleneck: current digital platforms appear to demonstrate greater capability for monitoring kinematics (tracking the quality of motion) than for kinetic measurement (force quantification). Strength interventions currently function as standalone silos (eg, [24]), lacking the integrated biofeedback seen in the coordination-motivation axis. This gap may also reflect clinical and safety factors, including conservative protocols for early postoperative resistance training and publication trends favoring adherence studies over strength training trials.

Discussion

Summary of Principal Findings

Examined through the CAMS framework, the current corpus of digital orthopedic rehabilitation studies reveals a descriptive imbalance between behavioral engagement and physical load assessment. Coordination (29/35, 83%) and Motivation (26/35, 74%) were the most commonly addressed domains, reflecting the maturation of engagement-focused and movement-tracking technologies in home-based settings. By contrast, Strength-focused interventions appeared in only 34% (12/35) of studies, most of which required clinically supervised resistance hardware, limiting their applicability in decentralized care models. This gap, between kinematic monitoring (tracking the quality of movement) and kinetic measurement (quantifying mechanical force), is the central finding of this review.

The shift toward hybrid (14/35, 40%) and home-based (13/35, 37%) delivery models across the corpus is consistent with the broader adoption of telerehabilitation during and after the COVID-19 pandemic. This distributional pattern suggests that decentralized care has moved from being a contingency measure to an established component of orthopedic rehabilitation pathways, though the heterogeneity of included interventions and outcome measures means these observations are descriptive rather than conclusive.

From Kinetic Monitoring to Kinetic Integration

The co-occurrence of 60% (21/35) between Coordination and Motivation pillars (Figure 4) suggests that this pairing forms the functional core of current digital rehabilitation tools. Conventional physiotherapy relies on direct clinician observation for corrective feedback; current AR-based and IMU-based systems (eg, [3]) replicate elements of this closed-loop feedback in nonsupervised home settings, supporting the neuromuscular repetition volumes required for motor relearning.

Clinical Implications

The prevalence of hybrid delivery (14/35, 40%) suggests that a phased model, initial in-clinic assessment followed by digital home-based maintenance, may represent an emerging standard of care for postsurgical orthopedic rehabilitation. This model balances safety and therapist oversight in the acute phase with the scalability and patient autonomy of digital tools during extended recovery. The growing availability of markerless AI-based alignment monitoring [3,13] further supports this model, removing the need for sensor placement and enabling higher-quality alignment tracking for patients with limited technological literacy.

Based on the evidence mapped in this review, the following principles are suggested for clinical consideration. Platforms addressing the Coordination-Motivation axis alongside Alignment offer broader functional coverage and may be preferable to single-pillar adherence tools. Markerless vision systems should be considered for early detection of compensatory movement patterns in home settings. Clinicians should recognize that current DHTs are predominantly kinematic — direct strength measurement requires supplementary in-clinic assessment until affordable kinetic wearables become available. Hybrid delivery models offer a pragmatic balance between clinical oversight and home-based scalability. These suggestions are based on descriptive mapping findings and require validation through comparative clinical trials.

Limitation and Future Directions

This review has several limitations. First, the CAMS framework is a novel, unvalidated taxonomy proposed here as an exploratory classification tool; its categories reflect the authors' conceptual mapping rather than empirically derived dimensions. Second, the high degree of heterogeneity across intervention types, outcome measures, dosing protocols, and follow-up periods precluded formal meta-analysis, and the descriptive findings cannot be interpreted causally. Third, performance bias is an inherent challenge in digital health trials where blinding participants and therapists is not feasible, and most included studies relied at least partially on patient-reported outcomes. Fourth, Web of Science was not searched due to lack of institutional access, which may have resulted in missed records not indexed in the 5 databases used, though substantial overlap with Scopus and IEEE Xplore is expected for this multidisciplinary technology-focused literature. Finally, intervention durations varied considerably across studies, ranging from single inpatient sessions to programs extending several months postsurgery, leaving long-term functional durability, including joint longevity and secondary injury

XSL•FO
RenderX

prevention, largely unaddressed in the literature, regardless of intervention length.

Future research should prioritize 3 directions. First, empirical validation of the CAMS framework across diverse clinical and technological settings is needed to establish its utility as a classification and prescriptive tool. Second, trials specifically targeting the Strength pillar, particularly studies integrating smart resistance hardware with kinematic monitoring systems, are required to close the gap identified in this review. Third, longitudinal studies with follow-up extending well beyond the early postoperative period are needed to evaluate whether digital rehabilitation pathways support durable functional recovery and safe return to sport.

Conclusions

This scoping review mapped 35 [1,3,10-42] studies of digital technologies used in postsurgical orthopedic rehabilitation between 2020 and 2025, using the proposed CAMS framework to characterize their functional coverage. Within this literature, Coordination and Motivation were the most frequently addressed domains, while Alignment and, in particular, Strength were less consistently represented. This pattern may reflect current technological capabilities for quantifying postural correction and mechanical load, though the descriptive nature of this review precludes definitive conclusions about the underlying causes. Hybrid delivery models, combining initial clinical supervision with subsequent home-based digital support, were the most common approach across the included studies. These findings suggest several directions for future research, including empirical validation of the CAMS framework, development of accessible tools for quantifying physiological load, and longitudinal studies evaluating functional outcomes beyond the early postoperative period. As an exploratory taxonomy, CAMS may offer a useful starting point for classifying and comparing digital rehabilitation technologies in future research.

Acknowledgments

The authors would like to thank Dr Chan Kin Yuen, orthopedic surgeon, for his invaluable guidance and clinical insights throughout this study. This manuscript was prepared with the assistance of generative AI tools (ChatGPT, OpenAI; Claude, Anthropic) for the purposes of language editing, proofreading, text refinement, structural organization, and reference formatting. All scientific content, interpretation of findings, conceptual framework development, data extraction, quality appraisal, and final manuscript decisions were performed and verified by the authors. The authors take full responsibility for the integrity and accuracy of the work.

Funding

This study was supported by the Asia Pacific University of Technology and Innovation Research Development Internal Grant (RDIG/07/2024) and the Guangdong Key Disciplines Project (2024ZDJS137). Abstract

Background: Digital transformation in health care, including telemedicine, wearable devices, robotic process automation (RPA), and electronic medical records (EMRs), is reshaping outpatient care delivery. However, consolidated evidence on how these technologies influence patient care quality (PCQ) remains limited.

Objective: This study evaluated the impact of emerging digital health technologies on PCQ dimensions in outpatient clinics through a systematic literature review combined with expert perspectives.

Methods: A systematic review following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines was conducted across ABI/INFORM, ScienceDirect, MEDLINE, and Google Scholar to identify studies published between 2017 and 2022. Studies examining digital technologies and their effects on outpatient PCQ were included. After screening and eligibility assessment, 53 studies were retained for synthesis. In parallel, semistructured interviews were conducted with 19 subject matter experts from public health, health informatics, and outpatient clinical practice. Findings were thematically analyzed using SERVQUAL (Service Quality Model) dimensions: responsiveness, reliability, empathy, communication, and tangibles, and triangulated across both datasets.

Results: RPA led to substantial reductions in waiting times, while telemedicine improved accessibility and continuity of care, as highlighted by 14 of 19 experts. Wearable devices enhanced remote monitoring and patient engagement but required adequate digital literacy. Several studies (n=7) reported that EMR usability challenges negatively affected patient-physician communication. Overall, improvements were most evident in responsiveness and communication, while empathy and patient-centeredness remained comparatively weaker without targeted training and workflow adjustments.

Conclusions: Emerging digital health technologies can enhance outpatient PCQ, particularly in operational efficiency, access to care, and communication. This review is innovative in that it integrates evidence across telemedicine, wearable monitoring, RPA, and EMRs within a unified SERVQUAL framework, offering practical guidance for implementing patient-centered digital health strategies in outpatient settings.

KEYWORDS

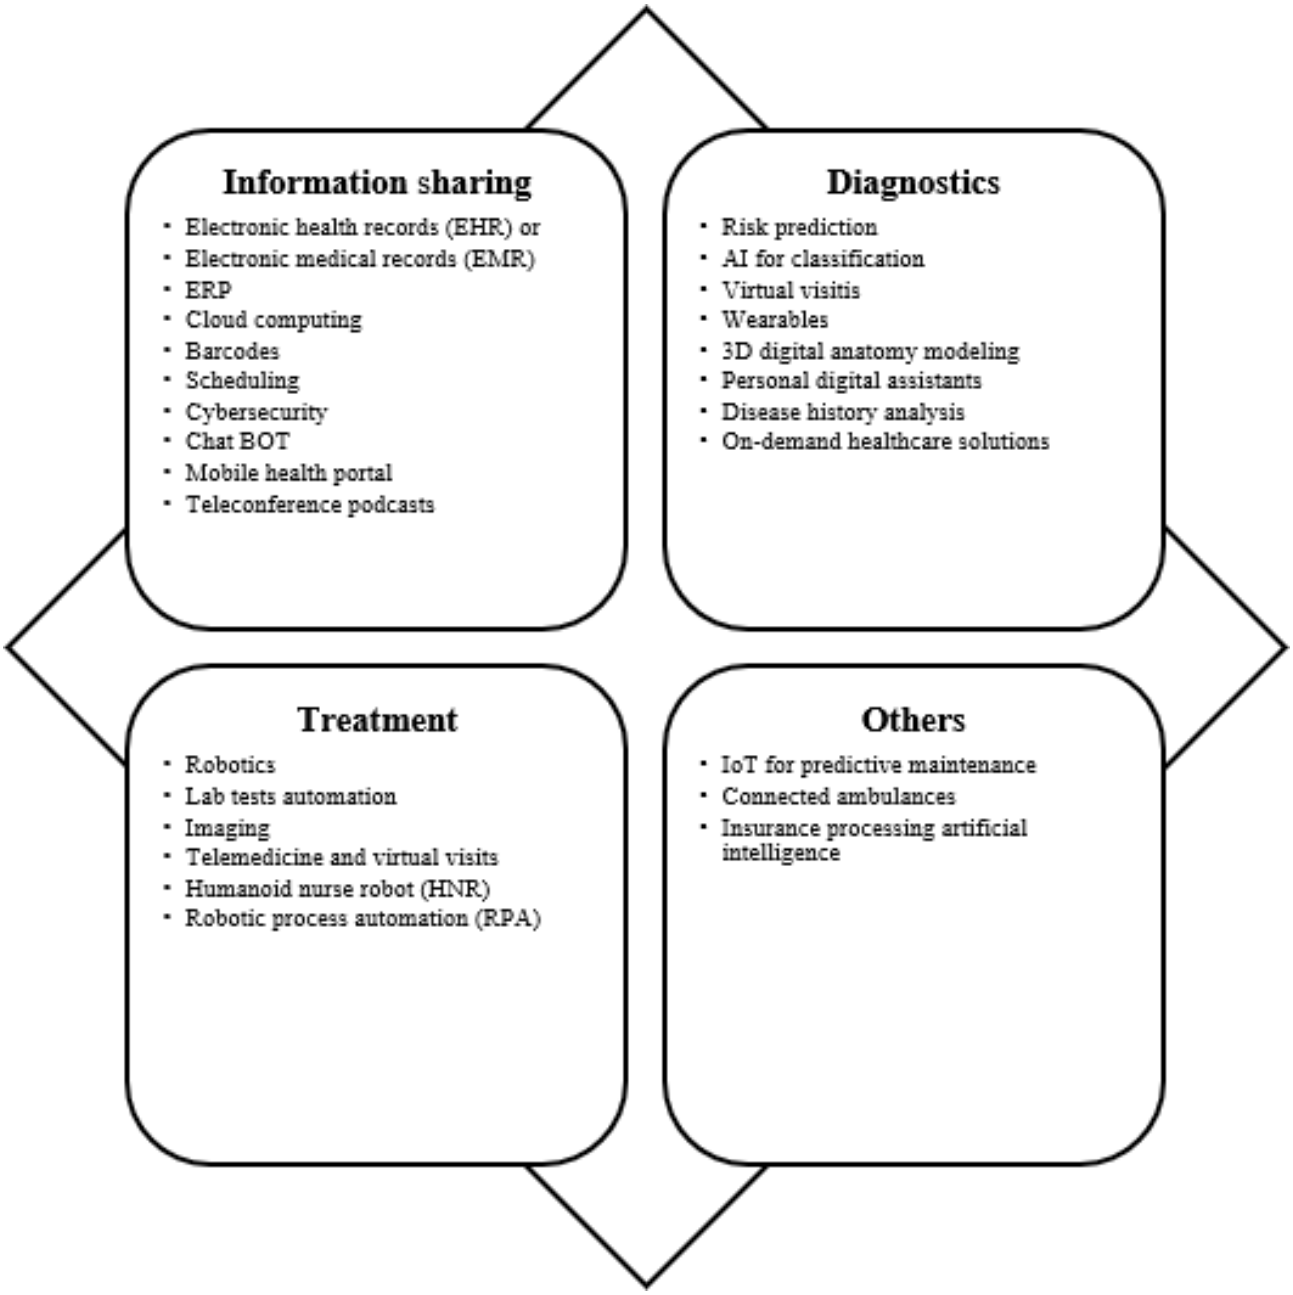
digital health; telemedicine; robotic process automation; patient care quality; outpatient care; SERVQUAL

Introduction

Background

The surge in health care demand directly correlates with expenses and resource allocation, underscoring the imperative to prioritize enhancing service quality on the management agendas of health care operators. This prioritization is crucial due to its profound impact on patients' perceived value, satisfaction levels, and loyalty [1]. A comprehensive comprehension of service quality in health care commences with grasping its conceptualization. Despite its importance, there is no unified common understanding of patient care quality (PCQ). Instead, there are several interpretations, starting with a complex and abstract definition that defies standardization and quantification, acknowledged as fundamental to customer satisfaction and contentment [2]. Second, it involves clients' perceptions and assessments of the service, elucidating the disparity between expectations and experiences [3]. This perspective resonates with those defining service quality as the differential between clients' initial expectations and those developed postservice interaction [4]. Third, service quality encompasses a service provider's efficacy in satisfying consumers effectively, thereby fostering heightened profits, market share, sustainable customer satisfaction, and corporate marketing prowess [5,6]. Moreover, service quality is intricately intertwined with service delivery, evaluated through diverse determinants governing performance and consumer benefits

XSL•FO
RenderX



[7]. Finally, customers significantly influence service delivery, assessing quality via a 5-gap model encompassing knowledge, standards, communication, delivery, and the differential between expected and actual service quality [2].

There is an increasing demand for outpatient services, leading to an increase in the patient volumes seen, increased waiting times through the patient journeys, overworked caregivers, and increased overtime hours worked. Evaluating the patient's satisfaction with the quality of outpatient clinic service delivery [8]. Health care operators realized the need to change the way they work [9]. Digital transformation improves 4 key operational decision-making areas: patient flow, staffing, scheduling, and supply chain [10].

To address health care challenges and intense competition, technology adaptation has become a priority for decision-makers. Figure 1 illustrates some of the technologies used by the health care sector to tackle these various challenges. Digital transformation involves a process aimed at enhancing an entity by instigating significant changes to its attributes through the integration of information, computing, communication, and connectivity technologies [11]. As highlighted by Allen [12], it serves as a pivotal step in preparing for a consumer-centric "Future of Health." Cloud adoption, including Platform as a Service (PaaS), Infrastructure as a Service (IaaS), and Software as a Service (SaaS) [12], along with advancements in AI and the Internet of Things (IoT), are actively driving global digital transformation efforts [13]. Esteemed health systems perceive digital transformation to become more customer-oriented while simultaneously evolving their operations, work culture, and technological landscape. This includes outpatient clinics leveraging digital capabilities to fundamentally reshape their client relationships, focusing on incremental milestones to deliver value. However, successful transformation faces several challenges, including talent acquisition, data management, establishing key performance indicators, and budget allocation. Notably, having executive leadership dedicated to championing digital transformation is essential for success [14]. Barriers in health care digital transformation encompass the cybersecurity workforce shortage and reliance on legacy systems [13]. Key technologies driving digital transformation include automation, connected ambulances, on-demand health care solutions, telemedicine, virtual visits, patient portals, health care wearables, and disease history analysis. These innovations aim to streamline workflows for clinicians and hospitals, ensuring accurate patient data and health performance indicators to facilitate more effective treatment plans in shorter timeframes. Hospitals stand to benefit from optimized workflows, improved client interaction, cost reduction, secure electronic medical records (EMR) databases, and enhanced communication with medical staff [15]. Patients, on the other hand, gain access to personalized health care services, simplified access to personal health records, convenient appointment scheduling, improved online communication with doctors, and real-time tracking of crucial health metrics [16].

Figure 1. Available technologies for health care. ERP: enterprise resource planning; IoT: Internet of Things.

Rationale

Consequently, the primary focus of this review article revolves around investigating the impact of adopting emerging technologies on PCQ, encompassing both clinical and nonclinical dimensions, for assessment and monitoring purposes from the perspective of health practitioners operating within an outpatient setting to determine their impact on patient experience. These dimensions, as highlighted by Abbasi-Moghaddam et al [17] and Berwick [18], include safety, effectiveness, patient-centeredness, timeliness, efficiency, and equity. Assessing health care quality proves challenging due to its intangible nature, with evaluations varying based on factors such as the specialization, size, and complexity of health care organizations [5]. It involves strategic decision-making across various disciplines within health care, with perceptions differing among different professional fields [19].

Substandard health care quality can lead to patient dissatisfaction, stress, and despair [7]. It is estimated that poor-quality health care contributes significantly to health care costs, accounting for approximately 30%, owing to reduced productivity, wasteful clinical practices, high rates of medical errors, and costly health issues stemming from individual behaviors [20]. The World Health Organization [21] identifies factors such as inaccurate diagnosis, unnecessary treatments, unsafe clinical practices, and inadequately trained health care professionals as drivers of escalating illness burden and health care costs, commonly referred to as the cost of poor quality (COPQ). The broader economic and social costs of substandard care amount to trillions of dollars annually on a global scale due to long-term disability and lost productivity.

Despite extensive research exploring the determinants of health care quality and their impact on various operational aspects, there remains a gap in understanding the evolution of these

XSL•FO
RenderX

determinants over time and the role of emerging technology adoption in enhancing PCQ. This research seeks to address this gap by examining whether investments in emerging technologies aimed at improving outpatient clinic quality determinants result in positive patient experience from the perspective of health care professionals operating in outpatient clinic settings. By examining a wide range of published articles and existing literature, this review aims to provide a comprehensive understanding of patients' perspectives. Specifically, the integration of technologies such as robotic process automation (RPA), telemedicine and virtual visits, mobile health (mHealth) portal, videoconferencing, other educational technology, 3D digital anatomy modeling, insurance processing AI, health care wearables, personal digital assistants (PDAs), disease history analysis, teleconference podcasts, EMRs, on-demand health care solutions, and connected ambulance is being evaluated. These technologies have the potential to streamline processes, improve efficiency, and enhance the overall patient experience throughout their treatment journey.

Thus, the main research question to be explored through further methodologies is does the use of emerging technologies in outpatient clinics lead to better quality determinants and enhanced patient experiences?

This study was guided by the following hypothesis: emerging technology adoption and integration enhances all dimensions of PCQ in outpatient health clinics.

Recent review studies have examined the role of individual digital health technologies, such as telemedicine, wearable monitoring devices, and EMRs, in improving health care delivery and patient outcomes. However, these reviews typically focus on single technologies or specific clinical contexts, providing limited insight into how multiple digital health innovations collectively influence PCQ in outpatient settings. As digital transformation increasingly involves the simultaneous implementation of interconnected technologies, a more integrated understanding of their combined effects on health care service quality is needed. To address this gap, this systematic review synthesizes evidence across multiple digital health domains and evaluates their impact on PCQ using SERVQUAL (Service Quality Model) dimensions. By consolidating fragmented evidence and incorporating expert perspectives, this review offers a more comprehensive assessment of how emerging digital technologies shape our PCQ and provides practical insights for health care decision-makers [22-25].

Objectives

To answer the research question and test the research hypothesis, the following objectives are identified:

1. Identify the dimensions that influence the perception of PCQ in outpatient clinics
2. Assess the present emerging technology endeavors integrated into determinants of health service quality in outpatient clinics
3. Authenticate the favorable patient experience stemming from emerging technology initiatives implemented within determinants of health service quality in outpatient clinics

This research will directly benefit health care providers and quality experts, particularly those working in hospitals with outpatient clinics, medical centers, or satellite clinics. Additionally, academic scholars, research scholars, accreditation professionals, continuous improvement specialists, regulatory bodies, and occupational health and safety professionals will also find value in this study.

Methods

Overview

This study followed the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines for systematic reviews (Checklist 1) and the COREQ (Consolidated Criteria for Reporting Qualitative Research) checklist for expert interviews (Checklist 2). The methodology followed in this research consists of 2 main steps: systematic literature review (SLR) and subject matter experts (SMEs) interviews. The 2 steps were intentionally designed to provide complementary perspectives on the central research question, each contributing a distinct layer of insight. The systematic literature review established the theoretical foundation, identifying key quality dimensions across health care technology interventions. The expert interviews offered contextual validation from stakeholders actively involved in implementation. The SLR is used to gather secondary data and analyze its relevance to the study objectives. This method was selected due to its ability to offer a comprehensive, evidence-based synthesis of prior research, aligning with best practices recommended by Nunn and Chang [26] and Siddaway et al [27]. Systematic reviews are particularly well-suited for health care–related inquiries because they apply a transparent, replicable methodology that ensures rigor in identifying, integrating, and evaluating diverse sources.

Eligibility Criteria

Studies were selected according to predefined inclusion and exclusion criteria to ensure relevance, methodological consistency, and alignment with the review objectives, as shown in Textbox 1.

XSL•FO
RenderX

Textbox 1. Inclusion and exclusion criteria.

Inclusion criteria

- Outpatient or ambulatory care setting
- Use of emerging technologies (telemedicine, robotic process automation, electronic medical record or electronic health record, AI, wearables, and educational tech)
- Reported patient care quality or satisfaction outcomes
- Peer-reviewed empirical or systematic review studies

Exclusion criteria

- Inpatient or hospital-only focus
- Non–peer-reviewed (editorials and conference abstracts)
- Technology not linked to patient care or service quality

Information Sources

A systematic search was conducted across 7 major databases: ABI/INFORM Global, ScienceDirect, MEDLINE (via PubMed), Google Scholar, Embase, Cochrane Library, and CINAHL. Studies published between 2017 and 2022 were prioritized. The search strategy was designed to capture digital health innovations in outpatient care and their impact on patient experience, quality, and satisfaction. Database-specific search syntax, MeSH and Emtree terms, synonyms, and field codes were used. To ensure validity and reliability, studies published between 2017 and 2022 were prioritized.

Search Strategy

Overview

The search included three key concept clusters:

1. Digital health technologies: such as telemedicine, EMR and electronic health record (EHR), AI, mHealth apps, and wearables
2. Outpatient care: such as ambulatory care, outpatient clinic, and primary care
3. Patient-centered outcomes: patient experience, patient satisfaction, and quality of care

Boolean operators AND and OR combined these clusters, and truncation and wildcards were applied where supported. For each database, search strings were adapted to reflect its indexing and search syntax. Detailed search strings and database queries are provided in this section.

Boolean Search Strings Across Databases

The following Boolean search strings were used for the database searches:

1. (“digital health” OR “eHealth” OR “telehealth” OR “mobile health” OR “mHealth” OR “health IT” OR “digital innovation”) AND (“outpatient care” OR “ambulatory care” OR “primary care clinic” OR “ambulatory services”) AND (“patient experience” OR “patient satisfaction” OR “quality of care” OR “patient-centered care”)
2. (“telemedicine” OR “virtual care” OR “remote consultation” OR “video consultation”) AND (“patient satisfaction” OR “patient perception” OR “patient experience”)
3. (“robotic process automation” OR “RPA”) AND (“healthcare” OR “medical services”) AND (“outpatient” OR “ambulatory care”)
4. (“electronic health record” OR “EHR” OR “EMR” OR “HER”) AND (“patient-centered care” OR “quality of care” OR “service quality”)
5. (“wearable devices” OR “healthcare wearables” OR “mHealth apps” OR “mobile health portal” OR “smartwatch health app”) AND (“outpatient clinic” OR “ambulatory services”)
6. (“artificial intelligence” OR “AI” OR “machine learning” OR “deep learning”) AND (“insurance processing” OR “clinical decision support” OR “diagnostic support”) AND (“outpatient” OR “ambulatory care”)
7. (“3D anatomy modeling” OR “educational technology” OR “digital simulation” OR “virtual reality training”) AND (“patient education” OR “health education”) AND (“outpatient setting” OR “ambulatory clinic”)
8. (“personal digital assistant” OR “clinical decision support system” OR “mobile clinical assistant”) AND (“physician competence” OR “clinical performance”) AND (“outpatient” OR “ambulatory care”)

Database-Specific Notes

The following provides database-specific notes on searches.

- ABI/INFORM Global: all Boolean strings applied with limits, including English language, peer-reviewed journals, and publication years 2017 - 2022.
- ScienceDirect: used Boolean strings with filters for research articles and review articles, publication years 2017 - 2022.
- Google Scholar: keywords applied sequentially due to limitations on advanced Boolean combinations; the first 200 results for each query were screened.
- Medline (PubMed):
  - Used MeSH terms: “Telemedicine”[MeSH], “Electronic Health Records”[MeSH], “Patient Satisfaction”[MeSH]
  - Combined with title and abstract searches: (digital health[tiab] OR eHealth[tiab] OR mHealth[tiab])
  - Filters: English language, human studies, and publication years 2017 - 2022
- Embase:

XSL•FO
RenderX

  - Used Emtree terms: “telemedicine”/exp, “electronic health record”/exp, “patient satisfaction”/exp
  - Field modifiers: ti,ab for title/abstract
  - Filters: English language and publication years 2017 - 2022
- ABI/INFORM Global, ScienceDirect, CINAHL, Cochrane Library, and Google Scholar:
  - Boolean operators applied with syntax adjustments per database
  - First 200 results screened in Google Scholar due to limits
- Notes on reproducibility:
  - All database-specific queries, including MeSH and Emtree terms, truncation, and field codes, are fully documented
  - Any item not applicable to a database was noted (such as MeSH terms in Google Scholar).

This detailed reporting ensures transparency and reproducibility of our search methodology, in accordance with PRISMA-S (Preferred Reporting Items for Systematic Reviews and Meta-Analyses literature search extension) guidelines.

Data Synthesis

Overview

To supplement the literature review, semistructured interviews were conducted with 19 SMEs across the fields of public health, health care informatics, and blockchain-based health technology. The experts were selected using purposive sampling, ensuring diversity in terms of geographic location (United Arab Emirates, Europe, and North America), professional role (policymakers, IT developers, and medical practitioners), and years of experience (ranging from 8 to 25 years). The interview protocol covered themes such as data privacy, trust in decentralized systems, donor engagement, and integration challenges within health care infrastructures. Responses were coded thematically and triangulated with findings from the literature review.

This study was reviewed and approved by the Institutional Review Committee (IRB) at the American University of Sharjah in the United Arab Emirates. All expert participants provided written informed consent for interview participation.

Risk of Bias Assessment

To ensure methodological rigor and transparency, the risk of bias of all included studies was assessed using established appraisal tools appropriate to the study design. Randomized studies were evaluated using the Cochrane Risk of Bias Tool 2, while observational studies were assessed using the Newcastle-Ottawa Scale. For nonrandomized intervention studies, the ROBINS-I was applied where relevant. Two reviewers independently conducted the quality and risk-of-bias assessments, and any disagreements were resolved through discussion and consensus to ensure consistency and reliability. The results of the risk-of-bias evaluation were documented in summary tables and considered during the synthesis and interpretation of findings. Studies identified as having a higher risk of bias were carefully examined during analysis to ensure that conclusions regarding the impact of digital health technologies on outpatient PCQ were not disproportionately influenced by lower-quality evidence.

Screening and Selection

Screening followed PRISMA guidelines, with a flow diagram illustrating identification, screening, eligibility, and inclusion steps.

Data Collection

To organize the findings of the literature and interview questions, several models focused on suggesting dimensions to measure PCQ were reviewed. The SERVQUAL model was selected for this study due to its widespread application, simplicity, and robust structure in assessing service quality across diverse sectors, including health care [28]. It operationalizes service quality through 5 distinct dimensions: tangibility, reliability, responsiveness, assurance, and empathy, which align closely with patient-centered care indicators [29]. Several researchers advocated for implementing the SERVQUAL model as a robust method for assessing service quality in outpatient health care facilities [2]. While alternative models such as the HEALTHQUAL [30] and HCAHPS [31] also assess health care quality, SERVQUAL offers a more generalized and flexible structure that allows for comparative analysis across settings and time, making it suitable for exploratory research in dynamic or cross-cultural health care environments [32]. Furthermore, unlike HCAHPS, which is limited to inpatient experiences and largely administrative reporting, SERVQUAL captures perceived service gaps directly from users, making it more relevant for studies focused on user satisfaction and perceived service deficiencies [33]. Thus, its adaptability, empirical grounding, and comparative advantage in measuring perceived service quality support its use in this context.

The SERVQUAL model is a widely used framework for measuring and managing service quality across various industries. It was developed based on the premise that customers’ perceptions of service quality are influenced by the gap between their expectations and their actual experiences with a service. SERVQUAL breaks down service quality into 5 dimensions, often represented by the acronym RATER. First, reliability, which refers to the ability of a service provider to deliver its services consistently and accurately. Customers expect services to be performed dependably and accurately. Second, assurance relates to the knowledge and courtesy of employees and their ability to inspire trust and confidence. It includes factors such as employees’ competence, credibility, courtesy, and ability to convey trust and confidence. Third, tangibles refer to the physical evidence and appearance of facilities, equipment, personnel, and communication materials. This dimension encompasses the appearance of physical facilities, equipment, personnel, and communication materials. Fourth, empathy which involves the degree of caring, individualized attention, and understanding that the service provider gives to its customers. It relates to the provider’s ability to understand and empathize with customers’ needs and concerns. Fifth, responsiveness, which refers to the willingness of the service provider to help customers and provide prompt

XSL•FO
RenderX

service. It involves aspects such as a willingness to assist customers promptly, attentiveness, and responsiveness to customer requests or inquiries.

The SERVQUAL model is typically assessed using a survey questionnaire that measures customers' perceptions and expectations across these 5 dimensions. Customers are asked to rate both their expectations of an ideal service (ie, how they believe a service should be) and their perceptions of the actual service received. The difference between customers' expectations and perceptions provides insights into the gaps in service quality. This survey questionnaire was used in interviewing 23 SMEs, yet only feedback from 19 experts operating in an outpatient clinic setting was considered. Those respondents operate in different capacities as outlined in Table 1 below.

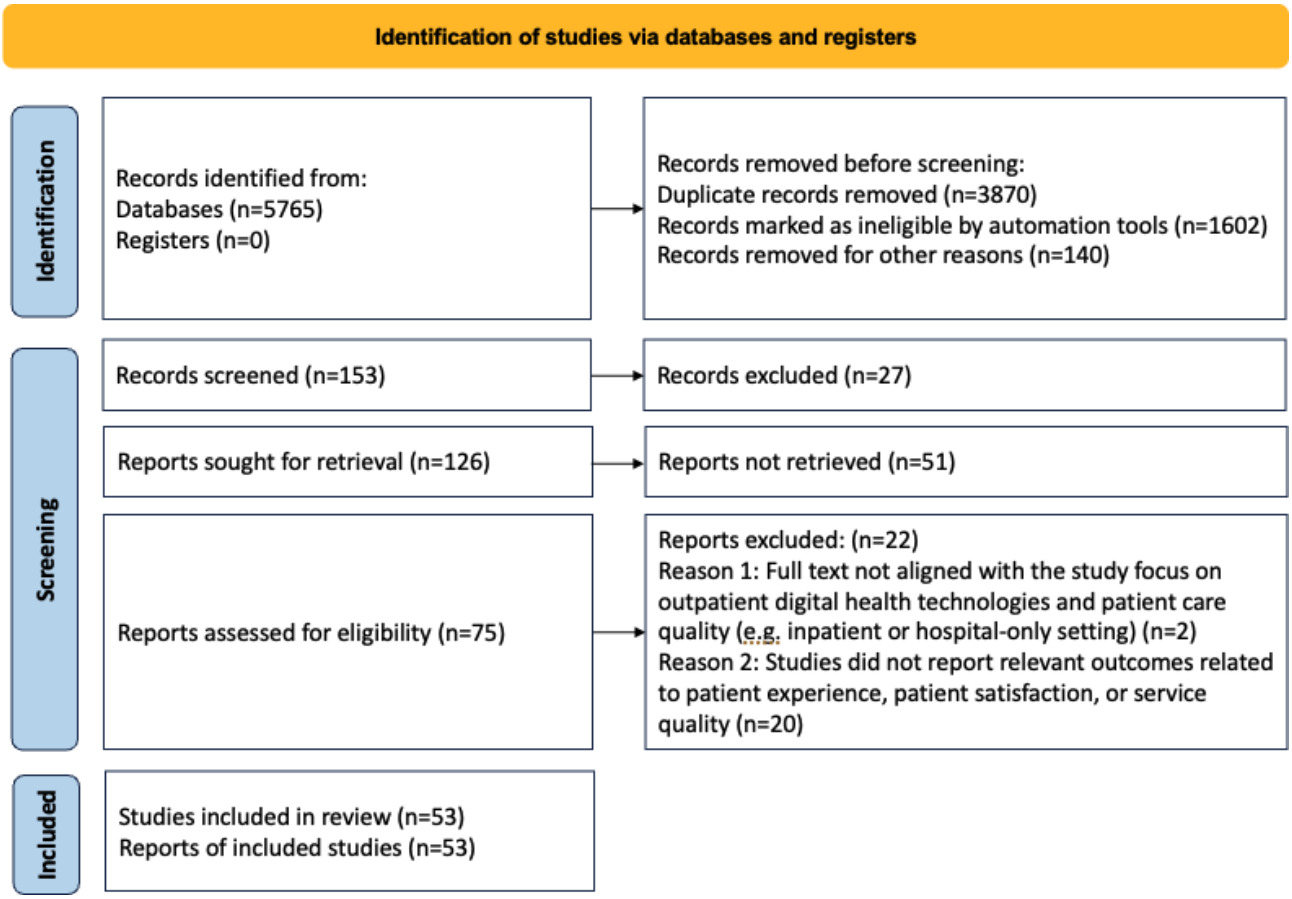
Through this research review paper, ethical measures are followed in terms of honesty in data reporting, objectivity, confidentiality, integrity and sincerity, human error and negligence avoidance, and transparency in results sharing.

Table . Interviewed SME[a] demographics.

Job title	Age bracket (years)	Years of experience
Continuous improvement project manager	40 - 49	11 - 15
Receptionist	30 - 39	6 - 10
Clinic information officer	30 - 39	3 - 5
Customer care associate	30 - 39	3 - 5
Administrator	40 - 49	6 - 10
Receptionist	30 - 39	11 - 15
Charge nurse (Aviation Medicine Clinic)	40 - 49	16 - 20
Officer	40 - 49	≥20
Registered nurse	50 - 59	≥20
Doctor	40 - 49	16 - 20
Manager clinical systems	40 - 49	11 - 15
Registered nurse	30 - 39	6 - 10
Registered nurse	30 - 39	11 - 15
In-flight nurse	30 - 39	6 - 10
Aviation nurse	40 - 49	11 - 15
Executive director, nursing services	40 - 49	≥20
Respiratory therapist	50 - 59	≥20
Practical nurse	30 - 39	6 - 10
Registered nurse	40 - 49	≥20

[a]SME: subject matter expert.

Ethical Considerations



This study was approved by the IRB Committee of the American University of Sharjah in the United Arab Emirates (Protocol Number 25-091). Written informed consent was obtained from all interview participants.

Results

The initial search generated 5765 records, which were screened by title and abstract. After applying inclusion and exclusion criteria and assessing full texts, 53 relevant articles published between 2017 and 2022 were included (Figure 2).

XSL•FO
RenderX

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram.

Literature reviewed part of the SLR consists of research studies and case studies. The review of the case studies was not to offer an exhaustive ethnographic account, but rather to illustrate the practical implications of identified trends. An augmented version of SERVQUAL was applied selectively as a structuring tool during the literature synthesis phase to help organize findings under recognized quality dimensions. Other dimensions such as trust, data governance, and interoperability emerged more prominently in expert and case study findings, which necessitated a broader, more adaptive analytical approach. This divergence reflects the evolving nature of health care service delivery in the digital era and underscores the need for hybrid evaluative frameworks that go beyond traditional service quality models.

Interview respondents confirmed that safety is the most important quality dimension, followed by patient-centeredness from a patient perspective, as demonstrated in Table 2. The study assumes that emerging technologies generally yield positive outcomes across quality dimensions for a favorable patient experience. Tables 3 and 4 provide a summary of the SMEs' feedback on the impact of technology on organizational improvement objectives and PCQ dimensions, respectively. Some of the organizational objectives are focused on PCQ, such as overall satisfaction, patient education, and patient information sharing.

Table . Which quality dimension is considered the most important from a patient perspective?

Dimension	Responses, n
Not disclosed	1
Effectiveness	2
Efficiency	1
Equity	3
Patient-centeredness	4
Safety	5
Timeliness	3

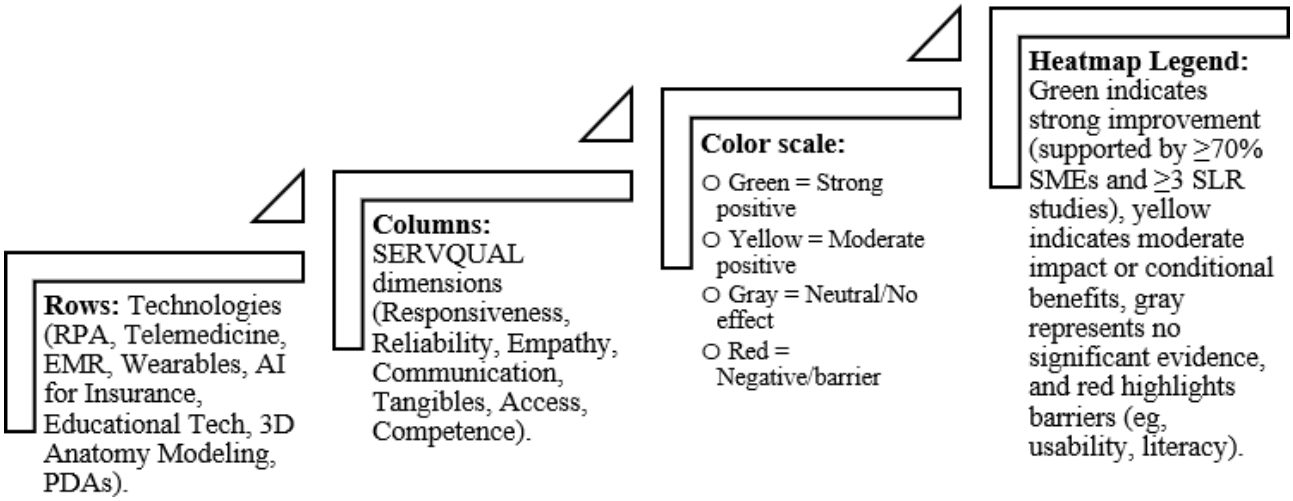
[d]PI: positive impact.

[e]When there is a tie in feedback, the highest scale is considered (eg, equal representation of 2-SPI, 1-SPI, and O-NI).

One of the major findings both the SLR and interviews revealed is the patient-centeredness. Patients differ significantly in their attitudes and preferences; some may be submissive, readily accepting prescribed treatments, while others might be technology enthusiasts who prefer to engage with digital health tools. Additionally, there are those who might challenge medical advice and seek more information or alternative options. Recognizing and addressing these variations is crucial for delivering personalized and effective care, especially if technology is used [34].

Discussion

Principal Findings



In the next sections, the results are discussed in two stages: (1) SLR findings structured by SERVQUAL dimensions, and (2)

XSL•FO
RenderX

SME insights triangulated with literature trends. Key quantitative outcomes from reviewed studies (eg, reductions in waiting time and improved satisfaction scores) are tabulated, while qualitative themes emphasize usability barriers, empathy gaps in telemedicine, and digital literacy challenges. Findings from the SLR and expert interviews (n=19) were mapped against SERVQUAL dimensions to illustrate the impact of emerging technologies. Figure 3 presents a heatmap showing technology influence across dimensions, while Table 1 details key quantitative effects and expert agreement rates.

This study examined whether the adoption of emerging digital health technologies improves PCQ in outpatient clinics. By synthesizing findings from 53 peer-reviewed studies and triangulating them with insights from 19 SMEs, the results indicate that digital technologies generally enhance several dimensions of outpatient service quality. The most consistent improvements were observed in responsiveness, communication, and operational efficiency through technologies such as robotic process automation, telemedicine, and EMRs. However, the findings also highlight that technological implementation alone does not automatically improve patient-centeredness or empathy, and that factors such as usability, digital literacy, and clinician training influence the extent to which technology translates into improved patient experiences. Overall, the results partially support the study hypothesis that emerging technologies enhance PCQ dimensions, while also emphasizing that human factors and organizational readiness remain critical to achieving patient-centered outcomes.

Figure 3. Heatmap of technology impact on SERVQUAL dimensions. EMR: electronic medical record; PDA: personal digital assistant; RPA: robotic process automation; SERVQUAL: Service Quality Model; SLR: systematic literature review; SME: subject matter expert.

Dimension 1: Responsiveness and Timeliness (Waiting Time and Service Time)

Excessive patient waiting time at outpatient clinics yields undesired levels of patient satisfaction and demands the need to be efficiently managed from a cost and duration perspective [8]. Patients perceive being at the receiving end of service quality when there is an patients strictly follow their scheduled appointments and doctors are available according to the promised time communicated to them [35].

The most promising technologies cited or appraised by SMEs are RPA, EHR, and connected ambulances. RPA relies on a combination of workflow, business rules, and presentation layer integration with information systems to act as a semi-intelligent user of the system, which can be used in preauthorization, updating patient records, and billing (repetitive tasks) [36]. RPA can be used for temporary or permanent outpatient clinics [37]. documented the use of RPA and its positive impact on the waiting time for an urgent care service for COVID-19. RPA was used to develop a web platform digital solution that uses modern Hode-JS, RESTful, and SOAP technologies to process data entries by the nurses, in addition to automating the administrative process at the EHR, replacing human intervention when interpreting data entry. The queuing system number generated by the EHR for the patient and displayed on a visual display, in addition to the patient's federal identification number, are the main field dependencies of this solution. Once the nurse concludes the defaulted health screening, the patient's federal identification number is input whereby the digital solution searches for the data linked to this identifier and completes the medical care registration form with all the mandated information for a complete medical record and links it to the queuing system number. This ensures a definitive linkage to the patient's health record, queuing number after the medical care registration, expediting the patient's journey immediately to the doctor's consultation. This solution is installed and used at the nursing workstations by properly trained nursing caregivers [37]. Despite the success stories of using EHR on responsiveness and accuracy, observational studies highlighted a negative impact on patient-physician communication behaviors when physicians are engaged with computers and ignoring their patients [38]. These moments of silence or screen gaze could be due to complicated systems or lack of training. Also, the frustration of physicians with the EHR system may translate into dissatisfaction, resistance to use, and missing some key information [39].

RPA has proven to be the technology of the future, providing sustainable solutions that reduce costs and delivery time, improve quality, and the speed and operational efficiency of business process complexities [7,36]. Additionally, it integrates different systems using software robots to automatically acquire and integrate data from clinical applications, lab information

XSL•FO
RenderX

systems, third-party portals, insurance portals, radiology information systems, enterprise resource planning (ERP) and human resources (HR) applications, and scheduling applications. RPA frees employees from the repetitive tasks of scheduling so they can apply their skills to scenarios that require human interaction and touch and automate the eligibility requests to access information for better communication to providers and patients [40]. RPA drastically reduced the amount of time staff spent on repetitive and routine activities from appointment scheduling, hence optimizing appointment scheduling, patient account creation and verification, file handling and processing, inventory management, claims processing, and test management [41].

Another form of digital transformation is in the use of connected ambulances, which are vehicles equipped with advanced communication technology that allows them to transmit vital patient information, such as medical history, vital signs, and real-time video, to health care providers before the patient arrives at the hospital. If care is not ensured in the emergency department, follow-up treatment in the outpatient clinics will be negatively impacted. These ambulances are essentially mobile telemedicine platforms, enabling health care professionals to assess and prepare for incoming patients more effectively [42]. The impact of connected ambulances on service reliability in outpatient clinics can be significant. By providing health care providers with detailed information about incoming patients, including their medical condition and needs, connected ambulances facilitate better preparation and coordination of care upon the patient's arrival. This can lead to reduced waiting times, more timely interventions, and improved overall patient outcomes. Overall, the use of connected ambulances can help outpatient clinics improve service reliability by streamlining processes, enhancing communication, and optimizing resource allocation to better meet the needs of patients [43].

Tables 3 and 4 depict respondents' perspectives on the influence of RPA on various organizational aspects, driving its adoption. It also delineates the impact of RPA on quality dimensions (including responsiveness, waiting, and service time), predominantly indicating favorable effects across organizational domains. Regarding connected ambulances, respondents affirmed they would indirectly positively affect responsiveness, waiting times, and service efficiency, as well as other dimensions, except for physicians' professional competence, credibility, and technical performance.

Table 5 demonstrates a strong alignment between expert opinion and the systematic literature regarding the impact of digital technologies on outpatient health care services. RPA received the highest level of SME consensus (84%), followed by telemedicine (74%) and AI-enabled insurance processing (71%), indicating that experts perceive these technologies as having the greatest potential to improve operational efficiency, reduce waiting times, and streamline administrative processes. Telemedicine also had the strongest evidence base in the literature, followed by EMR and EHR systems and RPA, reflecting substantial research support for their effectiveness. Across technologies, reported benefits consistently included enhanced efficiency, improved patient access, strengthened data integration, better remote monitoring, and increased patient education, although challenges such as digital literacy and usability remained important implementation considerations. Overall, the findings suggest broad agreement between SME perspectives and published evidence regarding the value of digital technologies in improving outpatient health care delivery.

Table . SME[a] consensus rates and literature support per technology (19 SMEs and 53 SLR[b] studies).

Technology	SMEs reporting positive impact (%)	Number of SLR studies supporting	Key outcomes reported
RPA[c]	84	7	↓ Waiting times (20% - 40%), ↑ efficiency
Telemedicine and virtual visits	74	11	↑ Access, ↑ satisfaction, digital literacy required
EMR[d] and EHR[e]	63	9	↑ Data integration, usability issues noted
Health care wearables	68	6	↑ Remote monitoring, literacy barriers
AI (insurance processing)	71	5	↑ Claim turnaround, ↓ admin time
Educational technology	60	4	↑ Empathy training outcomes
3D anatomy modeling	58	3	↑ Patient education, trust
PDAs[f] and decision support tools	55	3	↑ Physician decision support

XSL•FO
RenderX

Dimension 2: Reliability (Competence)

Applying reliability principles to health care has the potential to help reduce "defects" in care or care processes, increase the consistency with which appropriate care is delivered, and improve patient outcomes. It is a failure-free operation over time and an individual patient's experience over time, particularly effectiveness, timeliness, and patient-centeredness. Providing reliably good care over time requires understanding and addressing the reasons that patients are returning to the clinics [44]. In health care, reliability must be built across, not just within, groups and organizations; it has come to be used as a proxy for safety despite reliability and safety not being equivalent [45].

In outpatient clinics, the application of robotics and automation is broadly designated, such as robot areas, to assist patients and disseminate information about various units of the specialized clinic and hospital as a whole. Those robots can handle several visitors without becoming tired, stressed, or overloaded and direct the patient to the correct physician of choice. They are deemed attractive to patients, especially children, enhancing the overall patient experience. Moreover, humanoid nurse robots (HNRs) are being used to care for older adult patients, offering 24/7 and 7/7 service with minimal cost, inclusive of lifting and therapeutic assistance. Telemedicine robots are helpful in telemedicine applications where a virtual doctor takes all the physiological parameters and diagnoses a disease using audiovisual aids. Those systems are extremely useful in the case of pandemics whereby the patients are located in remote areas and cannot reach physicians for clinical diagnosis and treatment; those robots are used as a low-cost remote interface [46]. Vendors have developed sophisticated remote-controlled cars with advanced cameras, lenses, and connected microphones, which enable the physician to interact with the patient's bedside despite being miles away [47]. Nowadays, different versions of telemedicine such as online health platforms [48] and remote presence virtual and independent telemedicine assistants are widely used by hospitals [49].

Furthermore, an on-demand health care solution refers to a service or platform that provides immediate access to medical care and resources whenever and wherever needed. This could include telemedicine platforms, virtual consultations, remote monitoring devices, or mHealth apps. On-demand health care solutions leverage technology to connect patients with health care providers in real-time, offering convenience, accessibility, and timely assistance [50].

Tables 3 and 4 illustrate the viewpoints of participants regarding how telemedicine and virtual visits influence different organizational aspects, prompting their acceptance of this technology. It outlines the impact of these advancements on 9 quality measures, such as service reliability and assurance, indicating predominantly positive effects across organizational realms. Nonetheless, respondents noted that while telemedicine enhances most quality measures, it falls short in improving data collection capabilities and demands patients to possess technological proficiency for maximal benefits. Moreover, some studies suggest that reducing the visit length using technology is associated with medical errors such as inappropriate antibiotic prescriptions [51]. Conversely, on-demand health care solutions are seen to positively affect all quality measures.

Integrating technical support services with the implementation of EMRs in health care outpatient centers and clinics is essential for ensuring smooth operational performance, maintaining system reliability, and promptly addressing any technical challenges that may arise during system use [52]. Technical support teams play a fundamental role throughout the lifecycle of EMR deployment, beginning with the initial implementation phase and continuing through ongoing system optimization and maintenance.

During the early stages of EMR implementation, technical support teams provide critical assistance with system installation, configuration, and data migration. Their specialized expertise ensures that health care organizations can transition from traditional record systems to digital platforms with minimal disruption to clinical workflows and patient care processes. By carefully managing these technical transitions, support teams help reduce operational interruptions and facilitate a smoother adoption of EMR systems across health care facilities [53].

In addition to implementation support, technical teams are responsible for conducting training sessions and developing educational materials that help health care professionals effectively use EMR systems. These training initiatives typically include guidance on accurate data entry, system navigation, and the use of advanced system functionalities. Well-trained health care personnel are better able to use EMR capabilities efficiently, which contributes to improved accuracy, enhanced documentation quality, and more efficient patient care delivery [54].

Technical support teams also play a key role in the day-to-day operation of EMR systems by providing timely troubleshooting services and resolving technical issues that may occur during routine clinical use. Their responsibilities often include performing regular system maintenance tasks such as applying software updates, installing security patches, and optimizing system performance to ensure reliability and data protection. Furthermore, these teams collaborate closely with health care providers to customize EMR systems according to specific clinical workflows and operational requirements. They also facilitate the integration of EMR systems with other health care information technologies, including laboratory information systems and picture archiving and communication systems (PACS). Such integration enhances interoperability between different health care platforms, enabling more efficient data exchange and improving the overall effectiveness of health care delivery [55,56].

Another critical function of technical support teams involves maintaining the security and regulatory compliance of EMR systems. Health care organizations must adhere to strict data protection regulations, including standards such as the Health Insurance Portability and Accountability Act (HIPAA). Technical teams therefore implement comprehensive security mechanisms, including access control protocols, data encryption, and periodic security audits to safeguard sensitive patient information from unauthorized access or potential breaches. Ensuring regulatory compliance not only protects patient privacy

XSL•FO
RenderX

but also helps health care organizations avoid legal and financial risks associated with data security violations [57].

To ensure continuous system availability, many technical support providers also offer 24-hour helpdesk services and emergency assistance. This round-the-clock technical support is particularly important in health care environments where uninterrupted access to patient data is essential for timely clinical decision-making. Rapid response to system failures or technical issues helps minimize downtime and ensures that health care professionals can access critical patient information whenever needed, thereby supporting effective clinical care and patient safety [57].

Beyond operational support, technical teams continuously monitor the performance and usage patterns of EMR systems to identify opportunities for improvement. They gather feedback from health care staff and collaborate with EMR vendors to implement system updates, enhancements, and new functionalities that align with evolving health care standards and best practices. Through this ongoing monitoring and system refinement process, health care organizations can maintain efficient, reliable, and secure EMR infrastructures. Ultimately, the integration of dedicated technical support services with EMR implementation and maintenance significantly enhances the effectiveness of EHR systems and contributes to improved health care quality and patient outcomes [58].

The adoption of EMRs has significantly transformed health care delivery by improving operational efficiency, documentation accuracy, and accessibility of patient information. As health care systems increasingly transition from paper-based records to digital platforms, EMR systems offer multiple advantages that enhance both clinical and administrative functions within health care organizations.

One of the primary benefits of EMR implementation is the streamlining of administrative tasks. Processes such as patient record management, documentation, and prescription handling become more efficient through digital systems, allowing health care providers to reduce time spent on manual paperwork. As a result, clinicians can allocate more time and attention to direct patient care, ultimately improving the quality of health care services provided [59].

EMRs also provide a comprehensive and accurate overview of a patient's medical history, enabling health care professionals to access complete and organized clinical information in a timely manner. This improved accessibility supports more informed clinical decision-making and reduces the likelihood of medical errors that may arise from illegible handwriting, incomplete documentation, or fragmented paper records. By ensuring that patient data are clearly documented and readily available, EMRs contribute to safer and more reliable health care delivery [60].

In addition, EMR systems facilitate remote access to patient records, which significantly enhances communication and collaboration among health care providers. Physicians, specialists, and other health care professionals can access patient information from different locations, allowing for faster consultations, coordinated care, and improved clinical outcomes [61]. Patient engagement is also strengthened through EMR-integrated patient portals, which enable individuals to view their medical information, communicate electronically with health care providers, and manage appointments through online platforms. These features empower patients to become more actively involved in managing their own health and health care decisions [62].

Furthermore, the digital nature of EMR systems allows health care organizations to aggregate and analyze large volumes of clinical data. This capability supports advancements in population health management, enables more robust clinical research, and facilitates quality improvement initiatives across health care systems. By leveraging EMR-generated data, health care providers and policymakers can identify health trends, evaluate treatment outcomes, and implement strategies that enhance the overall effectiveness and efficiency of health care delivery.

While initial implementation costs can be substantial, long-term cost savings are realized through increased efficiency, reduced paperwork, and better management of chronic conditions [63]. Furthermore, the interoperability of EMRs improves continuity of care by enabling seamless sharing of patient information between different health care providers and systems [60]. Enhanced compliance with regulations such as HIPAA and robust security measures ensures the protection of patient data, further bolstering the benefits of digital transformation in health care using EMRs [64].

Tables 3 and 4 illustrate the perspectives of respondents regarding the influence of EMR on different organizational aspects, motivating their interest in adopting this technology. It also outlines the effects of EMR systems on quality dimensions, such as technical support services, which show improvement with the digitization of medical records and related clinical operations. This primarily indicates a positive impact across various organizational sectors.

Dimension 3: Environment of Service Delivery (Cleanliness)

Cleaning and disinfection of surfaces in clinics are strategies to minimize the occurrence of health care–associated infections. Given that clinics with it increase patient volumes are environments that act as a pool for bacteria and viruses that may spread in the clinic causing infectious disease. For stringent infection control, an intensified cleaning and disinfection process is applied [65]. Moreover, strict policies and procedures to eliminate cross-contamination in outpatient clinics are essential [66], such as disposable glove changes, caregiver's hand washing, clinic surfaces being disinfected often, tools and equipment cleaning and sterilization, and single-use supplies disposal.

Cleaning robots are used in outpatient clinics; they use intelligent navigating dry vacuum pumps for dry or wet mopping activities, being an integral part of disinfecting the physical space from germs and pesticides. Moreover, the UV radiation-based robot is used to disinfect the clinic from microbes and clean washrooms using sensing systems. Spraying and disinfection robots widely spread antiseptic combinations over large indoor and outdoor areas [46].

XSL•FO
RenderX

Tables 3 and 4 depict the respondents' views on how robotics affects various organizational aspects, driving their inclination toward adopting this technology. It also delineates the impact of robotics on quality dimensions, including the environment of delivering service, primarily indicating a favorable influence across organizational sectors. Robotics enhances surgical precision (outcome of surgery), resulting in expedited recovery and rehabilitation, thereby improving surgical outcomes.

Dimension 4: Communication

Interpersonal communication plays a key role in the patient's treatment plan; not only does it impact patient satisfaction levels with the offered clinical service but also it places them in the role of a partner in the journey building an environment of empathy, friendliness, kindness in treatment, safety, and trust. Enhanced communication guarantees that patients have access to their health information and ultimately enhances the quality of patient care within an outpatient clinic setting [67]. Moreover, communication errors can be a profound contributing factor in outpatient clinic sentinel events resulting in poor health outcomes alongside elevated distress levels in patients and their family members. Effective communication skills are deemed a core clinical skill expected from every clinical caregiver when effectively exchanging information between a patient and them and include communication with the family and carer as well. Among the key elements of effective communication in clinics is the ability to foster relationships, the 2-way exchange of information, convey empathy, engage patients in decision-making and care planning, and manage complexity and uncertainty [68].

Patient preferences are leaning toward using technology when communicating about their symptoms with their health providers in clinics especially after discharge from outpatient clinics. Email communication, phone, text messaging, mHealth portal apps, social media, online discussion forums, and videoconferencing [69]. Furthermore, patient education is a crucial element within health care. It is known as forecasters for increased patient engagement levels in shared decision-making, improved medication and treatment adherence, higher levels of satisfaction, and even better overall treatment outcomes. Most patients are simply not capable of processing large amounts of new medical information in a short period of time. Apps for smartphones and tablets have the potential to actively educate patients by providing them with timely information using push notifications [70]. Finally, Owens et al [71] conducted a study to evaluate the use of ambient voice recognition, coupled with natural language processing and AI in patient-physician relationships. The feedback of 288 patients suggests a strong positive correlation between the use of this technology and patient-physician communication, which improved patients' satisfaction.

The impact of on-demand health care solutions on the communication quality dimension is significant. First, these solutions facilitate seamless communication between patients and health care providers, overcoming barriers such as geographical distance or time constraints. Patients can easily connect with health care professionals via video calls, chat messaging, or phone calls, enabling timely access to medical advice and assistance [72]. Moreover, on-demand health care solutions often incorporate features that enhance the quality of communication. These may include secure messaging platforms, multimedia capabilities for sharing images or documents, and real-time data exchange functionalities. By providing clear channels for communication, these solutions enable patients to effectively convey their symptoms, concerns, and medical history to health care providers, leading to more accurate diagnoses and personalized treatment plans [73]. Additionally, on-demand health care solutions can improve communication among health care teams. They enable seamless collaboration and information sharing between primary care providers, specialists, and other health care professionals involved in a patient's care [74]. This interdisciplinary communication fosters coordinated and integrated health care delivery, ultimately improving patient outcomes [75].

Tables 3 and 4 present the viewpoints of the respondents regarding the impact of mHealth portal apps and videoconferencing on various organizational aspects, which motivate their adoption of these technologies. It also delineates the effects of these apps on quality dimensions, notably communication, predominantly indicating a significantly positive influence across organizational sectors. Particularly for mHealth portal apps, an equal number of respondents expressed a perception that, unlike their counterparts, they observe no impact on physicians' professional competence, credibility, technical performance, as well as patient-centeredness and empathy (staff demeanor). However, for the sake of this research, the favorable responses were taken into consideration.

Dimension 5: Empathy (Staff Demeanor)

Terry and Cain [76] stressed the criticality of empathy throughout the patient care journey and optimal patient-caregiver relationship. It increases both the patient's satisfaction and compliance and elevates the caregiver's ability to cater to the clinical needs of their patients. Furthermore, it has a strong correlation and positive impact on the health outcomes of patients and decreases the risk of any potential malpractice liability. Empathy in its core element does not change yet evolves to align with the digital advancements in the channels of provisioning and communicating clinical services.

With the widespread use of telemedicine in outpatient clinics, the construct of digital empathy has become an increased necessity and must be integrated into the academic and training curricula of health professionals [76]. An increasing trend in the use of digital health tools to engage patients and enhance outcomes is seen; with its effectiveness being dependent on the consistency of the patients' use and engagement, with empathy being the foundation of such tools. This has further increased the importance of not only the caregiver's increase in their telemedicine levels but also the importance of architects being more considerate with their home designs, especially with working from home being the future of work, especially within the lifespan; the same homes may have to accommodate chronically ill patients. Hence, making the design of sustainable and healthy homes a new trend, that is, designing for well-being in residential health care. It is more than having a healthy physical body and includes social, spiritual, emotional, and

XSL•FO
RenderX

intellectual well-being. Incorporating nature into the environment through biophilic design creates a sense of serenity, therapeutic, and well-being effect in the homes of patients [77].

Tables 3 and 4 provide insights into how educational technology influences various aspects within outpatient clinics, shedding light on why these clinics are increasingly inclined to adopt such technology. The findings suggest that educational technology has a predominantly positive effect across different areas within outpatient clinics, indicating its potential to enhance patient care, staff interactions, and overall clinic operations. This underscores the importance and potential benefits of integrating educational technology into outpatient clinic settings, not only for improving efficiency and effectiveness but also for fostering positive patient experiences and enhancing the quality of care provided through more empathy levels by the care providers [78]. Tables 3 and 4 depict respondents' perspectives on the influence of RPA on various organizational aspects, driving its adoption. Respondents observed that while RPA improves most quality dimensions, it does not significantly enhance patient-centeredness or empathy (staff demeanor). It also delineates the impact of RPA on quality dimensions (including responsiveness, waiting, and service time), predominantly indicating favorable effects across organizational domains. Such findings are in line with the study by Chen et al [79], who suggested that efficiency improvement that results in shorter visit duration can negatively impact the provision of counseling and the patient-physician relationship and communication.

Dimension 6: Nurse Care

According to the study by Oermann and Templin [80], patients perceive high nursing quality when they are cared for by nurses who are knowledgeable and resourceful. Having direct access to the nurse and can communicate and spend enough time not being rushed during the clinic visit. Moreover, they consider the fact that a nurse educates them and teaches them more about their illness (especially among those who are less educated, have lower income levels, and have been living with chronic illness) and the medications that they require; reiterating the treatment plan and expectation setting alongside coaching them on how to remain healthy was a quality differentiating factor. Additionally, having the ability to reach out at any given time for clarifications, concerns, or guidance is becoming more critical than ever.

Patients are expecting more detailed explanations about their health situation to increase their understanding and minimize their anxiety levels and complaints; making the use of 3D digital anatomy modeling an aid to teaching and its use in patient education and operation planning. Clinicians will be expected to ensure that the information is retained and risks and benefits weighed up in the 3D computer animation. Patients' understanding improved, their trust levels increased in the professional treatment, and their anxiety reduced toward their medical conditions and treatment plans [81].

Tables 3 and 4 illustrate the opinions of participants regarding the influence of 3D digital anatomy modeling on different organizational facets, motivating their interest in embracing this technology. It also outlines how this technology affects 9 quality aspects, including nursing care, mostly suggesting a positive effect across organizational domains and that it permits a more effective 2-way dialogue with the patient. Nonetheless, respondents noted that for 4 dimensions, they observed no impact of this technology on (1) improving productivity, (2) physicians' professional competence, credibility, and technical performance, (3) responsiveness and waiting and service time, and (4) access to care and health care inequality.

Dimension 7: Access to Care and Health Care Equality

Access to medical care is a comparatively multifaceted phenomenon categorized by potential access and realized access. The latter is what matters in outpatient clinics, as it resembles the use of physician time for all specializations, which makes the design of robust policies to optimize this quality determinant. If patients can't reach care, their satisfaction levels will drop negatively, impacting their treatment journey [82].

Digital transformation improves access to health care services and supports health insurance processing large numbers of claims and payments, which upscales the service of outpatient clinics [83]. Davenport and Kalakota [36] pointed out that machine learning, neural networks, deep learning, and precision medicine are where AI predicts what treatment protocols are likely to succeed for a patient based on various patient attributes and his or her treatment context. In addition, Bruce and Hardy [84] added that the use of natural language processing (NLP) is where AI involves the creation, understanding, and classification of clinical documentation and published research, viewing disease history and analyzing unstructured clinical notes on patients, preparing reports, and transcribing patient interactions. An example is IBM's Watson and Google DeepMind Health. AI combined with consumer wearables and other medical devices is applied to oversee early stages of heart diseases, allowing caregivers to monitor and detect potentially life-threatening episodes at an early stage.

Tables 3 and 4 present the perspectives of respondents concerning the impact of AI in insurance processing on various organizational aspects, stimulating their inclination toward adopting this technology. It also delineates the influence of this technology on 9 quality dimensions, with particular emphasis on access to care and health care inequality, generally indicating a positive impact across organizational realms. It is noteworthy that some respondents highlighted its tendency to diminish the soft skills of insurance professionals despite its benefits. Regarding health care wearables, participants affirmed that they observed a beneficial influence across various quality aspects except for patient-centeredness and empathy (staff behavior) and responsiveness, waiting, and service time, as they believe these dimensions remain unaffected by this technology. One main challenge to information-access equality is patients' digital literacy and access. Negative attitudes toward technology, disinterest in learning new skills, physical and mental disability, and financial hardships are among the reasons for technology avoidance [85]. Such challenges may undermine the benefits gained from technological adoption, such as telemedicine, and make it a curse rather than a blessing.

XSL•FO
RenderX

Dimension 8: Physician's Professional Competence, Credibility, and Technical Performance

This dimension is concerned with the physician consultation stage of the patient journey in terms of the way the doctor diagnoses and explains the treatment plan to the patient, reflecting their competency level as a key determinant of quality for their clientele. Moreover, leadership training, systems theory and analysis, cross-disciplinary training and multidisciplinary teams, understanding and respecting the skills of other practitioners, population health management, palliative care and end-of-life and resource management and medical economics, health policy and regulation, less ''captain of the ship'' and more ''member/leader of the team,'' empathy and customer service, time management, conflict management, providing performance feedback, understanding cultural and economic diversity, and emotional intelligence were identified as the core physician skills required for the next generation of health care delivery [86].

Medical information technology throughout the continuum of the physician's lifelong journey has become a widespread phenomenon providing physicians access to teleconference podcasts, consulting resources in PDAs for enhanced patient management decisions at the point of care. Medical simulators are another form of technology that is also increasingly being used for targeted training and assessment that would elevate the technical skill set levels of care providers [87]. A reliable disease history analysis is integral to assessing a physician's professional competence, credibility, and technical performance. Physicians who possess a thorough understanding of their patients' medical histories demonstrate competence in their ability to gather and analyze pertinent information critical to diagnosis and treatment decisions. This competence enhances their credibility among patients and colleagues alike, fostering trust and confidence in their clinical judgment [88]. Furthermore, a meticulous disease history analysis enables physicians to demonstrate technical proficiency in identifying relevant patterns, risk factors, and potential complications associated with a patient's health status. By effectively using this information, physicians can deliver more precise and tailored care, thereby enhancing their overall performance and ensuring optimal patient outcomes [89]. Thus, a reliable disease history analysis is not only essential for providing high-quality health care but also for upholding the standards of professional competence, credibility, and technical proficiency expected of physicians [90].

Tables 3 and 4 showcase respondent viewpoints regarding the effects of PDAs on insurance processing across organizational facets, encouraging proclivity toward its adoption. It outlines the impact of PDAs on 9 quality dimensions, notably focusing on physician's professional competence, credibility, and technical performance, generally indicating a positive influence across organizational domains, except for patient-centeredness and empathy, where respondents perceived no effect from this technology. Notably, some respondents pointed out the low quality of data collected by PDAs and that using PDAs dilutes accountability and responsibility. In examining disease history, participants confirmed a positive impact across all dimensions except for the environment of delivering service (cleanliness). Conversely, in evaluating teleconference podcast technology, all dimensions showed a positive effect except for responsiveness, waiting times, and service efficiency.

In summary, each technology comes with benefits and some negative impact on some of the quality dimensions. Training and good change-management practices can help overcome these negative aspects and better integrate the technology into the patient care system [91]. Table 4 provides a summary of the positive and the negative impacts of technologies adopted in health care based on the literature review and SMEs' feedback.

The study is limited by its qualitative nature and reliance on SME perspectives, which may not generalize across all outpatient contexts. Additionally, limited patient-reported outcomes restrict conclusions on direct patient experience impact. Quantitative evaluations using patient satisfaction surveys, randomized trials of specific digital tools, and cost-effectiveness analyses are needed. Further exploration into digital literacy interventions and human-centered technology design is recommended to optimize patient-centered outcomes.

This systematic review contributes to the literature by providing an integrated synthesis of how emerging digital health technologies, including telemedicine, wearable monitoring, and clinical automation, collectively influence PCQ in outpatient settings. The review is innovative in its holistic approach, moving beyond technology-specific evaluations that dominate existing reviews and instead examining the combined impact of multiple digital health modalities within a unified analytical framework. By organizing and interpreting evidence across fragmented research streams, the study advances theoretical understanding of digital transformation in health care and clarifies the pathways through which digital tools enhance accessibility, efficiency, and patient-centered care delivery. In practical terms, these findings offer actionable insights for health care leaders, policymakers, and technology developers seeking to implement digital solutions that improve service quality and patient outcomes in real-world outpatient care environments.

Taken together, the findings demonstrate that emerging digital technologies influence outpatient service quality through multiple operational and clinical pathways. Automation technologies primarily improve efficiency-related dimensions such as responsiveness and workflow coordination, while digital communication tools strengthen patient-provider interaction and access to care. In contrast, technologies that rely heavily on patient engagement, such as telemedicine platforms and wearable monitoring devices, reveal the importance of digital literacy and user-centered system design. These findings align with recent literature suggesting that digital transformation in health care improves operational performance but requires complementary organizational strategies to fully enhance patient-centered care. The results therefore reinforce the importance of integrating technological innovation with training, workflow redesign, and patient engagement strategies to achieve meaningful improvements in health care quality.

Despite its contributions, this study has several limitations that should be considered when interpreting the findings. First, the systematic review was limited to studies published in English between 2017 and 2022, which may exclude relevant research

XSL•FO
RenderX

published in other languages or earlier foundational studies. Second, the review synthesized evidence across different health care systems and geographical contexts, which may limit the generalizability of specific findings to all outpatient settings. Third, although expert interviews provided valuable contextual insights, the sample size of 19 participants may not capture the full diversity of perspectives across the health care industry. Additionally, some technologies included in the analysis are evolving rapidly, meaning that their impacts on PCQ may continue to change as implementation practices mature. Finally, the study primarily relied on qualitative synthesis rather than meta-analysis due to heterogeneity across study designs and outcome measures, which limits the ability to quantify the magnitude of technology effects on PCQ.

The findings of this review have several implications for both research and health care practice. From a theoretical perspective, the study demonstrates the value of applying service quality frameworks such as SERVQUAL to evaluate the impact of digital transformation on health care delivery. By integrating evidence across multiple technology domains rather than examining individual innovations in isolation, this review provides a more comprehensive understanding of how digital health ecosystems influence PCQ. From a practical standpoint, the results highlight that health care organizations should approach technology adoption as part of a broader transformation strategy that includes workforce training, workflow redesign, and patient engagement initiatives. Future research should further investigate how different technologies interact within health care systems and explore longitudinal evidence on their long-term effects on patient outcomes and health care equity. Ultimately, the effective integration of emerging digital technologies has the potential to strengthen outpatient care delivery and support more responsive, accessible, and patient-centered health care systems.

Conclusion

Using the augmented SERVQUAL model, the analysis presented in this research offers a structured evaluation of various emerging technologies' impacts on organizational aspects within health care and insurance processing domains. Each technology is assessed across 9 quality dimensions, enabling a comprehensive understanding of its effects on service quality, efficiency, and patient care. The findings reveal a predominantly positive influence of technologies such as RPA, telemedicine, robotics, EMR, mHealth portal apps, educational technology, 3D digital anatomy modeling, AI in insurance processing, health care wearables, PDAs, and teleconference podcast technology on organizational performance. These technologies demonstrate strengths across dimensions such as service reliability, communication, and technical support services.

Patients differ significantly in their attitudes and preferences; some may be submissive, readily accepting prescribed treatments, while others might be technology enthusiasts who prefer to engage with digital health tools. Additionally, there are those who might challenge medical advice and seek more information or alternative options. Recognizing and addressing these variations is crucial for delivering personalized and effective care, especially if technology is used [34]. Although automation is an important enabler for productivity boost, it treats every patient the same way, ignoring the fact that patients have diverse expectations and needs.

However, nuanced insights emerge from the analysis. While most technologies exhibit positive effects, challenges such as data quality issues, technological proficiency requirements for users, and limited impact on certain dimensions are identified. For example, while telemedicine enhances service reliability and accessibility, it may require patients to possess adequate technological skills for optimal use. For example, the use of EHR to reduce patient visits, coupled with poor usability of the system, which results in physicians' distraction, may negatively impact patient-centeredness. Proper integration of EHRs in clinical practice may boost the patient-physician communication dynamics, while poor usability and long keyboarding may jeopardize this communication. Moreover, although technology adoption provided significant reductions in visit and waiting time, shorter visit time may be associated with medical errors and lack of patient-centeredness. As a result, optimal visit time is necessary. Table 6 summarizes the components of the literature search strategy, including the databases searched, the timeframe covered, the language restriction, and the study types included in the review.

Table 7 summarizes the potential positive and negative impacts of the technologies identified in the literature, organized according to health care service quality dimensions and supported by evidence from the included studies.

Table . Components of the literature search.

Component	Details
Databases searched	ABI/INFORM Global, ScienceDirect, Medline (via PubMed), and Google Scholar

Table . Summary of potential impact of technologies.

Dimension and technology	Negative impact	Positive impact
Responsiveness		
EHR[a]	• Missing some key information due to EHR literacy and usability [39]	• Appointment scheduling [35] • Data collection accuracy [37]
RPA[b]	—[c]	• Waiting time reductions [36] • Better communication to providers and patients [40] • Improve efficiency and use [41]
Connected ambulances	—	• Improve incoming patients' treatment effectiveness [42] • Enhance communication and use [43]
Reliability		
HNR[d]	—	• Improve diagnoses and care [46]
Telemedicine	• Visit length reduction may increase medical errors such as inappropriate antibiotic prescription [51] • Reduction of data collection (SMEs[e])	• Improve health accessibility and improve use [47-49]
EMR[f]	—	• Maximizing system uptime and addressing issues that may arise [52,54] • Enhancing data security [57,64] • Enabling seamless sharing of patient information between different providers and systems [60]
On-demand health care	—	• Improve convenience, accessibility, and timely assistance [50]
Robotics	—	• Enhances surgical precision resulting in expedited recovery and rehabilitation
Cleanliness		
Cleaning robots	—	• Intensified cleaning and disinfection improvement [46,65]
Communication		
EHR	• Lack of patient-physician communication behaviors due to data entry and keyboarding distraction [38]	• Enhanced health information accessibility and overall PCQ[g] [67] • Patient engagement in decision-making [68]
Videoconferencing	—	• Increased patient engagement and enhanced treatment outcomes [69,72,73]
Apps	• Shorter visit duration can negatively impact provision of counseling and the patient-physician relationship and communication [79]	• Improve patients' education and timely information notifications [70]
Empathy		
Telemedicine	—	• Enhance patients' engagement
Voice recognition	—	• Improve patient-physician communication [71]
RPA	• No significant impact on empathy (SMEs)	—
Nurse care		

XSL•FO
RenderX

Dimension and technology	Negative impact	Positive impact
3D computer animation	—	• Increase trust levels reduce anxiety [81]
Access to care		
AI in health insurance, mobile apps, and wearables	• Digital illiteracy results in a negative attitude toward technology [85] • Diminishing the soft skills of insurance professionals (SMEs)	• Improve serviceability and satisfaction [36,83]
Professional competence		
Medical simulators	—	• Elevate the technical skill set levels of care providers [87]
PDA[h] and EMR	• Low quality of data collected by PDAs dilutes accountability and responsibility (SMEs)	• Fostering trust and confidence in care providers' clinical judgment [88-90]

[a]EHR: electronic health record.
[b]RPA: robotic process automation.
[c]Not available.
[d]HNR: humanoid nurse robot.
[e]SME: subject matter expert.
[f]EMR: electronic medical record.
[g]PCQ: patient care quality.
[h]PDA: personal digital assistant.

The SERVQUAL model facilitates a systematic examination of these technologies' impacts, enabling stakeholders to identify areas of strength and opportunities for improvement. By addressing challenges and leveraging strengths, organizations can enhance their adoption and implementation of emerging technologies, thereby optimizing service delivery, patient care, and operational efficiency within health care and insurance processing sectors.

Despite extensive efforts to identify and evaluate the determinants influencing digital transformation in health care, existing literature provides limited evidence regarding the measurable value, temporal evolution, and relative prioritization of these determinants, particularly from the patient perspective. Current research has largely focused on conceptual assessments and implementation considerations, while the empirical relationship between digital initiatives, return on investment, service quality, and human-centered care remains insufficiently explored. Therefore, future research should adopt quantitative and mixed methods approaches to validate these determinants, assess their impact over time, and establish evidence-based frameworks that balance technological advancement with patient expectations, operational efficiency, and quality of care.

Abstract

Background: This study investigates the capacity of 7 artificial intelligence (AI) models, 5 free and 2 paid, to generate functional software for designing low-cost, personalized assistive products.

Objective: The objective was to determine which models are most effective, accessible, and consistent in supporting nontechnical professionals in developing inclusive digital solutions and to assess the capabilities of commercially available and easy-to-access AI models to generate code from natural language interactions in the shape of a nontechnical assistive technology design process.

Methods: Each AI model was prompted using natural language, without any technical input, to create a Python program that converts an arcade gamepad into an adapted mouse-like controller. Sixteen progressively complex functions were requested through standardized prompts, delivered without additional feedback or correction. Model performance was evaluated based on the number of successfully implemented functions and the average number of prompts required.

Results: Paid models demonstrated markedly superior performance. Gemini Pro (Google) successfully implemented 14 of 16 requested functions with an average of 1.25 (SD 0.45) prompts, while ChatGPT Plus (GPT-5) achieved 11 functions with an average of 1.31 (SD 0.48) prompts. In contrast, free models produced between 0 and 4 functional outcomes, with DeepSeek and Gemini Free ranking the highest within their category. The enhanced outcomes of paid models were linked to improved contextual understanding, greater tolerance for natural language, and reduced conversational drift.

Conclusions: Paid AI models, particularly Gemini Pro and ChatGPT Plus, exhibit strong potential as tools for bridging the gap between health or education professionals and software development. They enable the creation of affordable, user-centered assistive technology without requiring advanced programming skills. Nevertheless, human oversight and foundational literacy in prompt design remain crucial to guarantee functionality, reliability, and ethical use.

Introduction

Background

Artificial intelligence (AI) can be defined as the ability of nonhuman systems, machines, or software to simulate functions inherent to human intelligence, such as perceiving, reasoning, learning, planning, and anticipating future situations [1]. The recent advancements in the field have made clear that generative AI will open new scenarios in which human-machine collaboration will enable faster and more adaptive software solutions to meet the needs of people with disabilities [2]. In these contexts, the professional programmer assumes a supervisory role, while users without technical experience can create functional prototypes through intuitive AI-powered interfaces. It is thought that, by 2030, integrated assistants, such as the so-called HyperAssistant, will be capable of accompanying individuals throughout all stages of development, bridging the gap between software conception and implementation [3].

AI is transforming the way software is conceived and produced by allowing nontechnical users to participate actively in programming. Traditionally, this process was restricted to those mastering specific languages and methodologies; however, generative models in the shape of conversational AI systems have reduced the gap between natural language and coding, fostering digital inclusion and democratizing access to digital creation [4,5]. Generative assistants increase productivity and allow users with limited skills to build functional prototypes by

XSL•FO
RenderX

using natural language–oriented programming, where users express requirements in everyday language and AI translates them into executable code, bridging human thought and computational structures. This AI integration in development environments additionally enhances efficiency through real-time suggestions and code autocompletion, while warning against technological overreliance [6-8].

Design and Characteristics of Effective Prompts for Interaction With AI

The dialogue between a user and an AI system depends on how instructions or prompts, as they are known in the AI environment, are formulated. Prompts act as mediators between human intention and automatic language generation, shaping the trajectory of interaction, structuring intent, and bridging human goals with machine logic [9]. The first key element to achieving functional prompts is goal definition. Effective communication with conversational systems requires explicit purposes that limit and contain the semantic context. A prompt without a defined end, such as "tell me about economics," produces generic responses, whereas "summarize in 200 words the effects of remote work on business productivity" provides focus and precision [10].

The second principle is linguistic specificity, referring to the fact that grammatically well-structured prompts enhance coherence. Since AI operates through probabilistic predictions, lexical clarity, thematic delimitation, and details about format or audience reduce ambiguity [11-13]. The internal structure should ideally include 5 essential elements: topic, style, tone, format, and context. It should also contain action verbs (such as analyze, compare, or synthesize) to guide specific cognitive-like operations [14,15]. This level of precision is fundamental, as prompt design directly influences the reasoning processes activated by the model [16].

Using these key principles and unifying different prompt explanations from the literature, we could divide prompts into 6 specific and differentiated types with their own goals (Table 1).

Table . Types of prompts used.

Prompt type	Goal	Example
Zero-shot or decision	Execute a task or produce a direct response without prior examples [17].	Explain the concept of neuroplasticity in simple terms.
Few-shot or iterative	Guide generation using prior examples [12,18].	Example 1: write a scientific abstract. Example 2: create a new one about artificial intelligence.
Chain of thought	Promote logical processes or explanations step-by-step [19].	Explain, step by step, how you arrive at the conclusion about the benefits of automation.
Sequential	Develop an idea or process step by step [11].	First, define the concept, then provide an example, and finally conclude.
Argumentative	Request a reasoned, well-supported position [11].	Argue why automation can be beneficial.
Verification	Review one's own output and detect errors or biases [20].	Review your previous answer and indicate possible inaccuracies.

Communicative Limitations of Nonexpert Users in Interactions With AI

Several studies agree that interactions between users and AI systems present communicative limitations stemming from the spontaneous and imprecise use of natural language. Users without technical training often formulate ambiguous prompts, making it difficult for the system to interpret communicative intent [21]. Additionally, the absence of nonverbal cues and the limited adaptability of artificial discourse exacerbate these differences, revealing that the effectiveness of interaction depends on the precision and structure of the language used [22].

From a qualitative perspective, users tend to treat chatbots as human interlocutors, reproducing communicative patterns based on empathy and reciprocity [23]. Users tend to apply Grice conversational maxims when evaluating virtual assistants. These maxims include quantity (providing the right amount of information), quality (saying only what is true and verifiable), manner (expressing oneself clearly and orderly, avoiding ambiguity), and relevance (keeping responses focused on the topic at hand) [24]. Complementarily, anthropomorphism, or trying to treat AI like a human, seems to induce a sort of relational dissonance that clearly shows a contradiction as users understand AI as nonhuman yet interact with it as if it were a human [25,26].

Generative models do not interpret implicit intentions but rather textual correlations; therefore, effectiveness depends on the specificity of the prompt [12,14]. Many users are unaware of this mechanism and rely on trial and error [27,28]. Furthermore, the absence of mental models about AI processing creates a cognitive gap between intention and response, reinforced by interfaces that simulate naturalness while not processing information cognitively naturally [29,30].

In summary, most users lack the metalinguistic skills required to design effective prompts, and bridging this gap demands a form of communicative literacy oriented toward AI.

AI in Education: Barriers, Assistive Products, and Opportunities for Digital Inclusion

At this point, it is essential to analyze how AI can be integrated into educational and disability support contexts, expanding

XSL•FO
RenderX

opportunities for student participation and learning. This link between technology and inclusion requires examining the barriers that still limit its effective use in classrooms. The analysis of possibilities for students with disabilities within the school setting must address the obstacles that hinder their access and active participation, emphasizing the importance of identifying factors that prevent the functional use of educational materials [31]. Students with disabilities face multiple barriers—including negative attitudes, lack of appropriate resources, and insufficient technological accessibility—which restrict their access to inclusive and equitable education [32].

Since the COVID-19 pandemic, information and communication technology has played a central role both in education and society [33]. However, the lack of technological accessibility remains a major barrier, as current learning materials heavily depend on digital tools. This not only affects curricular access but also the acquisition of digital skills essential for adulthood. Studies and hiring companies, such as iHire, highlight that 76% of people seek employment online, illustrating the importance of digital literacy for future labor inclusion [34,35].

To address these barriers, assistive products (APs) are key tools for ensuring the educational and social participation of students with disabilities. According to ISO 9999:2022, APs are products that optimize functioning and reduce disability, serving as intermediaries between personal abilities and environmental demands. The previous version of this standard (ISO 9999:2016) specified 3 key functions: facilitating participation, supporting or substituting body functions, and preventing limitations or restrictions in participation. APs associated with information and communication technology include both hardware and software, and the ISO 9999:2023 standard emphasizes their mixed nature, explicitly stating “including software” and recognizing their educational value within category e130 of the International Classification of Functioning [36-38].

Society and public administrations are responsible for ensuring that children with disabilities have access to the APs necessary for their personal and social development [39-41]. However, the World Health Organization warns that high costs and technical complexity limit access, particularly in educational contexts [42]. Although technological advances and globalization have partially reduced prices, technical barriers remain in specific contexts [43].

While many education and health professionals are familiar with physical APs, they often lack expertise in software-based solutions, which usually require technical support from IT specialists. This dependency increases costs and delays implementation. In this context, AI represents a major opportunity: its ability to generate and modify code accessibly allows the creation or adaptation of low-cost technological products, narrowing the gap between technical design and real student needs [44]. Although AI-generated software may not reach the technical refinement of professionally supervised development, it offers an effective, economical, and flexible alternative to enhance accessibility and educational participation for students with disabilities, particularly in low-resource or time-constrained contexts.

Methods

Overview

The software development process was carried out iteratively with the assistance of 8 different AI models, 6 of which were free and 2 were paid (Table 2). These models were selected to generate results applicable to contexts where cost may be a limiting factor. The chatbots were asked to program a software solution to convert an arcade fighting-style controller into a computer control device similar to an adapted mouse. Communication with the AIs was conducted using predetermined prompts prior to testing.

The objective was not only to obtain a functional program but also to significantly reduce the feedback provided to each AI and subsequently analyze each model’s ability to solve the problem as efficiently as possible, assessing whether it could produce a complete and functional solution. This approach enabled the comparison of performance, accuracy, and coherence across different platforms within the same experimental context, providing objective data on their real effectiveness in supporting software development through natural language instructions.

Table . AIs used, models, and price.

Company	AI[a]	Model	Price
OpenAI	ChatGPT (Free)	GPT-4.1 mini	N/A[b]
OpenAI	ChatGPT (Pro)	GPT-5	€23 (US $26.36)/month
Google	Gemini (Free)	Gemini 2.5 Pro	N/A
Google	Gemini (Paid)	Gemini 2.5 Pro	€21.99 (US $25.20)/month
Anthropic	Claude (Free)	Sonnet 4.5	N/A
DeepSeek	DeepSeek	DeepSeek V3.2	N/A
Microsoft	Copilot	o3 mini	N/A

[a]AI: artificial intelligence.

[b]N/A: not applicable.

To ensure experimental validity and avoid prior learning or contamination from conversational memory, each evaluation was conducted in entirely new conversations and, in the case of free plans, through newly created accounts. This strategy is

XSL•FO
RenderX

grounded in empirical evidence showing that conversational history can induce bias or interference between tasks, thereby affecting model responses [45]. Similarly, literature on data contamination in language models indicates that any prior exposure to the evaluated information alters the reliability of results [46,47]. Even slight reformulations or lingering contextual information can modify the direction and quality of the generated output [48]. Therefore, initiating each session in a clean environment constitutes a methodologically necessary measure to control carryover bias, prevent contextual leakage, and ensure independence between trials, thereby preserving the external comparability of performance and accuracy across the evaluated models.

Ethical Considerations

The Research Ethics Committee of Valencia Catholic University Saint Vincent Martyr approved the study (UCV/2023-2024/010).

Test Protocol

The first step in initiating the coding process was to define the functions that could be beneficial and link each of them to the prompts that would be sent to the different AIs (Table 3). The definition of these prompts and the design of the conversation were based on two key concepts:

1. Iterative execution: the initial prompt is sent; the generated code is tested for functionality; and if it works successfully, the next prompt is sent with the intention of iteratively adding new features to the designed program.
2. Error handling: no feedback is provided, only the message "it doesn't work, fix it." This approach is based on the understanding that a person without technical qualifications might not comprehend the underlying problems in the code and would likely just ask the AI to fix the errors encountered. Such a person might be able to inform the AI that, for example, the joystick is not working but not describe more complex interaction failures or interpret Python error messages.

Table . Function desired and chosen prompt.

Function	Prompt
1. Move mouse with joystick	I have no knowledge of programming. I have a generic fighting style Game Pad that has a single joystick and several buttons. I need you to code a program in Python that allows the joystick on this device to generate the movements of the computer mouse.
2. Single right and left click	I need you to code left and click buttons like the mouse has.
3. Allow button reassignment	I need you to code in an app that allows the program to reassign keys in the gamepad.
4. Double left click from a single button	I need you to add an extra button that performs a double click in single click.
5. Toggle hold for left click	I need you to add an extra button that holds left click when pressed and releases when pressed again.
6. Scroll page up and down	I need you to add two extra buttons for scrolling up and down.
7. Increase and decrease volume	I need you to add extra buttons for volume up and down.
8. Assign a program to a button	I need you to add an extra button that opens Google Chrome when pressed.
9. Perform an automatic click after 3 seconds of mouse inactivity	Make it so that when the mouse automatically clicks once when standing still for 3 seconds.
10. Allow double-click with a configurable delay	I need you to add a delay that allows two clicks made within 3 seconds to register as a double click.
11. Type the user's name with a button	I need you to add a button that writes the name Pelayo.
12. Pause and unpause	I need you to add a button that toggles between pause and play.
13. Ignore movement during the first second of joystick input	I need you to add a delay that ignores the first seconds of movement in any direction and then starts moving.
14. Automatically send a help email	I need you to add an extra button that automatically sends an email saying "Help" to francesc.banuls@ucv.es.
15. Generate an app that allows modifying sensitivity and delay time for automatic clicking	I need you to code in an app that allows me to change sensitivity of the joystick and how long the mouse waits after being still to automatically click.
16. Create a program and installer	I need you to compile the program made into an app by coding installer for this app.

XSL•FO
RenderX

Based on this premise, and to reduce inconsistencies, it was considered that modern AIs increasingly incorporate more integrated self-feedback mechanisms, independent from human input, and that models should be capable of performing such functions [49]. All testing was conducted by the authors, in the context of an autonomous reference center for disability in Valencia, Spain, during 4 days, from October 10, 2025, to October 14, 2025. Subsequently, all testing was conducted with the approval of the university's ethics committee with code UCV/2023-2024/010.

Additionally, all testing was conducted using a Kubii USB Arcade Controller reference ODARCADE, connected via USB to a Windows 11 computer using Python 3.13 and having installed the libraries pygame and pyautogui.

The selection and design of the prompt constitute a key methodological element in this study, as its structure determines the comparative validity among the different AI models analyzed. Its uniformity follows the principle of instructional consistency, emphasizing that coherence in the formulation of commands is essential to ensure comparability between conversational systems [10]. Complementarily, the structure of the prompt conditions the type of cognitive processing activated by the model; therefore, keeping it constant allows the isolation of the intrinsic effect of each architecture [11]. Minimal wording differences can change both performance and the relative ranking of models, reinforcing the need to use a standardized prompt. Accordingly, the prompts were designed based on 3 theoretical principles [12,28,50].

The first is defining a nontechnical user role, representative of professionals without programming training. Contextualizing the interlocutor's identity allows for adjusting response complexity, and that assigning an explicit role guides the model's generation toward a semantically coherent and functional framework. This role also demands that all models are accessed from their web-found standard versions without adjusting models or using specific more technical or specially designed models for programming. This can be seen in the use of Copilot instead of specific instances coded into GitHub or other programming platforms [10,11].

The second is presenting a sequence of actions formulated in natural language and logical order. Procedural prompts activate step-by-step reasoning that promotes coherent and structured results, facilitating the translation of human descriptions into computational processes (as the de facto interaction mode with chatbots), although such prompts may carry a higher risk of drift [11].

The third is detailing functional requirements, such as cursor control or command execution. Precision in parameters or specific conditions reduces ambiguity and improves consistency of the output, making the prompt a cognitive interface between human language and automated execution [12,28].

These 3 concepts serve as guiding principles to mediate between the natural language of a nontechnical professional and the AIs. To more faithfully emulate the real process of software design by a person without advanced technical knowledge, 2 conditions were established to determine when to terminate the programming attempts.

The first one is that 3 consecutive nonfunctional generations either fail to execute, only partially implement, or lose communication with the gamepad. It is understood that if 3 consecutive iterations cannot fix inherited errors without feedback, it is unlikely that subsequent ones will do so.

Prompts are considered successful when they can correctly implement the full capabilities described in Table 1 for each prompt without compromising existing functionality. They are considered partially successful when they either maintain previous capabilities but only partially implement new functions or when they correctly implement new functions but lose previous ones. Finally, prompts are considered unsuccessful when they either fail to execute or lose communication with the gamepad. Partially successful prompts are marked as such to better understand the performance of different models but are functionally considered unsuccessful as they did not achieve the desired function. As such, 3 unsuccessful or partially successful prompts (with 2 tries each) stop interactions with a model.

The other way in which interactions with models are stopped is when reaching the daily prompt limit in free plans, to better reflect that the prompt limit is one of the most significant constraints of these models.

Goals

The experimental design was developed with the explicit understanding that current AI systems are inherently nondeterministic and that the replication of results will be inconsistent [51]. Consequently, the study objectives reflect this fact:

- General goal 1: compare the effectiveness of the most widely used AI solutions as software programmers for creating personalized assistive products using nontechnical natural language.
  - Specific goal 1: describe the relationship between cost and effectiveness of the models used.
  - Specific goal 2: analyze the ease of use, consistency, and accuracy of each model.

Results

Overview

The 8 AI solutions initially proposed were used to progressively design robust code solutions, incorporating functions of increasing complexity inspired by APs with similar objectives.

The results can be divided according to the cost of the alternatives, distinguishing between those that are free of charge and those requiring a subscription. The latter provided more consistent results and better adaptation to the project's functional requirements, demonstrating a greater understanding of the requested functions. However, it is important to note that these results should be interpreted within the framework of the specific characteristics of the study and that even under identical

XSL•FO
RenderX

conditions, different outcomes could be obtained due to the nondeterministic nature of these technologies.

Paid Alternatives

The subscription-based alternatives delivered consistent results, generating code that can generally be considered successful in meeting the required functions. This category includes ChatGPT Pro, based on the GPT-5 model, and Gemini Pro, which uses Google's advanced Gemini Pro-2.5 model.

Regarding Gemini Pro, the AI solution developed by Google proved to be the most robust option. It successfully implemented 14 out of the 16 required functions within a single application, without any rollback of previously implemented features during the design process and generated functional code with an average of 1.25 (SD 0.45) prompts. Gemini was even partially able to anticipate the implementation of future functions in earlier items: item 2 was successfully integrated within item 1; item 6 was partially included in item 3 by adding a scrolling mode, although without the 2 specific keys intended for that function; and item 15 was partially addressed in item 3 through a joystick sensitivity slider. The only functions not achieved were items 14 and 16. Item 14 could be considered partially achieved, as the AI managed to open the email app and compose a message addressed to the correct recipient but was unable to send it. All partially achieved items are considered not achieved when counting successful items implemented. Regarding item 16, Gemini could not autonomously generate an installable app, and the alternative solutions proposed in Python were also nonfunctional.

One thing to note is that both items (14 and 16) did not work across the board for security reasons, as AIs are not capable of generating programs that have such deep access to your operative system. Seeing how the AIs approached a task they knew beforehand was impossible to fully be able to perform is interesting and shows the AIs' problem-solving skill navigating natural language generated prompts, which may be difficult or impossible to fulfill.

Complementarily, OpenAI's paid version (ChatGPT Pro using GPT-5) also demonstrated solid performance, successfully implementing 11 out of the 16 required functions and producing functional code with an average of 1.31 (SD 0.48) prompts. GPT-5 showed the same limitation as Gemini Pro with respect to sending the email in item 14 and was likewise unable to compile an executable file or provide stable Python-based compilation solutions. Additionally, OpenAI's AI had difficulties implementing joystick controls in item 1, which caused the device to move the cursor only downward and to the right. This error persisted in subsequent iterations, affecting later results such as items 13 and 15, which were only partially achieved due to the lack of precise joystick control. ChatGPT also displayed inconsistency, producing multiple files for different functions instead of integrating them into a single app and rolling back previously implemented features without justification or explicit request.

Free Alternatives

The free alternatives, in contrast to the subscription-based ones, produced notably less consistent results. In some cases, this was due to the limitations of the models themselves, which were unable to meet the functional requirements set for the task. In other cases, restrictions on the number of interactions significantly limited development, constituting a key distinction. It cannot be asserted that greater time investment would have yielded results equivalent to the paid versions, since the possibility of submitting additional prompts was not available. Therefore, in this study, the maximum number of interactions allowed by each model in its free version was established as a methodological limitation. Conversely, the models that failed to generate functional solutions can, for the time being, be considered inoperative for the intended function.

The free AI with the best performance was DeepSeek. This model generated the first 3 items in the initial prompt and even implemented item 2 without it being explicitly requested in item 1. However, the AI was unable to technically complete items 4, 5, and 6, implementing item 5 through a bind function that only allowed the assignment of a single key and caused the program to crash when attempting to add more combinations. This model generated functional items with an average of 1.88 (SD 0.34) prompts, achieving 4 out of the 16 required functions.

The second-best performance can be attributed to GPT Free. The free version of GPT successfully produced a functional prototype on the first attempt for the first 3 prompts but maintained the inconsistency observed in its paid counterpart. From the fourth prompt onward, it began producing nonfunctional code, leading to discontinuation after the seventh attempt. On average, it generated functional prototypes with 1.81 prompts and achieved 3 out of the 16 intended functions.

After GPT, in terms of performance, is Gemini Pro Free. Although it theoretically uses the same model as the paid version, its results differed appreciably. The free version produced correct and functional outputs up to the permitted prompt limit, forcing the process to stop prematurely. It successfully implemented the first 2 items and partially the third, generating a program that ran natively in the browser. Subsequently, time-based restrictions prevented continuation. On average, it produced functional prototypes with 1.88 prompts and achieved 2 out of the 16 complete functions.

The second-to-last worst-performing model is Claude. The Sonnet 4.5 model managed to implement only the first of the planned functions. After failing to execute functions 3, 4, and 5, its use was discontinued. Claude generated functional prototypes with an average of 1.94 (SD 0.25) prompts, achieving 1 out of the 16 proposed functions.

Finally, the individually worst-performing model is Copilot. Using its Deep Think model, Microsoft's AI failed to generate any executable Python files within the first 3 prompts, leading to the termination of testing after the fourth attempt. It did not produce any functional prototypes, with an average of 2 prompts and a total of 0 out of 16 functions achieved.

All models and a color-coded list of the items successfully implemented by each, along with the number of prompts required, are presented in Table 4. Additionally, prompts achieved and average prompts per model are presented in Figure 1.

Discussion

Principal Findings

The results obtained show that the paid AI alternatives produced robust code, achieving 14 out of 16 functions with Gemini Pro and 11 out of 16 functions with ChatGPT Plus, respectively. The free-to-use alternatives, on the other hand, managed to integrate a variable, though consistently lower, number of functions ranging from none to 4 successfully implemented. The discussion of the results obtained can therefore be divided into 3 key areas (Figure 1).

Superiority of Paid AIs

The use of paid AI systems offers several advantages, among which the most significant are access to more advanced models and the elimination or substantial expansion of the number of prompts allowed within a given period. These advantages naturally make paid AI solutions more reliable for performing complex tasks. The main improvements can be summarized in 3 key points.

Paid versions typically operate on newer, more advanced architectures with higher parameter capacity and improved optimization strategies and training based on larger and higher-quality datasets. In literature, larger and better-trained models consistently achieve superior results in both code generation and natural language understanding tasks. For instance, GPT-4 performs substantially better in programming tasks than earlier versions [52].

Due to these technical enhancements, paid models generally demonstrate a stronger grasp of natural language and communicative context, which increases the likelihood of successful interactions in this specific case scenario. They are also better at maintaining coherence across sequential instructions, retaining previously defined functions, and being better at avoiding contradictions and hallucinations. This allows them to integrate multiple features coherently and progressively with fewer rollbacks or loss of content [53-55].

The removal or significant reduction of restrictions on the number of prompts permitted per time interval is particularly relevant when considered alongside the highlighted advantages. Older free models often have weaker memory capabilities and greater difficulty minimizing inconsistencies, rollbacks, and errors across different interaction sessions [56]. Increasing the interaction limits from, for example, 5 per session in the free version of Gemini to 100, or from 10 every 5 hours in GPT-4.1 mini to 160 every 3 hours in GPT-5, not only eases time constraints but also reduces errors and can substantially improve code quality [57,58].

In summary, the differences in model capacity, contextual understanding, memory, and reasoning largely explain why paid AIs may achieve significantly more functional results than their free counterparts. This outcome is expected, as paying for a service naturally entails the expectation of better performance. However, another relevant point of discussion lies in comparing paid AIs with one another and questioning why Google's AI seems to have outperformed GPT in this specific scenario, despite the latter's longer development history and its recent update to version 5.

Differences Between Gemini Pro and GPT-5

Although it is not possible to access the internal technical details of Gemini Pro, or of any major AI model, the existing literature published by the companies behind these models appears to support the results obtained in this specific case scenario, pointing to 3 key aspects that may explain why Gemini stood out as the most robust alternative for generating code from natural language given the restrictions and tasks asked.

On the one hand, Gemini may have better alignment between intention and execution. According to the Google Gemini team, the training of Gemini Pro placed greater emphasis on the correspondence between high-level instructions and structured code generation, giving it an advantage in translating complex requirements into functional code. The model achieved scores above 74% on specialized programming benchmarks [59].

This may also lead to much greater stability and coherence in long sessions. In tasks involving multiple functions (such as the 16 required in this study), the ability to maintain coherence across many iterations is crucial. If Gemini Pro manages internal session states more effectively, it becomes less prone to "forget" previously implemented functions or to inconsistently rename elements [60].

On the other hand, and especially relevant to the study, prompt optimization may be more tolerant of natural language. A distinct training approach regarding the model's handling of natural language results in greater adaptability to intricate instructions, improved contextual understanding, and enhanced problem-solving abilities. This makes Gemini Pro more resilient to inaccuracies or ambiguities in prompts written in nontechnical natural language, whereas ChatGPT Plus may tend to require more carefully formulated instructions to produce reliable outcomes [59,60].

Limitations and Strengths of Free AIs

As previously mentioned, free AI systems may present significant limitations related to the use of simpler and more restricted models, limited numbers of prompts, and, in some cases, the restriction to process multimodal information. These constraints make free models more challenging to use or less adaptable to users' needs. The standardized subscription fee of US $20, as implemented by companies such as OpenAI and Google, remains possibly too expensive for low-resource contexts in many parts of the world.

In recent months, both companies have begun introducing country-based pricing, adjusting subscription costs to local purchasing power. OpenAI (2025) implemented multicurrency billing to reduce conversion costs, and in India, the Plus plan is now offered in rupees, alongside a lower-cost alternative named ChatGPT Go [61]. This strategy echoes *The Economist*'s Big Mac Index, which illustrates how multinational companies adjust prices according to economic context. AI can enhance accessibility in education, but its impact is constrained by the economic barriers preventing access to paid tools [62]. However, if AI design fails to account for income inequalities within a

XSL•FO
RenderX

single country, despite global cost-adjustment strategies, it may reinforce digital exclusion. Thus, exploring the use and functionality of free versions and comparing them with paid alternatives as a potential source of social inequality becomes a social necessity to ensure equitable access to knowledge and accessibility [63,64].

In our test, among the free options, Gemini Free managed to implement 2 functions with relative stability during the first iteration, approaching a third before reaching the interaction limit. Considering the performance of its paid counterpart under fewer restrictions, it is likely that free versions could offer solid, no-cost solutions, albeit requiring a significant time investment, provided the model seems to be able to maintain internal coherence across sessions [59].

In contrast, GPT Free and DeepSeek achieved a greater number of items but lost track of the ongoing programming process, producing unstable code that would require the user to identify errors and explain them to the chatbot. While this may be possible, it is difficult to fully assess how much feedback a nontechnical user may be able to provide, and as such, it is difficult to give certain conclusions about these models. Professionals with intermediate technical knowledge could use these 2 models effectively to develop software solutions, but nontechnical users may be unable to [65,66].

Finally, Claude and Copilot, in their free versions, showed no real ability to generate operational code. In the case of Claude, this is understandable, since its website explicitly states that only the Pro version provides such capabilities [67]. The second model, Copilot, simply appears unable to generate functional, plug-and-play code. This is also due to the several factors, such as copilot being used in the web version (not optimized to do such tasks) without any specific model or implementation chosen [68]. In both case scenarios, using Claude Pro with programming capabilities and a version of Copilot optimized for programming may generate more competent results.

These findings may point to the fact that not all free versions are equivalent: some models are sufficiently robust for basic tasks, while others are less capable with the task chosen, the prompt limit, the version used, and many other factors contributing to their success.

One key limitation to have in mind is that only 1 run has been carried out with each model to mimic a real case scenario of a nontechnical user using these models. Given the nondeterministic nature of these models, more different runs around the same task may produce different results.

Observations and Practical Implications

The observations, limitations, and implications for practice derived from this study can be summarized in 10 key points that integrate the main insights gained throughout the research. Four main points stand out as the implications of the results obtained.

Some AI models, such as ChatGPT (both 4.1 mini and 5), may produce inconsistent results, hallucinating or forgetting its progress. This can be seen by these models including renaming functions without apparent reason, changing project names, generating new programs instead of adding features to the existing one, or rolling back previously correct functions. This suggests that OpenAI models can generate the intended products but require a technical skill level beyond that of nonspecialist professionals, significantly complicating the process of obtaining functional prototypes for nontechnical users in this specific case scenario [66,69].

This behavior is sometimes categorized as AI “drift” and means that, during extended sessions, models may change behavior, forget previously defined functions, or misinterpret prompts that are conceptually equivalent. Maintaining a clear “narrative thread” and consistent prompt formulation is therefore essential. Natural language alone may not suffice, and the risk of accumulating errors that render the code nonfunctional remains high [70,71].

In this specific test, Gemini showed greater consistency interpreting natural-language instructions and required fewer technical reformulations or corrections. It also showed a lower risk of drift. In contexts where users represent the target population, these traits may reduce the barrier to entry and increase the likelihood of producing functional prototypes. The Pro version is notably more efficient and reliable, but the free version can achieve similar outcomes with sufficient time investment if the time between tries does not induce AI drift [72].

While AIs can generate code that is operational and useful, it must be remembered that its efficiency (execution time, memory usage, and design simplicity) is generally suboptimal. For this reason, professional supervision, or ideally full implementation, by a qualified software engineer remains preferable. Studies, such as EffiBench, have shown that AI-generated code tends to be, on average, less efficient than optimized human solutions [73].

The results obtained in this domain (low-cost AP adaptations with 16 functions with no feedback and in a single run) are constrained to the models and prompts used and to the absence of user feedback, maybe reflecting the condition of a nontechnical user. Other models or differently designed prompts might yield different outcomes. The practical implications are as follows:

1. For real-world AP adaptations: Collaboration with software professionals should always be prioritized when budgets allow. If it is not feasible, both paid models tested may be the most effective choice, as they perform better in programming tasks than other paid alternatives. When access to paid tools is possible, they remain the most robust option. However, free models such as Gemini Free, GPT Free, or even DeepSeek can provide functional results in exchange for greater time investment.
2. For low-budget or educational contexts: Free versions, particularly Gemini Free or GPT Free, can serve as valuable tools for initial prototyping, though additional iterations, revisions, and acceptance of functional limitations will be necessary [74].
3. Effective prompt design and problem segmentation: Breaking the task into smaller subfunctions and crafting

XSL•FO
RenderX

clear, stepwise prompts improves the success rate, especially in free models.

4. Continuous monitoring and automated testing: Implementing automated unit tests (eg, by prompting the AI to generate its own test cases) may help detect errors or inconsistencies in the generated code.
5. Caution with long sessions or evolving prompts: Avoid overly long or evolving prompts within a single session and restart the interaction when the model shows signs of drift to preserve consistency.

Conclusions

In conclusion, the comparative analysis of different AI models applied to the generation of functional software for designing personalized APs using natural language reveals clear differences in performance, usability, and consistency. Paid models, such as Gemini Pro and ChatGPT Plus, demonstrated greater efficiency and reliability, achieving 14 and 11 out of 16 required functions, respectively, while free alternatives ranged between 0 and 4. These results confirm that the technical advancements of newer and more sophisticated models, such as expanded context windows, improved multimodal communication, enhanced natural language comprehension, reduced drift, and fewer prompt limitations, directly influence the functional quality of the generated code.

Regarding the relationship between cost and effectiveness, Gemini Pro may stand out as the most balanced option, in this specific case scenario offering higher precision and coherence at a cost equivalent to other paid alternatives. For low-resource contexts, DeepSeek emerges as a viable free alternative that, despite its limitations, can produce acceptable results given sufficient time and technical supervision, while the free versions of Gemini can deliver solid outputs with adequate time investment.

In terms of ease of use and consistency, Gemini demonstrated greater tolerance for nontechnical natural language and more stable performance in long sessions, making it particularly suitable for users without programming knowledge, an essential aspect when the goal is to promote inclusive and low-cost design of APs.

Overall, the findings suggest that AI can serve as an effective bridge between health care or educational professionals and programming, enabling the creation of personalized assistive solutions without the need for advanced software development expertise. Nevertheless, the results also highlight the critical need for collaboration with qualified IT professionals, given the importance of human technical oversight, careful prompt design, and continuous testing to prevent drift and ensure the generation of stable software alternatives.

Future research could focus on exploring how AI models handle problem-solving from visual inputs (eg, images sent to chatbots), their capacity for self-generated prompt design, and the evaluation of emerging or alternative models.

Funding

This study was carried out within the framework of the research project PID2022-142309OB-100 funded by the Ministry of Science and Innovation, State Research Agency and in collaboration with the Capacitas Campus of the Universidad Católica de Valéncia San Vicente Mártir (UCV).

Abstract

Background: Acquired brain injury (ABI) is a heterogeneous umbrella term encompassing traumatic and nontraumatic etiologies and is frequently associated with persistent cognitive dysfunction. Conventional neuropsychological assessment remains central to clinical evaluation, but feasibility and measurement precision may be limited in individuals with motor impairment, aphasia, reduced stamina, or fluctuating arousal. Eye tracking offers an objective, low-burden approach that can quantify gaze behavior during task engagement and may provide complementary process-level markers of cognition.

Objective: This study aimed to systematically synthesize the evidence on eye-tracking paradigms used as a primary approach for cognitive assessment in ABI and to summarize findings by cognitive domain, paradigm, and clinical interpretability.

Methods: We conducted a PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020–compliant systematic review and registered the protocol in PROSPERO (CRD420251038768). PubMed, Web of Science, the Cochrane Library, Embase, EBSCOhost, PsycINFO, and Scopus were searched from inception to April 10, 2025. We included peer-reviewed English-language studies enrolling children or adults with ABI in which eye tracking was the primary assessment modality used to quantify at least one cognitive domain or clinically relevant cognitive-communication process. Two reviewers independently screened studies, extracted data, and assessed methodological quality using design-appropriate tools (Risk of Bias 2, Risk of Bias in Non-Randomized Studies of Interventions, Quality Assessment of Diagnostic Accuracy Studies 2, and the Newcastle-Ottawa Scale). A structured narrative synthesis was performed because of heterogeneity in paradigms and outcome definitions.

Results: Twenty-seven studies met the inclusion criteria (N=872 participants; females: n=354 and males: n=518), with most evidence derived from mild traumatic brain injury cohorts, and fewer studies involving stroke, mixed etiologies, and disorders of consciousness. Across domains, antisaccade and related paradigms were commonly associated with differences in inhibitory control and executive function, while predictive tracking, smooth pursuit, and target-blanking paradigms frequently captured alterations in attentional prediction and timing. Virtual reality (VR) free-viewing paradigms identified visuospatial exploration asymmetries in stroke-related neglect, and gaze-based human-computer interface approaches demonstrated above-chance task performance in a subset of patients with disorders of consciousness. Evidence for incremental validity beyond conventional assessment was mixed and often indirect, and safety reporting was uncommon. Overall certainty of evidence was generally low and limited by small sample sizes, cross-sectional designs, and heterogeneity in acquisition procedures, metrics, and analytic pipelines.

Conclusions: Eye tracking shows potential as an adjunctive, process-level approach for quantifying specific cognition-relevant behaviors after ABI, particularly within paradigms targeting inhibitory control and predictive attention. Current evidence is insufficient to support broad diagnostic claims or the routine replacement of conventional neuropsychological assessment. Future research should prioritize harmonized paradigms and reporting standards, external validation of classification models, longitudinal designs, and explicit feasibility and safety reporting to clarify when eye tracking provides incremental clinical value for precision neurorehabilitation.

Introduction

Background

Acquired brain injury (ABI) is an important health concern, and its definition varies according to whether the medical condition is present at birth [1,2]. It includes all types of brain injury occurring after birth and not due to genetic or congenital pathology [3]. Unlike progressive neurological disorders such as Alzheimer disease or Parkinson disease, ABI is typically induced by an event that disrupts the normal function of the brain and results in changes to neuronal activity that can be observed at the physical, metabolic, or functional level of the nerve cells [1-3]. There are 2 main categories under ABI, which include traumatic brain injury (TBI) and nontraumatic brain injury (nTBI) [4]. Among the most common causes of TBI in older children and adults are assaults, falls, and crashes in motor vehicles, as well as sports injuries and blast injuries, including military blast injuries [5]. nTBI is an umbrella term that includes brain lesions seen in strokes in which blood enters but does not reach brain tissue; infections (eg, meningitis and encephalitis); hypoxia or anoxia, where the brain is deprived of oxygen; brain tumors; exposure to toxins; and drug or alcohol abuse [6]. Epidemiological data show that ABI is a global health problem and one of the major causes of morbidity and mortality [7,8]. More than 20 million new cases of TBI alone are estimated to occur each year worldwide; in fact, some estimates put the overall number of all TBIs, whatever their cause, at between 64 and 74 million annually [9]. TBI can be mild, moderate, or severe based on the score on the Glasgow Coma Scale or the duration of loss of consciousness or posttraumatic amnesia [10,11]. In addition to traditional clinical scales, motor and cognitive functional outcomes are significant limitations when trying to predict long-term recovery following ABI [12]. As many as 65% of individuals with moderate-to-severe TBI continue to experience chronic cognitive impairments, most likely to impact memory (20% - 79%), attention (18% - 54%), processing speed (17% - 19%), and executive functioning (eg, planning, problem solving, and multitasking) during the chronic phase of recovery [13]. In the motor domain, more than one-third of people with severe TBI still present with signs of neuromotor dysfunction (eg, paresis, ataxia, and postural abnormality) two years following brain injury [14,15]. These cognitive disturbances and motor deficits directly impact gait stability, fine motor coordination, and activities of daily living, underscoring the need for precise assessment tools [16].

Rehabilitation after ABI is increasingly characterized by technology-assisted interventions that aim to support cognitive and functional recovery. Recent syntheses highlight growing interest in noninvasive brain stimulation, virtual and extended reality–based rehabilitation, computerized cognitive training, and robot-assisted interventions, while also emphasizing heterogeneity in protocols, target domains, and patient profiles [17-20]. This evolving landscape strengthens the need for outcome measures that are sensitive to change, feasible across clinical settings, and capable of capturing real-time performance during task engagement.

Eye-tracking technology, characterized by excellent temporal and spatial resolution, not only allows for the sensitive detection of subtle oculomotor abnormalities associated with these functional deficits but also can be used as an assistive interface to restore communication for patients lacking volitional motor control [21]. Eye-tracking systems, which convert eye movements into control signals, can also assist with assessment, environmental control, communication, and rehabilitation exercises, enabling smooth transition between assessment and intervention and providing the connection to the applications [22]. Eye-tracking technology enables the measurement of various aspects of eye behavior (eg, eye gaze and pupil size) and has been applied in psychology research to study visual attention and cognitive processing states [23-25]. Often, the technology involves the use of infrared cameras and light sources that track the pupil and corneal reflections, which are then translated into data streams that allow for information about various cognitive states [26,27]. There are various types of eye trackers available, with options designed for controlled laboratory settings, real-world environments, virtual reality (VR) or augmented reality headsets, high-precision head-stabilized systems, and more accessible webcam-based trackers [28-31]. Eye tracking measures key oculomotor parameters such as fixations, saccades, pupillometry, smooth pursuit, vergence, blinks, and other eye movements (gaze paths) [32,33]. In cognitive assessment, eye tracking has been used to screen attention, memory, executive functions, language processing, and reading fluency and has demonstrated promise in the early diagnosis of neurodegenerative diseases [34,35]. Eye-tracking technology has particular implications for cognitive assessment in cases of ABI. Its usefulness has been extended to detect oculomotor dysfunction due to mild traumatic brain injury (mTBI), including concussive injuries [36]. It has also proven useful for determining levels of consciousness in patients with extreme brain injury, as well as for examining spatial biases in visual exploration after stroke [37].

Rationale, Objective, and Theoretical Framework for Investigating Eye Tracking in ABI Cognitive Assessment

As ABI represents a substantial global health problem, the previous overview shows that eye-tracking technology can be a useful and powerful tool to explore cognitive states through oculomotor behavior. Conventional neuropsychological assessments remain central to cognitive evaluation after ABI. Nevertheless, administration and interpretation can be challenging in individuals with motor impairment, aphasia, reduced stamina, or fluctuating arousal, which may limit feasibility and measurement precision [34]. Sensitivity can also be reduced for subtle deficits that are common after mTBI, and repeated testing can be influenced by practice effects. Scoring and interpretation may vary across raters and clinical contexts,

XSL•FO
RenderX

and many instruments provide only a snapshot rather than capturing dynamic cognitive control during continuous interaction with the environment. In contrast, eye tracking offers a potentially less demanding, systematic, and more objective approach to assess some cognitive functions, such as attention, memory, and executive control, through the direct measurement of neural processing correlates manifested in gaze patterns (fixation duration, saccadic patterns, and pupillary responses) [35]. However, although promising applications and research are emerging and interest in the field of ophthalmoplegia continues to grow, the available evidence supporting the implementation of eye tracking for cognitive assessment across the broad spectrum of ABI, including multiple etiologies (TBI and nTBI), levels of severity, and phases of recovery, remains mixed. Importantly, ABI encompasses heterogeneous etiologies and clinical phenotypes, including traumatic injury, stroke, hypoxic-ischemic injury, and disorders of consciousness (DoC), with meaningful variation by severity and phase of recovery. This heterogeneity can influence both the choice of eye-tracking paradigm and the interpretation of findings, underscoring the need to synthesize evidence with attention to ABI subgroup and target cognitive domain. There is a gap in the literature regarding a consolidated synthesis of this evidence. Therefore, this study aimed to identify and synthesize the available literature on the use of eye-tracking technology for cognitive assessment in populations with ABI. This work is based on a theoretical foundation that closely links oculomotor control to cognitive functioning, such that ABI-related alterations are thought to reflect measurable changes in eye movement patterns, which in turn are related to the affected cognitive domains [36,37]. From a neurobiological perspective, oculomotor behavior is governed by distributed control systems that overlap with cognitive networks. Antisaccade paradigms rely on frontostriatal circuitry and executive inhibition, whereas smooth pursuit and predictive tracking recruit cerebellar and parietal contributions that support timing, prediction, and attentional allocation. Fixation stability, gaze variability, and pupil dynamics can index distinct components of cognitive processing rather than a single unitary construct. These mechanistic links support the rationale for using eye tracking as a process-level window into cognition, provided that paradigms and metrics are interpreted within their specific neurocognitive targets [38,39]. This effort should allow for a thorough evaluation of the existing scientific evidence and help guide future researchers and clinicians in the rehabilitation process of this patient population. Table 1 provides an overview of eye-tracking technologies [40-48].

XSL•FO
RenderX

Table . Overview of eye-tracking technologies.

Eye tracking technology	Description	Mechanism of action	Relevance to ABI[a] cognitive assessment	Advantages and limitations	Clinical applications
Tobii 5 (laptop-mounted) [40]	Binocular eye tracker (133 Hz[b]) with head tracking (33 Hz), mounted on a laptop.	Infrared tracking of pupil and corneal reflection; calibrated using Tobii Pro Lab software (Tobii AB).	Captures changes in gaze stability and saccade latency, useful post injury.	Portable, high sampling rate, and limitation may be sensitive to ambient lighting.	Used for fixation and saccadic movement assessment after ABI or mTBI[c].
RightEye System [41]	Computerized eye-tracking system evaluating oculomotor behavior.	Digitally tracks smooth pursuits, saccades, vergence, and reaction times.	Assesses oculomotor deficits and symptom severity in RHI[d] and concussion.	Comprehensive eye metrics, and limitation may be less sensitive to subtle impairments.	Concussion and neurovisual symptom assessment.
BEAM Task Eye Tracker [42]	Automated tracking system integrated with BEAM[e] cognitive tasks.	Monitors saccades in response to visual cognitive tasks on screen.	Correlates with neuropsychological symptoms (eg, depression and PTSD[f]).	Continuous, task-integrated, and limitation may be task-dependent metrics.	Mental health–linked eye tracking in the ABI context.
Tobii T60/T60 [43]	Seventeen-inch monitor with noninvasive eye-tracking unit.	Infrared beams detect gaze location and fixations.	Detects fixation patterns and attention to scenes and grids.	Stable and accurate, and limitations may be fixed setup and screen size.	Visual attention and scene perception in ABI research.
Tobii EyeX [44]	Monitor-mounted tracker (>60 Hz) for fixation-point recording.	Infrared corneal reflection for eye-gaze coordinates.	Differentiates visual fixation across GCS[g] levels.	Affordable, good for basic research, and the limitation may be lower resolution.	Fixation-based cognitive-status screening.
HTC Vive with Pupil Labs [45]	VR[h] headset with integrated eye tracking for immersive testing.	IR[i] eye cameras track gaze with 1° accuracy in virtual environments.	Assesses VR-based gaze symmetry, fixation, and orientation in patients.	Ecological validity, and the limitation may be potential motion sickness and setup cost.	VR cognitive assessment and rehabilitation for ABI/mTBI.
EyeLink 1000 [46]	High-speed eye tracker (up to 1000 Hz) and head-stabilized.	IR beam reflection records eye movements with high temporal precision.	Tracks reaction times and fixation accuracy in cognitive tasks.	High precision and limitation may require head stabilization.	Detailed oculomotor assessment in laboratory settings.
Gazepoint GP3 HD [47]	150 Hz eye tracker with 9-point calibration screen.	Measures saccades and working memory through gaze behavior.	Differentiates performance in working memory and inhibition tasks.	Compact and high frequency, and limitation may miss microsaccades.	Working memory and executive function testing in ABI.
Applied Science Laboratories D6 [48]	High-speed desktop tracker for effort testing.	Records gaze patterns to detect malingering/fake effort.	Validates effort and symptom exaggeration in mTBI.	Reliable classification and limitation may be specialized purpose.	Effort testing and malingering detection.

[a]ABI: acquired brain injury.

[b]HZ: Hertz.

[c]mTBI: mild traumatic brain injury.

[d]RHI: right hemisphere infarction.

[e]BEAM: Bethesda Eye and Attention Measure.

[f]PTSD: posttraumatic stress disorder.

[g]GCS: Glasgow Coma Scale.

[h]VR: virtual reality.

[i]IR: infrared.

Methods

Protocol and Reporting Standard

This systematic review was conducted and reported in line with PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidance, with all stages planned to maximize transparency and reproducibility [49]. The review protocol was prospectively registered in PROSPERO (CRD420251038768) to reduce the risk of selective reporting and to provide an auditable record of the prespecified methods [50]. Any deviations from the registered protocol were documented and justified within the paper to preserve methodological transparency [49,50]. Following peer-review feedback, the PROSPERO record was updated on February 26, 2026, to clarify eligibility criteria, including comparator requirements and inclusion of eligible case series, and to specify the design-appropriate risk-of-bias tools used in this review.

XSL•FO
RenderX

Review Question Framework (PICO)

To ensure conceptual clarity and consistent eligibility decisions, we framed the review question using a PICO-informed structure adapted for diagnostic and assessment technologies. The population comprised children and adults with ABI across etiologies, severities, and recovery phases. The index assessment modality was eye tracking, used as the primary approach to quantify cognition or clinically relevant cognitive-communication processes, with paradigms and derived metrics prespecified and mapped to cognitive domains. Comparators were not mandatory and, when available, included healthy controls, ABI subgroups, within-participant conditions (eg, baseline vs follow-up), and/or conventional neuropsychological measures. Outcomes were eye-tracking–derived metrics relevant to cognition (eg, antisaccade latency or error rates for inhibitory control, predictive tracking measures for attentional timing, and fixation or exploration indices for visuospatial processing), along with diagnostic or classification performance indices when explicitly reported. This framework guided study selection, data extraction, and synthesis and reduced the risk of misclassifying eye tracking as an intervention rather than an assessment approach.

Eligibility Criteria and Operational Definitions

We included peer-reviewed, full-text studies published in English that enrolled children or adults with ABI of any etiology, severity, and recovery phase. Eligible etiologies encompassed TBI, stroke, hypoxic-ischemic injury, infectious or inflammatory ABI, and DoC following ABI. Studies were eligible when eye tracking was used as the primary assessment modality to quantify cognitive functioning. Eye tracking was operationally considered "primary" when the paradigm and derived oculomotor metrics were central to the cognitive assessment objective and were used to operationalize at least one cognitive domain or a clinically meaningful cognitive-communication construct. For the purposes of this review, eligible cognitive targets included attention, executive function, memory and working memory, visuospatial exploration and neglect-related processes, language and cognitive-communication processes, social-cognitive paradigms, and gaze-based paradigms aimed at detecting command following, volitional control, or awareness in DoC. We included randomized controlled trials, nonrandomized intervention studies, and observational designs, including cohort, cross-sectional, and case-control studies.

We excluded protocols, conference abstracts, dissertations, reviews, animal studies, and single-case reports. We also excluded studies in which eye tracking was used only for technical device validation, usability testing without cognitive interpretation, or oculomotor characterization without an explicit link to a cognitive target or classification framework. Studies that included mixed neurological samples were eligible only when ABI data were reported separately or could be unambiguously extracted.

Information Sources and Search Strategy

We searched PubMed, Web of Science, the Cochrane Library, Embase, EBSCOhost, PsycINFO, and Scopus from database inception to April 10, 2025. The initial search was performed on March 5, 2025 and updated on April 10, 2025. No publication date restrictions were applied. Searches combined controlled vocabulary terms and free-text keywords related to eye tracking, oculomotor metrics, cognition, and cognitive assessment, and ABI and related etiologies. The strategy was iteratively refined to optimize sensitivity while preserving relevance, and the complete search strategy is reported in Multimedia Appendix 1.

To reduce the risk of missing relevant studies, the reference lists of included studies and of closely related reviews were screened, and forward citation tracking was performed for key sentinel studies identified during full-text screening. Only peer-reviewed full-text papers were included to align with the prespecified scope and to ensure interpretability of methods and results.

Study Selection

Records were exported to a single dataset and deduplicated using multiple identifiers, including title, authorship, year, and digital object identifier when available. Two reviewers (AC and RDL) independently screened titles and abstracts, followed by full-text assessment against eligibility criteria. Before formal screening, a calibration phase was performed to ensure consistent application of criteria. Disagreements were resolved through discussion, with adjudication by a third reviewer (RSC) when needed. Interrater agreement at the abstract and full-text stages was quantified using the Cohen kappa statistic, and agreement was interpreted using established benchmarks to support transparent reporting of selection reliability [51,52]. Reasons for exclusion at the full-text stage were recorded and are available upon request.

Data Extraction and Data Items

Two reviewers (AC and RDL) independently extracted data using a piloted extraction form, with discrepancies resolved by consensus and third-reviewer adjudication (RSC) when necessary. Extracted study-level information included design, setting, recruitment procedures, sample size, participant demographics, ABI etiology, severity indices where reported, and phase of recovery at assessment.

Eye-tracking–specific data were extracted at a granular level to support clinical interpretability and reproducibility. We recorded the eye-tracking platform and device model, sampling rate, calibration procedures, and success criteria when reported, head stabilization conditions, and the testing environment. We extracted paradigm characteristics, including task instructions, stimulus type, trial structure and duration, and any concurrent task demands such as dual tasking or working memory load manipulations. We extracted primary and secondary oculomotor metrics and documented how each metric was operationalized by the original authors. We then mapped each paradigm and metric to the prespecified cognitive target domain using the authors' stated rationale and the task requirements.

Comparator conditions were recorded when present, including healthy controls, ABI subgroups, baseline within-participant comparators, and conventional neuropsychological instruments used as reference measures. We extracted statistical information required for synthesis, including group differences,

XSL•FO
RenderX

within-subject changes, correlation coefficients, regression coefficients, and classification performance metrics such as sensitivity, specificity, and area under the curve when reported. Feasibility and data quality indicators were extracted when available, including calibration failures, exclusion due to inadequate tracking quality, missing data rates, and any preprocessing or artifact handling described by the authors. Safety information was extracted and coded as not reported, explicitly absent, or reported with no adverse events to avoid misclassification of missing safety reporting as evidence of safety.

Risk of Bias Assessment

Risk of bias was assessed independently by 2 reviewers using design-appropriate tools, with disagreements resolved by consensus and third-reviewer adjudication when needed. For randomized controlled trials, we applied Risk of Bias 2 across the standard domains and derived an overall judgment to inform interpretation of intervention effects [53]. For nonrandomized intervention studies, we applied Risk of Bias in Non-Randomized Studies of Interventions, with particular attention to confounding, selection bias, and outcome measurement, which are especially relevant in heterogeneous ABI populations [54].

For studies whose primary purpose was classification or diagnostic discrimination using eye-tracking metrics, we evaluated risk of bias and applicability using Quality Assessment of Diagnostic Accuracy Studies 2 (QUADAS-2), which is specifically structured to address concerns in patient selection, index test conduct and interpretation, reference standards, and flow and timing [55]. For observational cohort and case-control studies that did not meet diagnostic-accuracy criteria, we assessed methodological quality using the Newcastle-Ottawa Scale (NOS) to capture selection, comparability, and outcome or exposure ascertainment features that may drive systematic bias [56]. Risk-of-bias assessments were not used as exclusion criteria, but they were incorporated into synthesis and certainty judgments to maintain transparency in interpretation.

Data Synthesis and Effect Measures

Given the expected heterogeneity in paradigms, metrics, and ABI subgroups, we prespecified a primarily narrative synthesis structured by cognitive domain and eye-tracking paradigm, with additional stratification by etiology and recovery phase where feasible. Narrative synthesis followed established principles for integrating quantitative and qualitative evidence, with emphasis on consistency of direction and robustness across designs rather than vote counting [57].

When quantitative pooling was feasible, we planned meta-analysis only when at least 3 studies used sufficiently comparable paradigms, reported the same outcome metric, and provided adequate summary data. For continuous outcomes, we planned to compute standardized mean differences for between-group comparisons or standardized mean change for within-subject designs, with 95% CIs. Random-effects models were prespecified, given expected clinical and methodological diversity. When meta-analysis was not feasible, we summarized findings descriptively and reported effect sizes as presented by the original studies, clarifying the metric and its interpretation. Diagnostic performance indices such as sensitivity, specificity, and area under the curve were summarized descriptively and were not pooled due to heterogeneity in thresholds, paradigms, and reference standards.

Certainty of Evidence

Certainty of evidence was evaluated using GRADE principles, considering risk of bias, inconsistency, indirectness, imprecision, and publication bias [58,59]. Certainty ratings were planned for each main outcome group aligned with the synthesis structure, with judgments explicitly justified and linked to the corresponding risk-of-bias assessments. Ratings were planned to be presented in a summary of findings table to support transparent translation of the evidence base into clinical interpretability [58,59]. The methodological framework used in this systematic review is summarized in Table 2.

Table . Detailed summary of the systematic review methodology.

Section methodology	Details
Protocol and reporting	• Reporting standard: PRISMA[a] 2020 [49]. • Registration: prospective registration in PROSPERO[b] (CRD420251038768) [50].
Inclusion criteria	• Participants: children and adults with acquired brain injury (ABI) of any etiology, severity, and recovery phase, including traumatic brain injury, stroke, hypoxic-ischemic injury, and disorders of consciousness after ABI. • Technology: studies in which eye tracking was used as the primary assessment modality to quantify cognitive functioning. • Operational definition: eye tracking was considered primary when the paradigm and derived oculomotor metrics were central to the cognitive assessment objective and were used to operationalize at least one cognitive domain or a clinically relevant cognitive-communication process. • Cognitive targets: attention, executive function, memory and working memory, visuospatial exploration and neglect-related processes, language and cognitive-communication processes, social-cognitive paradigms, and gaze-based paradigms aimed at detecting command following, volitional control, or awareness in disorders of consciousness. • Eye-tracking metrics: studies reporting defined oculomotor outcomes (eg, fixations, saccades, smooth pursuit, vergence, or pupillary dynamics) with an explicit cognitive interpretation, including associations with conventional cognitive measures and/or discrimination or classification performance. • Study designs: randomized controlled trials, nonrandomized intervention studies, and observational designs (cohort, cross-sectional, and case-control). • Language: full-text papers published in English.
Exclusion criteria	• Focus of study: studies not centered on cognitive assessment using eye tracking in ABI populations. • Population: nonhuman studies, non-ABI samples, or mixed neurological samples without extractable ABI-specific data. • Technology use: studies using eye tracking only for technical device validation or usability testing without a cognitive framework, or studies describing oculomotor dysfunction without an explicit link to a cognitive target or classification approach. • Publication type: protocols, conference abstracts, dissertations, reviews, and single-case reports or case series.
Review question framework	• Population: individuals with ABI across etiologies, severity levels, and recovery phases, including pediatric and adult samples. • Index assessment: eye-tracking paradigms and derived oculomotor metrics used to quantify cognitive domains or cognitive-communication constructs. • Comparator or reference: healthy controls, ABI subgroups, within-participant baselines, and/or conventional neuropsychological measures when available. • Outcomes: domain-relevant cognitive inferences from eye-tracking metrics, associations with conventional assessments, group discrimination or classification performance (eg, sensitivity, specificity, and area under the curve), and feasibility and safety indicators.
Search period	• Coverage: database inception to April 10, 2025, with no publication date restrictions. • Initial search: March 5, 2025. • Update search: April 10, 2025. • Information sources: PubMed, Web of Science, the Cochrane Library, Embase, EBSCOhost, PsycINFO, and Scopus. Full database-specific strategies are reported in Multimedia Appendix 1.

Section methodology	Details
Study selection	• Deduplication: records were collated and deduplicated before screening. • Screening: 2 reviewers independently screened titles and abstracts, followed by full-text eligibility assessment, with third-reviewer adjudication when needed. A PRISMA 2020 flow diagram documented the selection process [49]. • Reliability: interrater agreement was quantified using the Cohen kappa statistic and interpreted using established benchmarks [51,52].
Data extraction	• Process: 2 reviewers independently extracted data using a piloted extraction form, with discrepancies resolved by consensus and third-reviewer adjudication when required. • Study-level items: design, setting, sample size, participant demographics, ABI etiology, severity indices where reported, and phase of recovery. • Eye-tracking technical items: device model or platform, sampling rate, calibration procedure, and success criteria when reported, head stabilization conditions, and testing environment. • Paradigm and outcomes: task procedures and stimulus characteristics, trial structure and cognitive load, primary eye-movement metrics, and mapping of paradigms and metrics to cognitive targets. • Comparators and statistics: comparator conditions (eg, controls, ABI subgroups, within-participant baselines, and conventional tests) and extractable statistics (group differences, within-subject changes, correlations, regression coefficients, and diagnostic performance indices when reported).
Risk of bias assessment	• Randomized trials: RoB 2[c] [53]. • Nonrandomized interventions: ROBINS-I[d] [54]. • Diagnostic accuracy or classification studies: QUADAS-2[e] [55]. • Observational cohort or case-control studies: Newcastle-Ottawa Scale [56]. • Process: 2 reviewers assessed risk of bias independently, with disagreements resolved by consensus and third-reviewer adjudication when necessary.
Data synthesis	• Primary approach: structured narrative synthesis organized by cognitive domain and eye-tracking paradigm, with stratification by etiology and recovery phase where feasible, following established narrative synthesis principles [57]. • Quantitative synthesis: meta-analysis was planned only when at least 3 studies used sufficiently comparable paradigms and reported the same outcome metric with adequate summary data; random-effects models were prespecified for continuous outcomes. • Diagnostic indices: classification and diagnostic performance metrics were summarized descriptively and were not pooled due to heterogeneity in thresholds, paradigms, and reference standards.
Safety and feasibility	• Safety: adverse events were extracted and coded as not reported, explicitly absent, or reported with no adverse events. • Feasibility: calibration failures, tracking-quality exclusions, and missing data were extracted when reported.
Certainty of evidence	• Approach: certainty of evidence for each main outcome group was evaluated using GRADE[f] principles [58,59]. • Reporting: certainty ratings were planned to be presented in a summary of findings table.

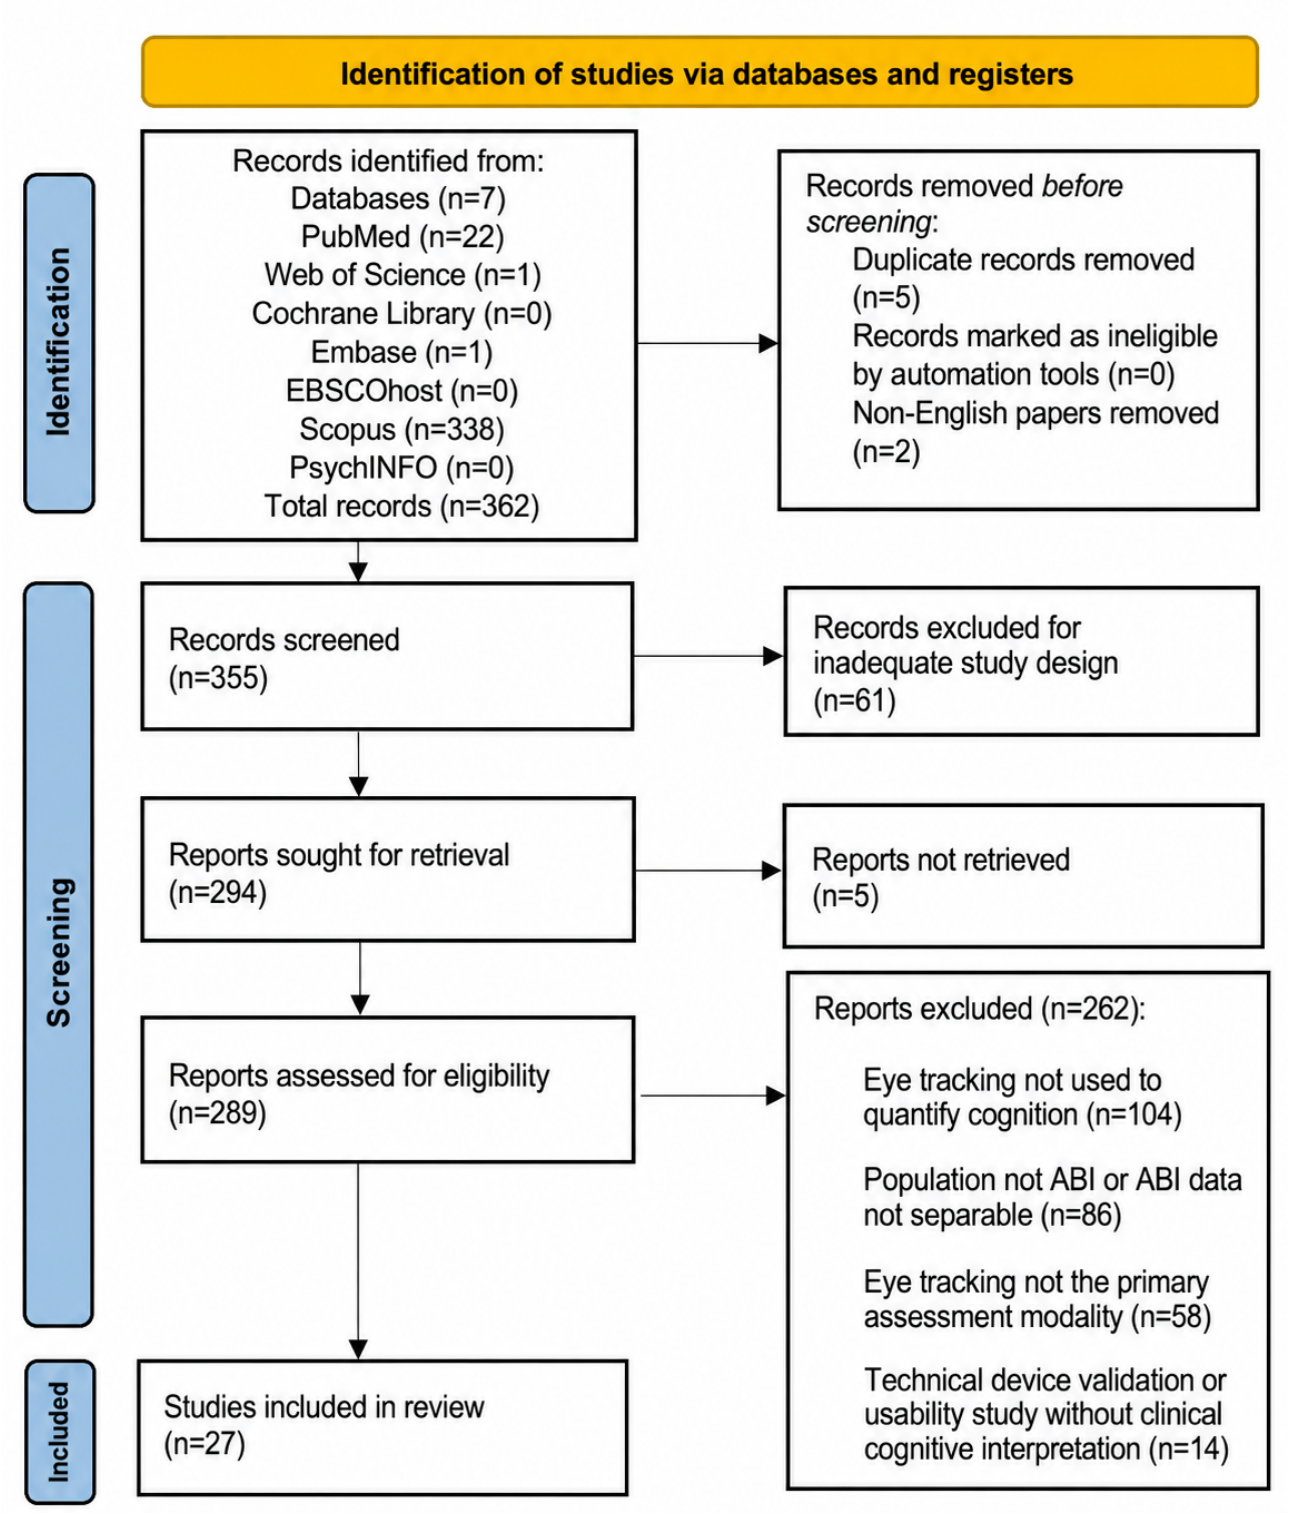
Ethical Considerations

As this systematic review involved secondary data analysis from previously published studies, no new ethical approval was required.



Results

Study Selection

The electronic search across 7 databases identified 362 records. After removal of 5 duplicates and 2 non-English records, 355 records underwent title and abstract screening. At this stage, 61 records were excluded due to inadequate study design, leaving 294 reports sought for retrieval. Despite targeted retrieval efforts, 5 reports could not be obtained, and 289 full-text reports were assessed for eligibility. Of these, 262 reports were excluded for prespecified reasons, most commonly because eye tracking was not used to quantify cognition (104 reports), the population was not ABI or ABI-specific data were not separable (86 reports), eye tracking was not the primary assessment modality (58 reports), or the paper focused on technical and device validation or usability without clinical-cognitive interpretation (14 reports). This process yielded 27 studies that met eligibility criteria and were included in the qualitative synthesis [60-86]. The study selection process is summarized in Figure 1.

XSL•FO
RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 flow diagram of evaluated studies. ABI: acquired brain injury.

Characteristics of Included Studies and Participants

The included evidence base (refer to Multimedia Appendix 1) was heterogeneous in both clinical populations and methodological approaches, with a strong predominance of TBI cohorts and fewer studies in nontraumatic ABI subgroups. Across included studies, a total of 872 participants were enrolled, including 354 females and 518 males, although sex was not consistently reported or analyzed as an effect modifier across all cohorts [60-86]. Most studies focused on mTBI, concussion, or persistent postconcussive symptoms, often in military or athletic samples [60-62,68-75,78-83,85]. Moderate-to-severe TBI was represented in a smaller subset of studies, generally using case-control paradigms to examine cognitive-communication or higher-order integration processes [63,64,67,76,77]. Stroke was represented primarily through a single visuospatial neglect study using a VR free-viewing paradigm [66], while DoC were represented through gaze-based

XSL•FO
RenderX

paradigms and human-computer interface (HCI) approaches designed to probe command following or awareness in patients with severe impairments [65,84]. One rehabilitation study enrolled adults with mixed etiologies (TBI and stroke) and examined oculomotor rehabilitation for reading-related deficits [86]. A single pediatric study examined mild closed head injury and tracked saccadic outcomes and cognitive performance longitudinally for more than 6 months [80]. Pediatric evidence was limited to one longitudinal study in children with mild closed head injury, which assessed saccadic performance and memory outcomes at acute, 3-month, and 6-month follow-up. This study suggested that developmental factors and age subgroup effects may influence oculomotor trajectories, with a pattern consistent with altered maturation or practice effects rather than a uniform deficit profile across all pediatric participants [80]. Because pediatric data were sparse and paradigms differed from those used in adult cohorts, findings in children should be interpreted cautiously and not generalized to the broader ABI spectrum without additional age-stratified studies using harmonized paradigms and reporting.

Study sizes were typically small to moderate. Median sample size across studies was 45 participants (range 10‐188), with 15 of 27 studies enrolling fewer than 50 participants and only 2 studies enrolling 100 or more participants [62,85]. Most studies were cross-sectional, with fewer longitudinal designs or repeated-measures components. Longitudinal or baseline-to-follow-up approaches were used in concussion cohorts to relate within-individual changes in eye-tracking metrics to symptom burden [79,83], and one pediatric study implemented repeated assessments at acute, 3-month, and 6-month time points [80]. The evidence base, therefore, offers breadth in paradigms and outcomes, but it remains uneven across etiologies, severity strata, and recovery phases, with limited prospective follow-up outside concussion-focused cohorts.

Results by Cognitive Domain and Clinical Use Case

Given the heterogeneity of paradigms and outcome definitions, no quantitative pooling was performed. Findings are therefore summarized narratively and organized by cognitive domain and clinical application, with attention to consistency across paradigms, ABI subgroups, and the extent to which eye-tracking outcomes were evaluated alongside conventional assessments.

Executive Function and Inhibitory Control

Evidence relevant to executive function and inhibitory control was derived largely from antisaccade and related paradigms, as well as from task batteries embedding oculomotor indices under attentional demands [68,73-77,80,83]. Across adult mTBI and chronic TBI samples, antisaccade paradigms generally demonstrated increased latency and/or elevated error rates relative to controls, consistent with impaired inhibitory control and executive regulation [74,76,83]. In chronic cohorts, executive dysfunction was often most apparent under task conditions requiring suppression of reflexive saccades or sustained inhibitory control, with several studies indicating that oculomotor indices captured impairments not always mirrored by global cognitive screening measures. In one exploratory study integrating antisaccade performance with diffusion measures and Stroop interference, longer antisaccade latencies were associated with greater symptom burden and poorer interference control in acute mTBI and were strongly correlated with white matter integrity markers in the splenium of the corpus callosum within the acute subgroup [83]. These observations support the plausibility that oculomotor inhibition metrics can reflect executive control processes and their neurobiological correlates in at least a subset of mTBI presentations.

Age- and severity-related modulation emerged as important contextual factors. In one study using embedded saccadic measures, older age was associated with slower saccadic response times and reduced inhibitory performance among those with a history of mTBI, suggesting that eye movement–based indices may capture vulnerability patterns that interact with age-related changes in attentional control [75]. Severity-dependent effects were also reported in chronic TBI cohorts, with moderate-to-severe groups typically exhibiting broader impairment profiles than mild TBI groups under similar saccade paradigms [76,77]. These findings are consistent with an injury-severity gradient, but they also highlight that the magnitude and detectability of inhibitory deficits depend on task selection, recording parameters, and analytic definitions.

Working Memory and Cognitive Load Effects

A smaller evidence base evaluated working memory or cognitive load effects through paradigms explicitly manipulating attentional demand, most commonly using n-back designs with embedded oculomotor outcomes [68,73] and related load-dependent paradigms [72]. Across these studies, oculomotor impairment tended to become more apparent as cognitive load increased. In chronic TBI cohorts, saccadic latency and error indices worsened at higher load levels, with greater impairment observed in more severe injury groups and with findings suggesting that load manipulations increase the sensitivity of eye movement indices to cognitive vulnerability [73]. A clinically oriented multimodal assessment incorporating a cognitively demanding paradigm reported that specific saccadic indices contributed to discrimination between chronic mTBI and controls, with conventional neuropsychological measures showing less consistent separation in that setting [68]. Evidence in this domain remains limited by the small number of studies and by task-specific implementations, but the direction of findings is broadly coherent with the notion that cognitive load amplifies executive and attentional demands reflected in oculomotor control.

Attention and Predictive Control

The largest body of evidence relevant to attention, predictive control, and attentional timing involved smooth pursuit, predictive visual tracking, target blanking, and gap paradigms designed to probe anticipatory control [70,72,74,78,79,81,82]. Several studies reported that mTBI or postconcussive symptom groups demonstrated altered pursuit or visual tracking performance, particularly under conditions that required prediction of target trajectories or compensation for missing visual input. In 2 studies using predictable smooth pursuit paradigms, mild TBI groups showed reduced target prediction and increased eye position error and variability relative to controls, with correlations between pursuit-related indices and verbal learning measures related to attention and executive

XSL•FO
RenderX

functioning [81,82]. In a predictive tracking task coupled with magnetoencephalography, deficits were most pronounced under gap conditions, suggesting that anticipatory control may be selectively impaired when the paradigm reduces reliance on continuous sensory feedback and increases top-down prediction demands [72]. Similarly, a visual tracking paradigm used in concussion monitoring showed that within-individual changes in tracking metrics were moderately to strongly correlated with symptom burden when assessed within 2 weeks post injury, whereas simple reaction time metrics showed weaker relationships to symptom scales despite measurable post injury slowing in throughput measures [79]. Together, these findings suggest that predictive timing and sustained attention components of pursuit or tracking paradigms may map more closely to symptom profiles than simple reaction-based outcomes in some concussion contexts.

Not all evidence converged on robust group differences. One study combining diffusion tensor imaging, neurocognitive assessment, and visual tracking reported that the concussion cohort showed largely comparable tracking performance to controls, despite imaging differences and evidence of slowed attention-related reaction time, indicating that tracking metrics may be sensitive in some cohorts but not uniformly abnormal across mTBI presentations [78]. In another study, behavioral eye measures were less discriminatory than imaging-derived indices in separating chronic mTBI from controls, underscoring that the comparative performance of eye tracking depends on the specific paradigm and the selected outcome metric [70]. These mixed findings collectively support the need to interpret attentional tracking outcomes as paradigm- and population-dependent rather than as uniform markers of impairment.

Visuospatial Exploration and Neglect Detection

Evidence for visuospatial exploration was limited but clinically instructive. In a VR free-viewing museum environment, stroke patients with spatial neglect demonstrated lateralized gaze and head-orientation asymmetries relative to controls, and the approach was described as capable of detecting atypical exploration patterns that were not captured consistently by conventional tests in all individuals [66]. This study supports the feasibility and potential incremental utility of immersive, naturalistic paradigms for detecting spatial biases, although generalizability remains limited because the evidence in this domain is currently based on a single study and a single implementation approach.

Cognitive-Communication and Social Cognition

Three studies examined cognitive-communication or socially relevant visual attention patterns through tasks that were not reducible to classic executive function paradigms, but nevertheless quantified cognition through structured gaze behavior [63,64,67]. In a visual-world paradigm assessing online speech–gesture integration, both groups showed facilitation from meaningful gestures, but this effect was attenuated in moderate-to-severe TBI, suggesting reduced integration of multimodal cues during language processing [67]. In severe TBI cohorts evaluating visual attention during interpretation of augmentative and alternative communication displays, grid-based formats were associated with greater visual effort than scene-based formats in both groups, and TBI participants showed less efficient gaze patterns overall, consistent with increased processing demands and reduced efficiency in extracting relevant information [63]. A separate free-viewing study focusing on engagement cues in contextual photographs showed that both groups oriented rapidly to human figures and adjusted fixation patterns according to task-relevant engagement content, with limited between-group differences, suggesting that some aspects of social attention may be relatively preserved depending on task demands and stimulus properties [64]. Taken together, this evidence indicates that eye tracking can quantify differences in processing efficiency and cue integration in cognitive-communication contexts, but the limited number of studies and the task-specific nature of outcomes constrain broad conclusions.

DoC and Gaze-Based Paradigms for Command Following

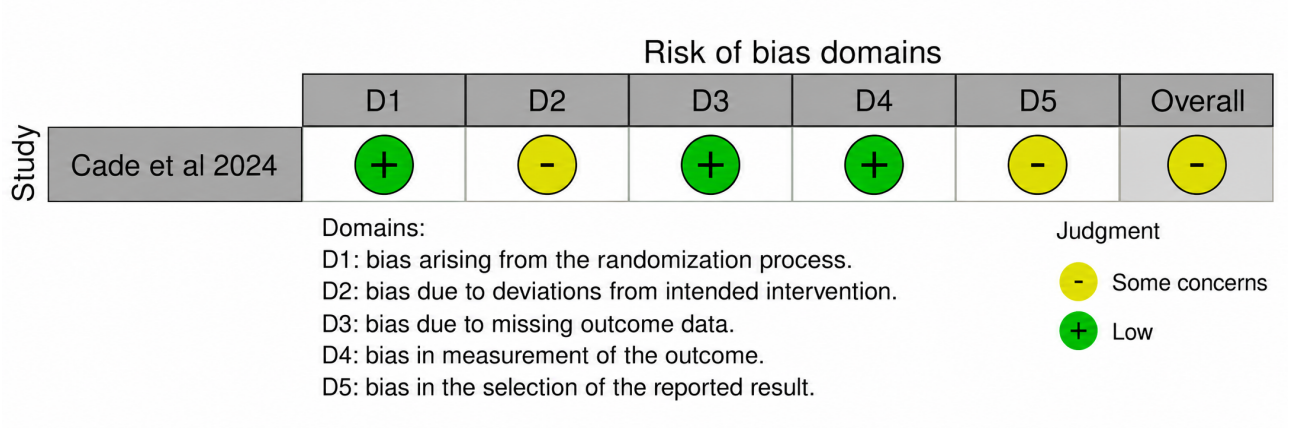
Two studies focused on DoC populations and used gaze-based paradigms to probe command following or awareness in contexts where conventional assessment is challenged by limited motor output [65,84]. In a gaze-tracking HCI approach designed for DoC, a subset of patients performed above chance on one or more structured tasks, and the authors highlighted the potential for such tools to complement bedside diagnosis and reduce misclassification, including identification of patients who might retain meaningful command-following capacity [84]. A second study combined gaze-tracking tasks with complementary neurophysiologic measures and suggested that multimodal features could relate to clinical status classifications in severe ABI populations [65]. The evidence in this domain remains limited by small samples, variable arousal, and setting-specific feasibility constraints, but the convergence of both studies on above-chance task completion in a subset of patients supports continued evaluation of eye-tracking HCI approaches as adjunctive assessment tools in severe disorders.

Incremental Validity Relative to Conventional Assessment

Direct evidence of incremental validity beyond conventional neuropsychological testing was limited because many studies did not prespecify incremental validity as a primary analytic goal and because neuropsychological comparators varied across cohorts and settings. When conventional measures were included, they were often used as correlates rather than as formal reference standards. Still, several patterns emerged. First, in paradigms tightly linked to attentional prediction and executive inhibition, oculomotor indices often showed associations with symptom burden and executive test performance, suggesting that they can capture clinically relevant variance in domains that are difficult to quantify with brief assessments alone [72,79,83]. Second, some multimodal or embedded-task approaches reported that oculomotor indices contributed meaningfully to group discrimination or classification in settings where conventional cognitive batteries showed limited differentiation, although this was not uniform across platforms and paradigms [68,70]. Third, other studies indicated that symptom-based or vestibular-ocular screening measures may

XSL•FO
RenderX

outperform certain computerized eye-tracking platforms for specific operational goals, emphasizing that incremental value is likely to be context dependent and may vary by hardware, paradigm, and target construct [61]. Collectively, the evidence supports cautious interpretation: eye tracking may add value for specific paradigms and populations, but the current literature does not justify a generalized claim that eye tracking routinely exceeds conventional testing across ABI.



Safety, Feasibility, and Data Quality Reporting

Safety reporting was sparse across the included studies. Only 1 of 27 (4%) studies explicitly reported no harms, while 26 of 27 (96%) studies did not report adverse events in a way that allowed clear classification [60-86]. Feasibility reporting was more common but remained incomplete. Thirteen of 27 (48%) studies provided at least some feasibility or exclusion information related to calibration, equipment failures, incomplete testing, or analytic inclusion, whereas 14 of 27 (52%) studies did not report feasibility indicators beyond general study completion statements. Where reported, feasibility challenges included calibration failure and fatigue limiting completion in a VR neglect assessment [66], equipment-related exclusions in a language-processing study [67], incomplete administration of conventional tests due to physical impairment in a severe TBI cohort [63], and differential analytic sample sizes attributable to unusable eye-tracking records in a prospective concussion cohort [79]. Several paradigms required head stabilization, specialized equipment, or controlled testing conditions, which may limit scalability in routine clinical environments [67,70,74,81,82]. These findings underline that feasibility and access considerations are integral to interpretation and translation, and that standardized reporting of calibration success, data loss, and exclusions remains an important gap.

Methodological Quality and Risk of Bias

Risk-of-bias assessments varied by study design and were interpreted with attention to the appropriate tool for each design. The complete risk-of-bias and methodological quality assessments are provided in Multimedia Appendix 2. The single randomized controlled trial was judged as having some concerns overall, reflecting limitations primarily related to deviations from intended interventions and the transparency of prespecified outcome reporting, while retaining low-risk judgments in several other domains of trial conduct and outcome measurement. Risk of Bias 2 domain-level judgments are provided in Figure 2.

Figure 2. Risk of Bias of included randomized controlled trial studies [60].

Diagnostic and classification studies showed more substantial and heterogeneous concerns. QUADAS-2 assessments, summarized in Table 3, indicated a high risk of bias across all 3 classification studies, primarily driven by nonconsecutive or volunteer sampling strategies and by data-driven selection of predictors and decision thresholds. Applicability concerns were great for Barry and Ettenhofer [71] and Samadani et al [85] because the target condition and/or reference standards were not directly aligned with cognitive-status classification in ABI (performance-validity simulation in the former and computed tomography–defined injury status in the latter). Ettenhofer et al [68] showed lower applicability concerns because chronic mTBI status was established using a standardized identification approach with medical record confirmation, but risk of bias remained high due to in-sample variable selection procedures and exclusions that may inflate classification performance. These considerations suggest that reported classification estimates should be interpreted cautiously, particularly when models and thresholds are derived and evaluated within the same dataset, and external validation is not available [68,71,85].

[a]RoB: risk of bias.

Observational studies assessed with the NOS generally demonstrated fair methodological quality, with fewer studies achieving good ratings and 1 study rated as poor. Specifically, among the 19 observational studies assessed with NOS, 6 were rated good, 12 were rated fair, and 1 was rated poor, indicating recurring limitations in comparability and exposure or outcome ascertainment despite generally acceptable selection domains in many case-control designs [63,64,66,67,70,72-74,76-83]. NOS ratings are summarized in Table 4. Nonrandomized intervention studies [65,68,69,84-86] were assessed separately for risk of bias using an intervention-focused tool, and the domain-level judgments are provided in Figure 3. Across these designs, confounding and participant selection were common sources of concern, consistent with the predominance of small samples and heterogeneous inclusion criteria.

Figure 3. Cochrane Risk of Bias in Non-Randomized Studies of Interventions (ROBINS-I) [65,68,69,84-86].

Certainty of evidence across outcome domains was generally low, driven by the predominance of nonrandomized designs, small samples, heterogeneity of paradigms and metrics, and limited external validation for classification analyses. Evidence was judged to be very low for most cognitive domains, with low certainty reserved for diagnostic or classification performance outcomes where classification metrics were reported but where risk-of-bias concerns and inconsistency limited confidence. Certainty ratings and primary reasons for downgrading are summarized in Table 5.

XSL•FO
RenderX

Table . Grading of Recommendations Assessment, Development and Evaluation (GRADE) certainty of evidence summary by cognitive domain and clinical use case. Certainty ratings reflect the overall body of evidence for each domain or use case. No quantitative pooling was undertaken; therefore, the summary reflects the direction and consistency of findings reported across studies. Domains may overlap because individual studies often reported multiple paradigms or outcomes.

Outcome domain or clinical use case	Evidence base (design and studies)	Summary of findings (narrative)	Certainty of evidence (GRADE[a])	Main reasons for downgrading
Executive function and inhibitory control (eg, antisaccade performance, inhibition errors, and reaction time variability)	Primarily observational (case-control or cross-sectional and classification studies; 10 studies)	Most studies reported worse inhibitory control or higher variability in ABI[b] or symptomatic mTBI[c] compared with controls, and/or associations with symptom burden; findings were not uniform across paradigms and populations.	Very low	Serious risk of bias (mostly nonrandomized and incomplete reporting), serious inconsistency (heterogeneous paradigms or metrics), and serious imprecision (small samples and limited external validation).
Working memory or cognitive load effects (eg, n-back and dual-task paradigms)	Observational (case-control) with some classification analyses (3 studies)	Across cognitive-load paradigms, oculomotor impairment tended to be more evident under higher load; evidence is based on a few studies and selected samples.	Very low	Serious imprecision (few studies and small samples) and indirectness (task-specific paradigms and selected populations), with additional concerns about risk of bias in classification analyses.
Attention and predictive control (eg, smooth pursuit, visual tracking, predictive pursuit, and target blanking paradigms)	Observational and mixed designs (case-control and longitudinal or pre-post in a minority; 10 studies)	Several studies reported altered pursuit or visual tracking or predictive control in ABI groups, particularly under conditions that increase anticipatory demands; other studies reported smaller or null differences, limiting consistency.	Very low	Serious inconsistency (mixed results across paradigms), serious imprecision (small samples), and serious indirectness due to heterogeneity in paradigms, acquisition settings, and outcome definitions.
Visuospatial exploration or neglect detection (eg, free-viewing VR[d] environments and spatial bias metrics)	Observational (1 study)	VR-based free-viewing eye tracking captured lateralized exploration patterns compatible with neglect phenotypes and may complement conventional tests; evidence is limited to a single study.	Very low	Very serious imprecision (single study) and indirectness (single setting or paradigm and limited generalizability).
Cognitive-communication and social cognition (eg, visual-world paradigms, AAC processing, and context interpretation)	Observational (case-control; 3 studies)	Eye-tracking measures suggested differences in efficiency of information processing and reduced integration of multimodal cues in ABI, but evidence is based on small, task-specific studies.	Very low	Serious imprecision (small samples), indirectness (task- and context-specific outcomes), and risk of bias related to selection and measurement.
Disorders of consciousness (DoC): command following or awareness detection using gaze-based paradigms	Noncomparative case series (2 studies)	A subset of patients achieved above-chance performance in gaze-selection tasks, suggesting potential to support bedside assessment; evidence is limited, and feasibility constraints were variably reported.	Very low	Very serious imprecision (small case series), serious risk of bias (noncomparative designs), and indirectness (variable arousal, assistive adaptations, and setting-specific implementation).
Diagnostic or classification performance of eye-tracking metrics (eg, discrimination of symptomatic mTBI vs controls and performance validity)	Diagnostic or classification studies (3 studies)	Eye-tracking–derived metrics showed discriminatory performance in specific paradigms, but thresholds, reference standards, and model validation procedures varied across studies.	Low	Risk of bias concerns (patient selection, index test conduct, and potential overfitting), inconsistency (different paradigms or thresholds), and imprecision (limited external validation).

Discussion

Principal Findings

This systematic review synthesized 27 studies evaluating eye-tracking–derived metrics as a primary approach to quantify cognition or clinically relevant cognitive-communication processes after ABI. The evidence suggests that eye tracking can capture measurable differences in gaze control and visual attention that are plausibly related to executive inhibition, attentional prediction, and cognitive load. Findings were most consistently reported in chronic or persistent mTBI cohorts, while evidence for moderate-to-severe TBI, stroke, hypoxic-ischemic injury, and DoC was comparatively sparse and methodologically variable. Direct evidence of incremental validity over conventional neuropsychological testing was mixed and often indirect because comparator measures and analytic strategies varied across studies and were not consistently designed to test incremental value. Safety and feasibility reporting was inconsistent, limiting firm conclusions about tolerability and implementation at scale. Overall certainty of evidence was low across domains, reflecting small samples, heterogeneity of paradigms and outcome definitions, and limitations in internal and external validity.

Interpretation and Clinical Implications

Eye-tracking outcomes can be interpreted at 2 complementary levels that should be kept conceptually distinct in clinical translation. Some outcomes primarily index sensorimotor oculomotor control, such as conjugate gaze stability, pursuit gain, and basic tracking precision. These can be clinically informative because visual sequelae are common after TBI, and ocular motor changes may reflect injury-related disruptions within the visual system or its supporting networks [87,88]. In contrast, paradigms such as antisaccade tasks, predictive pursuit under blanking or gap conditions, and cognitive load manipulations are more tightly coupled to executive inhibition, attentional prediction, and control processes. These paradigms can provide a process-level window into cognition, but their interpretability depends on careful alignment between task demands, analytic definitions, and the intended clinical construct. This distinction is important because a technically "abnormal" eye-movement pattern does not automatically imply impairment in a higher-order cognitive domain, and conversely, a patient may report cognitive symptoms despite relatively preserved performance on a specific oculomotor task.

From a biomarker perspective, the current literature supports a cautious stance. Eye-tracking metrics show promise as candidate behavioral biomarkers, but the present evidence base is not sufficiently standardized to support broad clinical adoption or claims of routine superiority over conventional assessment. Contemporary biomarker frameworks emphasize the need for rigorous validation, harmonized measurement pipelines, and clinically meaningful thresholds before a candidate measure can be used for diagnostic decision-making or treatment monitoring [89]. In our synthesis, diagnostic and classification analyses were reported in a subset of studies, but many relied on in-sample threshold selection, nonconsecutive sampling, or reference standards that were not directly aligned with cognitive-status classification. This pattern limits confidence in generalizability and reinforces the need for external validation and predefined analytic plans when classification performance is a central claim.

The clearest near-term clinical role for eye tracking may be as an adjunct rather than a replacement. In concussion and persistent symptom cohorts, eye tracking may be helpful when the goal is to quantify specific components of visual attention and control over short time windows, particularly when repeated measures are needed, and practice effects are a concern. Naturalistic and immersive implementations may also offer clinically meaningful advantages because they can capture cognitive-motor performance under conditions closer to real-world demands. VR-based neurocognitive testing that integrates eye tracking is an example of this direction, as it can link gaze behavior to task performance within ecologically relevant contexts [90]. At the same time, practical constraints remain nontrivial. Hardware costs, space requirements, calibration procedures, head stabilization needs, and trained personnel requirements can limit feasibility, particularly outside specialized centers. These barriers are consistent with broader concerns about implementation and scalability for technology-assisted assessment approaches in neurorehabilitation.

Specificity is another recurring concern that should be made explicit. Oculomotor metrics can be influenced by psychiatric symptoms, sleep disturbance, pain, medications, and demographic factors, all of which may be common after TBI and can co-vary with cognitive complaints. These influences do not invalidate eye tracking, but they constrain interpretation unless these covariates are measured and addressed analytically. In vulnerable or socially complex cohorts, comorbidities can be substantial and may contribute to both symptom burden and performance variability, underscoring the importance of careful phenotyping and confounder control in future studies [91,92]. Interpreting eye-tracking changes as cognition-specific without considering these influences risks overattribution and may inflate perceived diagnostic specificity.

Translation to Neurorehabilitation and Future Directions

The results also inform the difference between demonstrated clinical utility and future potential. At present, most studies provide evidence of association, group discrimination, or feasibility rather than evidence that eye tracking improves clinical decisions or outcomes. Translational claims should therefore be framed as emerging. Still, several pathways appear promising. First, eye tracking may support precision rehabilitation by providing objective, high-frequency measures that can be tracked longitudinally and linked to individualized targets. This aligns with broader arguments that eye tracking can serve as a scalable behavioral signal of cognition in

XSL•FO
RenderX

neurological conditions, provided that measurement is standardized and clinically interpretable [93]. Second, methodological work on quantifying and analyzing saccades, pursuit, and fixations offers a foundation for harmonizing metrics across devices and paradigms, which is necessary for multisite comparability and eventual normative datasets [94]. Third, broader clinical applications of eye tracking in medical practice suggest that eye tracking can be integrated into clinical workflows when the technical and interpretive challenges are addressed transparently [22].

A particularly important translational direction is the development of "digital biomarker" programs in which eye tracking is evaluated alongside complementary sources of evidence, including imaging, neurophysiology, and symptom trajectories. Reviews in other neurological conditions emphasize that eye-tracking metrics can be informative but require strong attention to measurement validity, confounding, and reproducibility to be credible as biomarkers [95]. Multimodal rehabilitation technologies, including VR and brain-computer interface concepts, may further enhance ecological validity and enable adaptive assessment and training paradigms, but these approaches require careful validation in ABI populations, especially regarding feasibility and tolerability in symptomatic cohorts [96,97]. In DoC, eye-tracking and HCI approaches may assist in detecting potential command following or residual cognition in select patients, but the literature remains small and sensitive to fluctuations in arousal and implementation constraints. These concerns align with broader discussions on recovery mechanisms and prognostication in DoC and reinforce the need for cautious interpretation of single-session performance metrics [98].

Future studies should prioritize methodological features that directly address the limitations identified in this review. Prospective registration, predefined primary outcomes, standardized reporting of calibration success and data loss, and device-specific acquisition parameters should become routine. External validation of classification thresholds and replication in broader etiologic subgroups are particularly important, given that the existing evidence is heavily weighted toward chronic mTBI and selected populations. In addition, longitudinal designs are needed to clarify whether eye-tracking metrics track recovery trajectories or identify subgroups at risk for persistent impairment. This is especially relevant given growing evidence that moderate-to-severe TBI can show chronic-stage cognitive decline patterns in some cohorts, which underscores the need for sensitive, repeatable measures over extended follow-up [99]. Finally, expansion beyond TBI is warranted. Eye tracking has been used to probe language processing and lexical integration, and emerging work suggests feasibility for remote or online eye tracking in language-related disorders, which may be informative for ABI cognitive-communication assessment if appropriately validated [100,101]. Similarly, additional evidence in prolonged DoC, stroke, and systems-level implementation could support a more balanced etiologic evidence base [102,103].

Strengths and Limitations

This review provides a structured synthesis across cognitive domains and clinical use cases, incorporating design-appropriate risk-of-bias tools and an explicit certainty-of-evidence framework. The broad inclusion criteria allowed capture of a wide range of paradigms, including traditional oculomotor tasks, embedded cognitive-load assessments, VR paradigms, and HCI approaches. These strengths increase coverage and relevance across settings.

Several limitations constrain inference. First, the literature is highly heterogeneous in paradigms, outcome definitions, acquisition procedures, and analytic pipelines, which preclude quantitative pooling and limit the ability to estimate typical effect size ranges with confidence. Second, most studies were cross-sectional and underpowered, increasing vulnerability to imprecision and selective reporting. Third, the evidence base is dominated by chronic mTBI cohorts and selected populations, limiting generalizability to other ABI etiologies and to broader clinical settings. Fourth, safety and feasibility reporting was incomplete, which limits translation conclusions and obscures implementation barriers. Finally, diagnostic and classification claims require caution, as model development and thresholding were often performed within the same dataset, and reference standards varied, creating a risk of overestimated performance.

Conclusion

Eye-tracking technology shows promising potential as an adjunctive approach for quantifying specific components of visual attention and oculomotor control that are plausibly linked to cognitive processes after ABI. The current evidence is most developed for paradigms involving inhibitory control, predictive tracking, and cognitive load in mTBI cohorts, while evidence for stroke, hypoxic-ischemic injury, and DoC remains preliminary and methodologically diverse. At present, the literature does not support broad claims that eye tracking routinely exceeds conventional neuropsychological assessment. Instead, the most defensible interpretation is that eye tracking may add clinically relevant information in paradigm- and population-specific contexts, particularly when standardized acquisition, transparent reporting, and appropriate confounder assessment are in place. Future research should focus on harmonized paradigms and reporting standards, external validation of classification thresholds, longitudinal designs, and explicit feasibility and safety reporting, with a goal of defining when and for whom eye tracking provides incremental clinical value within precision neurorehabilitation pathways.

Abstract

Background: A robust correlation exists between physical activity (PA) and stroke risk reduction, and wearable PA sensors have emerged as promising adjuncts for rehabilitation and risk self-management. However, evidence regarding their long-term efficacy in facilitating sustained behavioral change remains equivocal.

Objective: This study aimed to explore the barriers and facilitators influencing the effective use of PA sensors in older adults at risk of primary or recurrent stroke.

Methods: A systematic search and thematic synthesis of qualitative research was conducted, focusing on PA sensor use among older adults at risk of primary or recurrent stroke. Given the emerging qualitative evidence base, inclusion was extended to proxy populations with analogous cardiovascular risk and functional profiles. Data were analyzed using line-by-line coding of primary text to generate descriptive themes and synthesize overarching analytical constructs.

Results: A search of 6 bibliographic databases (January 2010 to December 2023) identified 18 eligible studies. This systematic review and thematic synthesis revealed predominantly technological (user experience and device attributes) and psychological (motivation) barriers. Key facilitators were psychological (feedback and motivation), technological (user experience), and social/environmental supports. Higher-level analysis revealed a critical interrelationship between effective user engagement and optimally assistive device characteristics.

Conclusions: This review revealed a synergistic user-device interaction driving sustained PA in older adults at risk of primary or recurrent stroke. Future interventions developed in collaboration with patients and informed by the factors identified by this study will improve participation in rehabilitation and functional outcomes in this population.

KEYWORDS

sensors; stroke; physical activity; rehabilitation; qualitative research

Introduction

The terms “physical activity” (PA) and “exercise,” although often used interchangeably, are distinct concepts. PA broadly refers to any bodily movement resulting in energy expenditure, while exercise is more precisely defined as a subcomponent of PA that is “planned, structured, and... done to improve or maintain one or more components of physical fitness” [1]. Within this context, physical fitness encompasses the attributes and abilities an individual possesses or acquires to perform PA or exercise. Physical inactivity, or sedentary behavior, is a significant global risk factor for mortality associated with numerous adverse health outcomes including stroke [2].

As with other cardiovascular diseases, the pathogenesis of stroke is influenced by a range of risk factors, broadly categorized into nonmodifiable, medically modifiable, and lifestyle-modifiable attributes [2]. Nonmodifiable factors include inherent characteristics such as age and genetic predisposition. Medically modifiable factors are amenable to pharmacological or surgical interventions. Lifestyle-modifiable (behavioral) factors are those that can be altered through changes to daily habits and practices. Hypertension, for example, the most significant modifiable risk factor for stroke, can be effectively managed through both medical and lifestyle interventions, including pharmacotherapy, PA, dietary changes, and weight management. Despite the established efficacy of these interventions, one study reported that fewer than 50% of patients had their stroke or cardiovascular disease risk factors appropriately assessed,

XSL•FO
RenderX

treated, or managed [3]. Similarly, a recent audit of stroke rehabilitation services in Australia revealed that a comparable proportion of patients received information on self-management strategies or support programs [3]. PA is a critical, accessible, and cost-effective means of mitigating underlying risk factors, such as hypertension, contributing to the primary prevention of initial stroke events and the secondary prevention of recurrent stroke [4,5].

A growing body of evidence suggests that increased PA confers substantial health benefits across all age groups [6]. Notably, reduced sedentary time demonstrably lowers health risks and mortality, even when accounting for activity levels and established risk factors. Regular PA also mitigates the progression of hypertension and has been linked to improved weight management, reduced adiposity, and a decreased incidence of type 2 diabetes mellitus—all major risk factors for stroke. While increased PA significantly improves walking speed and balance, the evidence regarding the impact on poststroke mortality, dependence, and long-term disability remains insufficient or unclear [7]. A survey conducted in the United States revealed that a significant majority (71%) of older adults, 65 years and older, engage in self-monitoring for health indicators such as weight, diet, or exercise [8]. However, despite the prevalence of digital health tools, only a small minority (12%) utilize PA sensors and companion mobile apps. The predominant method for tracking health measures in this group was pen-and-paper [8]. The limited adoption of technology for health monitoring among this demographic may be attributable to a combination of objective factors such as PA sensor accuracy and subjective considerations such as perceived usability, which may influence engagement levels among older adults.

The need for increasingly sophisticated and persuasive strategies to motivate sustained healthy behavior remains a central challenge for clinicians designing interventions and engineers developing wearable PA sensors. Remarkably, few qualitative studies have thoroughly investigated the use of PA sensors in older adults, specifically exploring reasons for nonadoption and discontinuation. A deeper understanding of these factors is essential for the effective design and implementation of PA sensor-based interventions for stroke prevention and rehabilitation [9]. With that in mind, the current study aimed to explore the barriers and facilitators influencing the effective use of PA sensors in older adults at risk of primary or recurrent stroke.

Methods

Methodological Framework

This systematic review and thematic synthesis was conducted and reported according to PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines (Checklist 1) and the JBI (Joanna Briggs Institute) framework for evidence synthesis. Study quality was evaluated using JBI critical appraisal tools. Review methods were established a priori, as detailed in the published protocol [10]. The inclusion of proxy groups, such as individuals with hypertension or age-related motor deficits, is justified by their functional and psychological alignment with stroke survivors. These cohorts experience near-identical ergonomic barriers, such as the manual dexterity required for small device interfaces, and share psychological burdens, including diminished self-efficacy due to device failure, for example. By prioritizing the phenomenology of functional experience over narrow neurological diagnoses, this study applies conceptual transferability to enhance thematic depth where disease-specific evidence is still emerging [11-13]. The primary objective of the study was to identify and synthesize patient-perceived factors acting as either barriers or facilitators, influencing the use of wearable PA sensors in the context of stroke prevention and rehabilitation for older adults.

Inclusion and Exclusion Criteria

Peer-reviewed articles published in English between January 1, 2010, and December 31, 2023, that had a primary focus on wearable PA sensor use were included in the analysis. Studies were required to have a qualitative design or a significant qualitative component. The target population included older stroke survivors and populations with analogous clinical profiles. Eligible participants were characterized by shared cardiovascular risks (eg, atrial fibrillation, hypertension), metabolic conditions (eg, type 2 diabetes, dyslipidemia), and lifestyle-related factors. Inclusion was further defined by stroke-related functional deficits, specifically, impaired physical mobility (gait and balance), cognitive decline (executive dysfunction), and reduced independence in activities of daily living [14]. Study participants were stratified into 3 age cohorts to reflect distinct clinical and life-stage profiles. The 50‐ to 64-year age group (“Young-Old”) was included to capture the critical transition period where stroke risk doubles, and this allowed for an analysis of whether PA sensor–based interventions performed differently in individuals with higher neuroplasticity and higher work/life stress [2,15]. The 65‐ to 84-year group (“Old-Old”) represents the standard geriatric stroke demographic. Finally, those aged 85+ years (“Oldest-Old”) were analyzed separately to ensure the unique frailty and comorbid complexities of the oldest-old did not skew the results of the younger cohorts.

Search Strategy

The methodology for this synthesis followed the prepublished protocol [10]. A high-sensitivity search strategy was conducted across MEDLINE, EMBASE, CINAHL, Cochrane, PsycINFO, and Scopus using MeSH and keywords related to wearable PA sensors and exercise. To maximize recall within an emerging qualitative evidence base, population-specific filters (eg, “stroke”) were omitted; instead, the search was broadened to include all studies of populations with analogous risk and functional profiles. These results were supplemented by manual bibliography scans of included studies. This approach ensured a comprehensive capture of qualitative data despite the paucity of stroke-specific literature.

Screening and Data Extraction

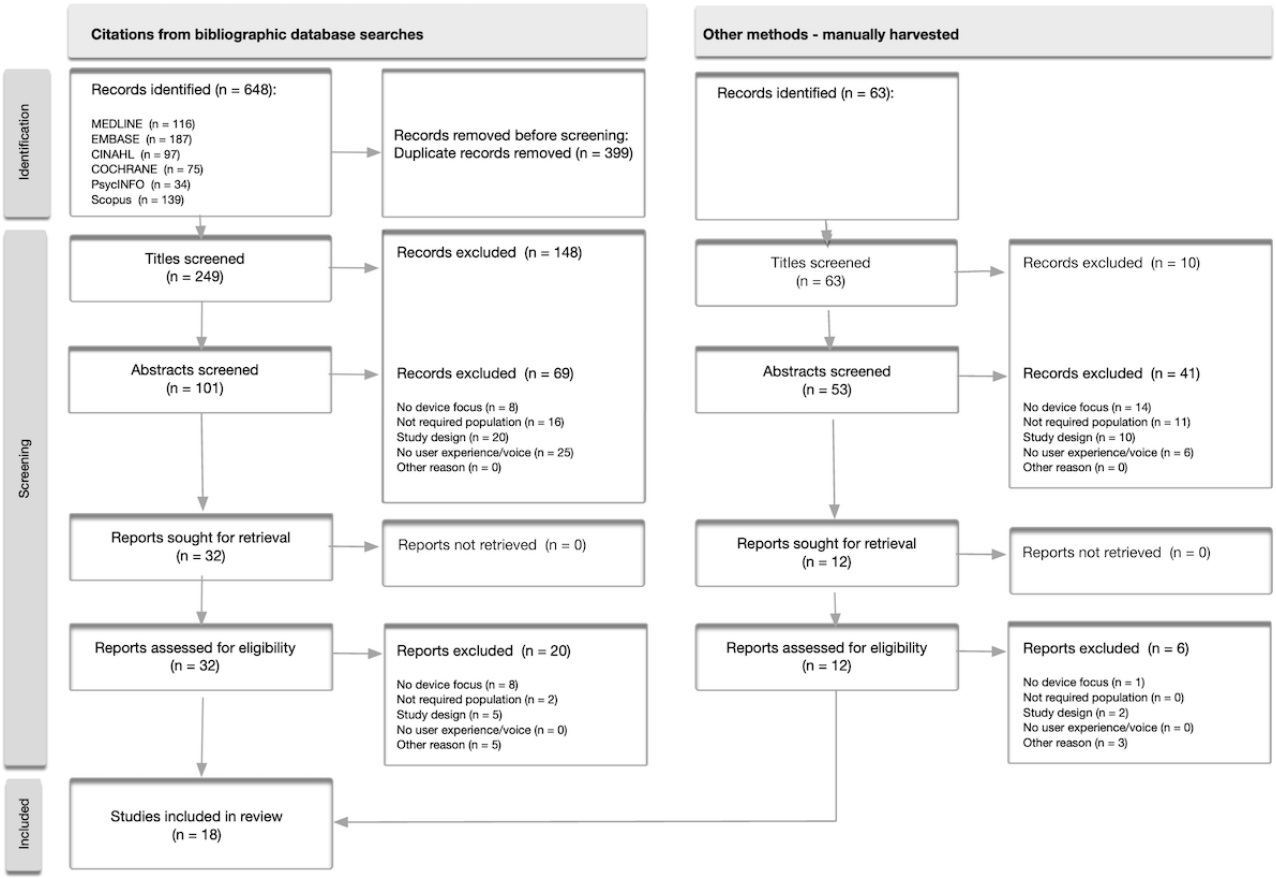
Following the prepublished protocol, publication titles and abstracts were independently screened by two reviewers (IM and PH), with a pilot test conducted to ensure interrater reliability. Disagreements were resolved through consensus or third-party adjudication. Full-text screening and deduplication

XSL•FO
RenderX

were managed via Covidence. A standardized form was used to extract study characteristics (eg, demographics, research design, intervention specifics) and participant data, which were subsequently managed in NVivo. Methodological quality was evaluated using CASP (Critical Appraisal Skills Program) and JBI checklists [16,17]. Quality assessment focused on congruity of perspective, research questions or objectives, methodology, bias, participant voice, ethical standards, analysis, and conclusions. Papers were also evaluated for analytical richness, reflecting qualitative depth and interpretation with respect to the study aims.

Data Analysis

This systematic review and thematic synthesis was conducted in 3 stages, summarized below, and discussed in more detail in the study protocol [10].



- *Stage 1. Inductive coding of included studies*: Reviewers independently coded the included studies, identifying salient sections and discussing coded sections as a team. A set of a priori codes based on the Person-Environment-Occupation-Performance and Technology Acceptance Model provided a provisional structure, with themes differentiated according to valence under binary (barrier and facilitator) top-level nodes [18,19].
- *Stage 2. Summarize under descriptive themes*: Related codes were aggregated into broader "descriptive themes" that summarized concepts across studies without going beyond the source texts. These higher-level descriptive themes were generated, discussed, and refined iteratively. Coded region frequencies (coding densities) and referenced study counts were analyzed to identify major and minor themes. The use of density metrics is well established in qualitative research, somewhat like matrix-coding queries, and is indicative of theme recurrence for included papers only [20,21].
- *Stage 3. Generate analytical constructs*: Descriptive themes were analyzed in relation to the research questions and objectives. Links between descriptive themes were mapped to generate analytical constructs and visualized diagrammatically to develop a coherent understanding from the evidence base.

Results

Study Selection and Characteristics

A systematic search of 6 electronic bibliographic databases yielded 648 records. An additional 63 records were identified through manual harvesting from other methods (ie, screening citation lists of included studies). After duplicate removal and screening, 44 studies were sought for full-text retrieval. Finally, 18 studies met the inclusion criteria and were included in this systematic review and thematic synthesis. The selection process and search results are summarized in the PRISMA flow diagram (Figure 1).

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram for systematic reviews.

[k]YNG: Young-Old (50–64 y).
[l]DEU: Germany.
[m]STR: stroke survivor.
[n]ELD: Oldest-Old (≥85 y).
[o]COG: cognitive.
[p]SWE: Sweden.
[q]SYS: systematic review.
[r]MIX: mixed methods.
[s]NR: not reported.
[t]GBR: Great Britain.
[u]DNK: Denmark.
[v]NLD: Netherlands.
[w]CAN: Canada.
[x]CHE: Switzerland.

Of the included studies, 1 was a systematic review that included quantitative and qualitative studies, 3 employed mixed methods, and 14 were qualitative. Studies were conducted in North America (n=5), Australia (n=3), Great Britain (n=3), and Europe (n=7). A detailed breakdown of the quality and risk of bias assessment for each study is provided in Table S1 in Multimedia Appendix 1. The characteristics of the included studies with country designations according to International Organization for Standardization 3-letter standards (eg, DEU: Germany and CHE: Switzerland) are summarized in Table 1.

Approximately 78% (n=14) of the studies included individuals with metabolic risks like obesity, prediabetes, or type 2 diabetes. Participants with vascular risks, such as hypertension, heart disease, and high cholesterol, were even more common, appearing in 83% (n=15) of the studies. All 18 studies included participants with lifestyle-related risks, specifically high sedentary behavior and poor dietary choices. Functional deficits further defined these populations: 89% (n=16) of studies reported on participants with motor or physical limitations such as joint pain from osteoarthritis, reduced walking speed, or the use of mobility aids like walkers. Participants with cognitive deficits (eg, memory loss or forgetfulness, impaired task comprehension, and execution) were represented in 4 (22%) studies, and participants with impaired activities of daily living affecting self-care and mobility were represented in 6 (33%) studies.

Specific stroke-related representation was documented in 5 studies. Johansson et al [26] systematically reviewed 24 studies of stroke survivors, while Støve and Larsen [31] included patients with stroke (80%) in active inpatient rehabilitation with hemiparesis. Similarly, Hamilton et al [25] reported a sample where 60% had a neurological primary diagnosis, including stroke, alongside significant motor deficits. Finally, Mercer et al [35] included a participant with stroke-related gait asymmetry (shuffling) that impacted activity sensor accuracy, and Farina et al [27] included a participant with stroke-related vascular dementia but no acute motor symptoms.

Synthesis of Findings

The thematic coding frame in Table 2 was applied to all included studies and reviewed for consistency of interpretation. This process, known as “axial coding,” ensured coded themes remained connected to and understood within the context of the source studies [13].

Table . Low-level theme and subtheme nodes.

Theme	Subtheme
Built environment and technology	Acceptance, accuracy, attitudes, community, customizable, damage, familiarity, functionality, home, influences, privacy, reliability, safety, usability, usefulness, wearability
Cognitive	Attention, awareness, comprehension, language, memory, planning
Natural environment	Safety, terrain, weather
Neurobehavioral	Balance, gait, motor, sensory, vision
Physiological	Endurance, fatigue, flexibility, injury, mobility, strength
Psychological	Accountability, adherence, attainment, autonomy, competence, feedback, goals, habits, mood, motivation, preconceptions, privacy, self-awareness, self-efficacy, trust, well-being
Social support	Caregiver, information, peer, professional, training
Societal and economic	Attitudes, commitments, cost, cultural, norms, strata
Spiritual	Fulfillment, meaningfulness, values

XSL•FO
RenderX

Coding densities informed the generation of the higher-level descriptive (aggregate) themes and subthemes listed in Table 3. Density cutoff points were used to classify major (n≥30), minor (n=10 - 29), and negligible (n<10) themes. Finally, descriptive themes were analyzed with respect to the research questions and objectives of the current study.

Table . Descriptive themes and subthemes.

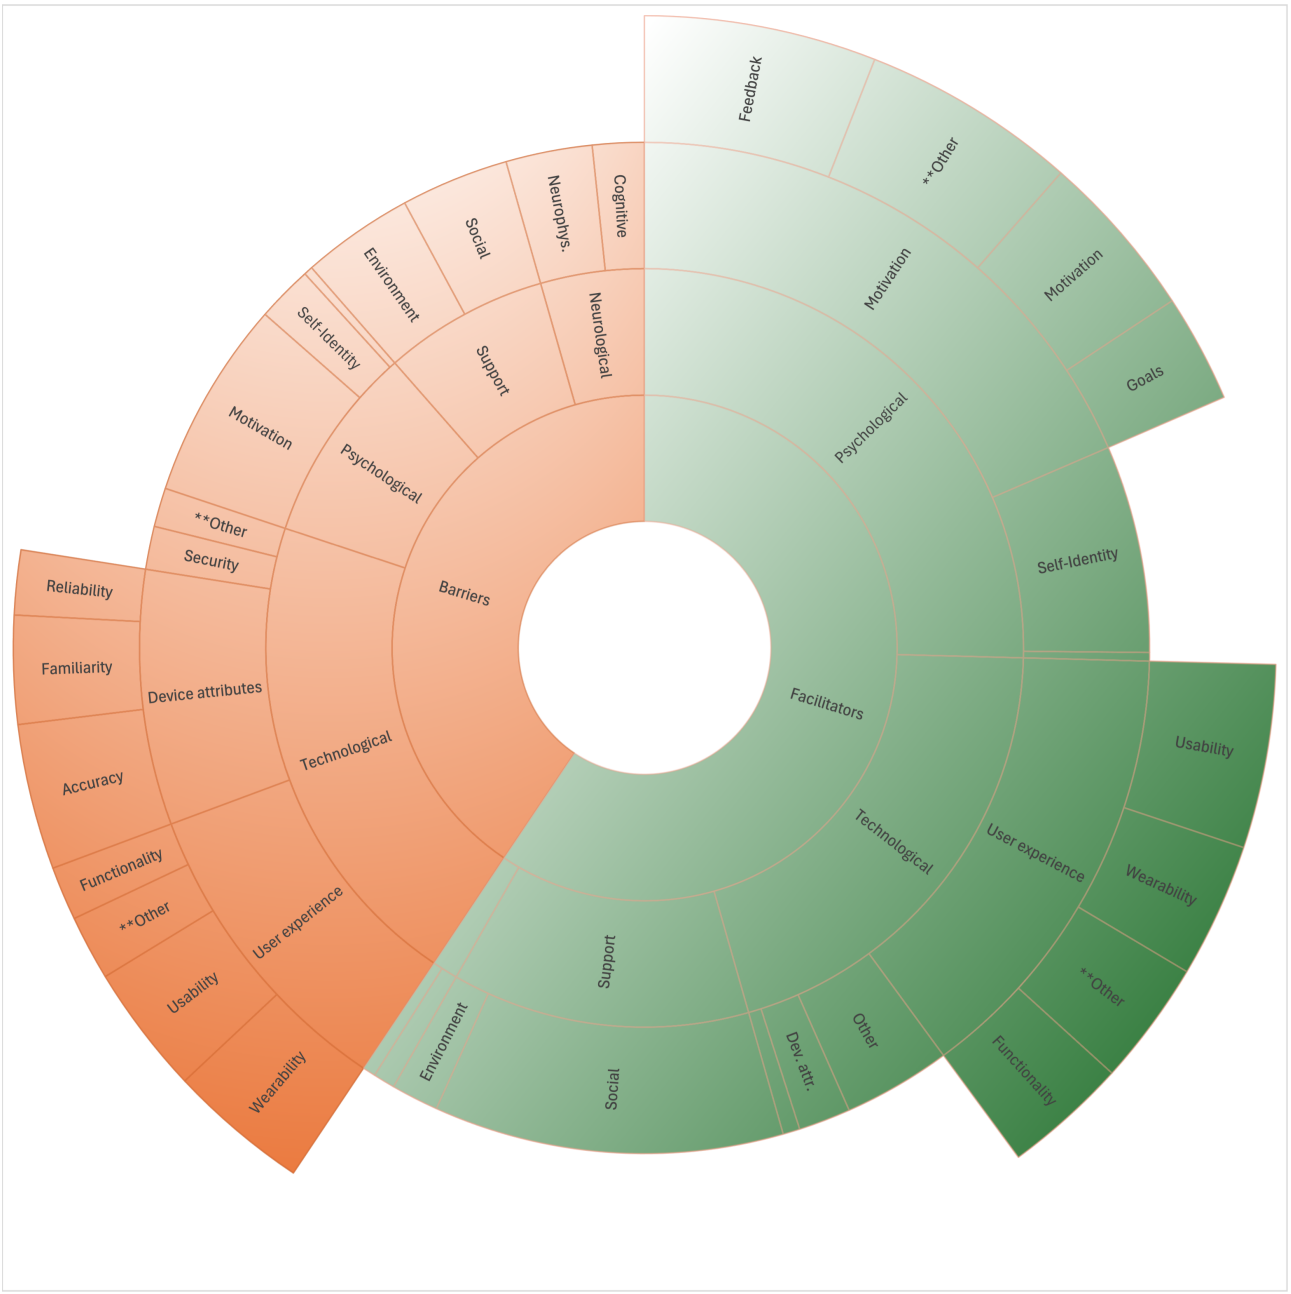
Theme	Subtheme
Technological	User experience, device attributes, security, other
Psychological	Self-identity, motivation, affective
Neurological	Neurophysiological, cognitive
Support	Social, environment

Densities were also used to visualize descriptive barrier and facilitator themes and subthemes. For readability, descriptive themes in this section have been indicated by quotation marks, and subthemes have been italicized.

Major Barriers

Major barrier themes were largely "technological," more specifically related to user *experience* (24.5% of barrier themes) and *device attributes* (20.1%), and "psychological," related to *motivation* (15.6%). *User experience* themes summarized in Multimedia Appendix 1 (Table S2) included older adults perceiving themselves as not "tech-savvy" but able to use basic functions such as step count. The perceived obtrusiveness of the PA sensor, both aesthetically and functionally, was a recurrent barrier theme. Devices were perceived to be designed for younger people and not older adults due to form factor, usability, and functionality. A lack of customization and the perceived irrelevance of some metrics hindered sustained engagement. Underlying *device attribute* themes referred to metric accuracy, the ability to register low-intensity activities such as standing, slow walking (strolling), or gardening, and to correctly record other activity types like yoga or strength training. The inability of PA sensors to correctly differentiate between similar activities such as sitting versus standing or to accurately track specific movements relevant to stroke recovery (eg, differentiated movements in hemiparesis) were seen as serious limitations. Users wanted more granular and relevant data (eg, time spent in moderate to vigorous PA) and exercise categorization (eg, fat-burning, cardio, peak); cadence and stride length for running and walking; stairs climbed as measures of vertical movement; swim metrics including laps, stroke type, and count; and strength training metrics such as repetition and set counts. *Motivation* themes referred to the "honeymoon period" or novelty effect of PA sensors quickly diminishing. Users lost interest once they felt they fully understood their activity patterns or had achieved their desired goals. Buzzing reminders were seen as annoying, especially when activity change was not possible, such as while driving. Goals that were not established in partnership with a therapist were often perceived as unrealistic, presenting a significant barrier to adherence. PA sensor unreliability or an inability to accurately measure certain activities (eg, nonlinear occupations and nonrepetitive movements) was demotivating. Users expressed a desire for real-time feedback that helped them to understand the impact of their PA level, for example, on blood sugar, rather than just step counts.

Major Facilitators



Major facilitator themes were "psychological" related to *motivation* (31.2% of facilitator themes), "technological" related to *user experience* (24.4%), and "support" related to both *social* and *environmental* support (21.4%). Underlying *motivation* themes summarized in Multimedia Appendix 1 (Table S3) included PA sensors that significantly increased self-awareness of PA levels. Achieving goals leads to feelings of inspiration, satisfaction, accountability, and a desire for additional effort. Long-term use was perceived to be strongly linked to intrinsic motivation, driven by personal enjoyment, feelings of accomplishment, and perceived benefits. Features like virtual incentives, nudges, reminders, and other forms of positive encouragement could act as effective extrinsic motivators, especially initially. PA sensors that effectively incorporated behavior change techniques such as self-monitoring, goal setting, and feedback promoted self-efficacy and PA. Individualized and tailored goals, and personalized feedback, for example, based on health status and functional capacity, were seen as critical for sustained motivation. Findings suggested that engagement with PA sensors was often nonlinear, with some users temporarily disengaging and later resuming use rather than abandoning the device entirely. Recognizing these flexible usage patterns is essential for developing interventions that foster long-term adherence. Underlying *user experience* themes included preferences for devices with simple, intuitive interfaces that required minimal user input. Users preferred PA sensors that were comfortable and unobtrusive, which did not interfere with daily activities and routines. Users expressed interest in tracking a more diverse range of activities such as swimming and cycling. The ability to customize goals, feedback type (vibration or visual), frequency of prompts, and data display was critical for effective motivation and sustained use. *Social* support themes related to therapists introducing and setting up the PA sensor, providing clear usage instructions, and interpreting data. This included personalized advice, goal setting, and addressing emotional responses to feedback. Social interaction and group engagement, both face-to-face and online via social networks, were regarded as powerful motivators. Embedding PA sensors into the clinical care process, with therapists actively discussing data and translating it into actionable insights, enhanced the perceived value and utility of the PA sensor. *Self-identity* themes referred to PA sensors significantly enhancing self-awareness of activity levels. Users were often surprised by their baseline level. Objective data helped users clarify real versus perceived activity. Tracking

XSL•FO
RenderX

progress and achieving goals, especially with immediate feedback, directly contributed to increased self-efficacy and confidence in the user's ability to be active and manage their health. For some, using the tracker shifted their self-perception, moving them from a state of pre-contemplation (unmotivated) to maintenance of a healthier lifestyle.

Visualized together in Figure 2, major barriers clustered mainly around *user experience* and *device attribute* aggregates, while facilitators were clustered around *user experience* and *motivation*. Drilling down to the underlying (low-level) themes, it was apparent that major *user experience* barriers were related to *wearability*, *usability*, and *familiarity* in descending order, and major *device attribute* barriers were *accuracy*, *reliability*, and *familiarity* in descending order. For facilitators, which comprised 60% of themes, most were clustered around *motivation*, *user experience*, and *support*. Underlying *motivation*, *feedback* (*motivation* more specifically), and *goals* in descending order were coded most frequently. Major *user experience* descriptive facilitators were *usability*, *wearability*, and *functionality*. Social and environmental *support* facilitators included most notably *professional*, that is, therapist and *caregiver* assistance.

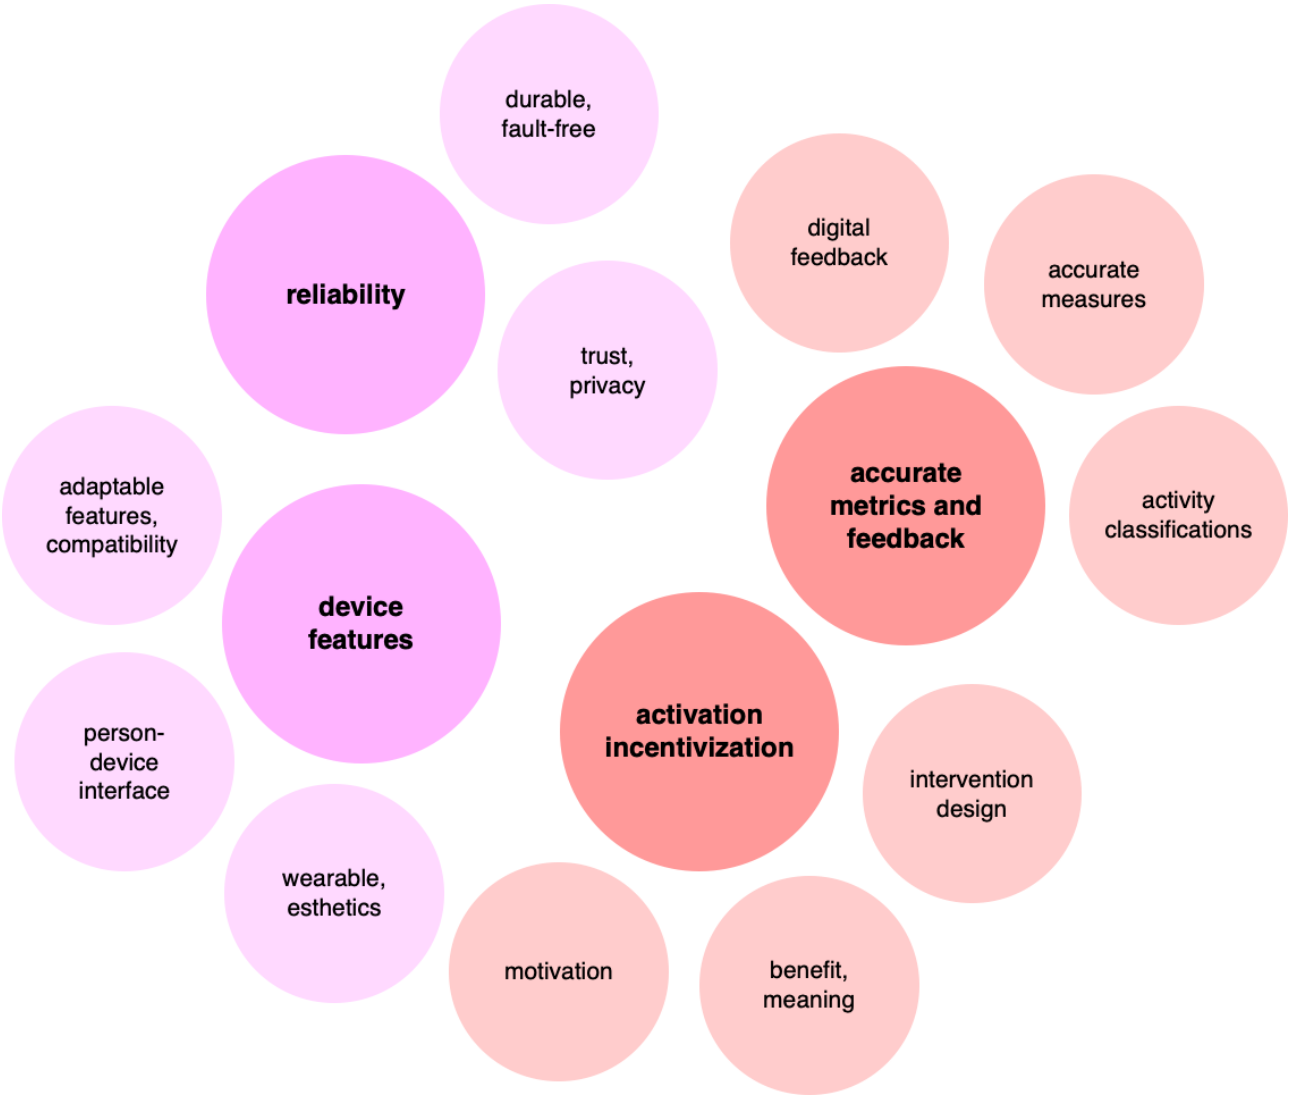


Figure 2. Major barrier/facilitator descriptive and substrate themes. Dev. attr.: device attributes; Neurophys.: neurophysiological

The initial analysis revealed major barriers clustered around device themes: subjective *accuracy*, *wearability*, and *usability* (Figure 3). In this context, *accuracy* referred to the perceived precision of the PA sensor; *wearability* to characteristics that influenced the user's ability and willingness to wear the PA sensor consistently for extended periods (eg, size, fit, esthetics); and *usability* referred to the ease with which users interacted with the PA sensor and companion app.

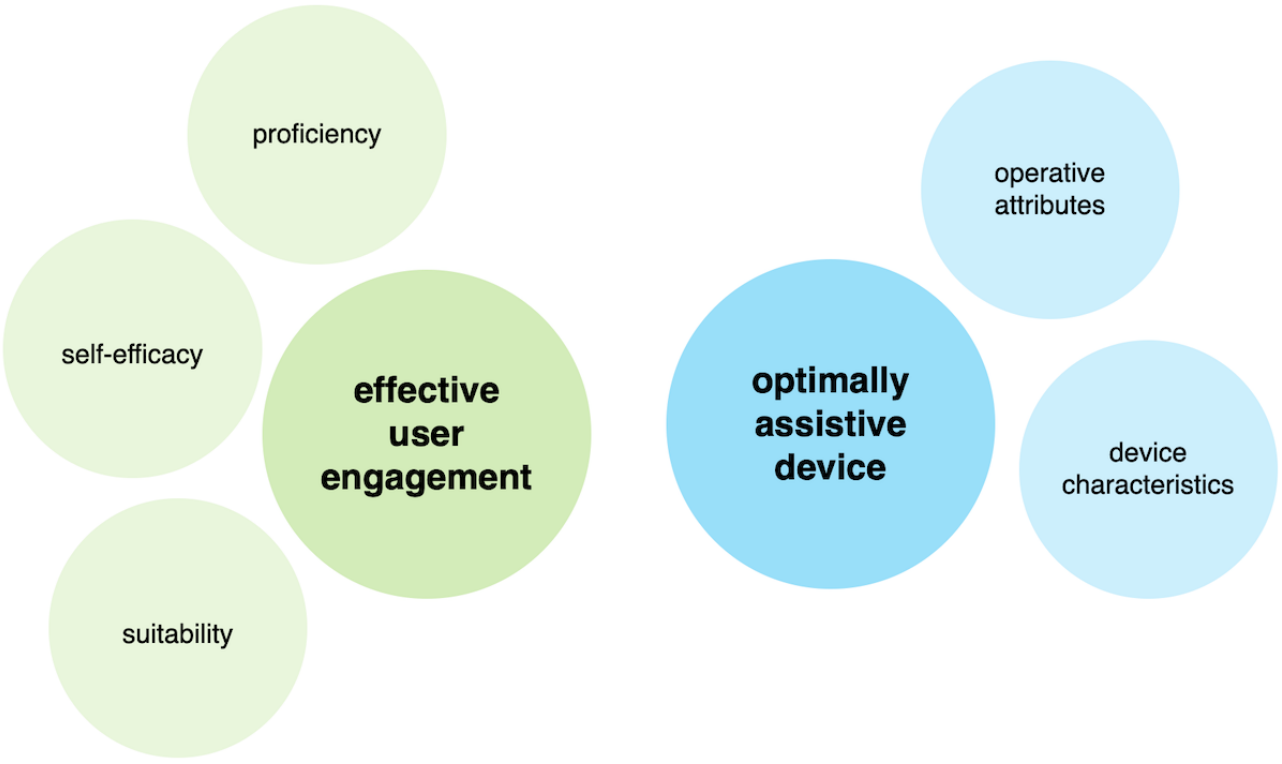
XSL•FO
RenderX

Figure 3. Major barrier clustering by descriptive theme.

Predominant facilitators were "psychological," that is, *feedback*, *motivation*, *self-awareness*; device-specific; or related to professional support from the physician or therapist (Figure 4).

XSL•FO
RenderX

Figure 4. Major facilitator clustering by descriptive theme.



Building on the descriptive themes, higher-level analytical or theory-driven constructs were developed. Two distinct analytical constructs emerged, one person-centric, emphasizing factors related to user experience and engagement, and the other essentially device-centric, focused on aspects attributable to the PA sensor itself. Together, these suggested a synergistic interrelationship between effective user engagement and optimally assistive device factors, highlighting their combined contribution to long-term behavior change (Table 4 and Figure 5).

XSL•FO

Table . Analytical constructs, descriptive themes, and subthemes.

Analytical construct and descriptive themes	Subthemes
Effective user engagement	
Proficiency	• Requisite skill(s) and knowledge: *degree of complexity; training and information* • Independent operation: *acceptability; ease of use*
Self-efficacy	• Supportive environment: *cost, commitments, natural environment; professional support; family, peers, friends, carers*
Suitability	• Appropriate for population: *cognitive, sensorimotor ability/impairment; cultural congruence; older adults, chronic conditions* • Thoughts and preconceptions: *values, attitudes; expectations; self-awareness*
Optimally assistive device	
Operative attributes	• Activation, incentivization: *motivation; intervention design; perceived benefit and meaningfulness* • Accurate metrics, feedback: *accurate measures; activity type/classification; useful and appropriate feedback*
Device characteristics	• Reliability: *durable, fault-free; trust, privacy* • Device features: *aesthetics and wearability; person-device interface; adaptable features, compatibility*

Figure 5. High-level analytical constructs.

Effective user engagement, as a "person-centric" analytical construct, represented the extent to which users meaningfully and effectively interacted with PA sensors. Contributing to this overarching construct were 3 key descriptive themes: *Proficiency* referred to the level of skill and technical knowledge required by the user and their capacity to use the PA sensor independently. Inadequate training, lack of technical skills, inability to resolve usage issues independent of external support, and poor instructions were major technical barrier themes evident in 9 of the studies included in the current analysis [25,26,28,30,32,34-37]. When users felt confident in their ability to operate a PA sensor correctly, they were more likely to engage with it. *Self-efficacy* referred to the individual's belief in their capacity or readiness to initiate PA to achieve their goals. This encompassed the ability to integrate PA within personal and broader social/cultural contexts to establish or

XSL•FO
RenderX

participate in enabling social networks, exercise buddies, peers, and family, and to become better informed about their health, the benefits of regular activity, and maintaining long-term self-motivation. An interaction between motivation and adherence was also evident, suggesting an interplay between the analytical themes discussed in this section, that is, how PA sensors might facilitate a sense of self-efficacy or self-empowerment that in turn promoted increased activity. A lack of self-efficacy or belief in one's ability to effectively engage in PA and achieve goals was identified as a significant theme in 8 of the studies [22,25,28-30,33,34,39]. Human support from peers, family, coaches, and clinicians was seen as an essential adjunct that aided increased PA together with PA sensor usage; the absence of these supports was evident in 4 studies as major barriers [24,25,32,36]. *Suitability* referred to the appropriateness and acceptability of the PA sensor within the target population. This reflected how well the PA sensor aligned with the physical, cognitive, and cultural needs of the user.

Optimally assistive device, as a "device-centric" analytical construct, referred to the inherent characteristics of the PA sensor and its capacity to effectively promote increased PA. Contributing to this were 2 primary descriptive themes: *Operative attributes* that referred to the functional performance of the PA sensor, accurately capturing and conveying relevant activity data to the user. This included precision, for example, accurate step counts, correct activity classification, and the clarity, relevance, and appropriateness of feedback provided. *Device characteristics*, on the other hand, referred to the design elements of the PA sensor. This included user-friendliness and ease of use of the PA sensor, functional capacity, that is, support for required or expected functionality, timeliness and appropriateness of information provided, and integration with other devices such as the companion app. Perceived inaccuracies and PA sensor defects were major barriers evident in 8 of the studies [23,27,29,33,36,37,40,41]. Similarly, themes that referred to a perceived lack of PA sensor validation, or characteristics that did not appear to have been designed for the abilities of older persons outlined earlier (eg, form factor, usability, functionality), highlighted broader device characteristic issues. Wearability themes reflected how easily people were able to use the PA sensor in everyday life situations and adapt usage to daily routines.

Discussion

Principal Findings

This study was primarily undertaken to address noted inconsistencies in the long-term efficacy of device-based PA interventions, particularly in older adults at risk of primary or recurrent stroke. Through a review of the qualitative literature, nuanced human and device-related factors influencing sustained engagement in this specific population were explored through a qualitative lens. By synthesizing lived experiences, insights emerged that explained why these inconsistencies occurred, reflecting individual and contextual factors at play. This qualitative depth is crucial for bridging the implementation gap between technological potential and real-world impact. These findings extend the understanding of existing models by demonstrating how device characteristics must be inherently assistive and person-centric to promote sustained engagement, especially in more vulnerable populations.

The preliminary synthesis was underpinned by a binary schema, categorizing overarching descriptive themes under top-level barrier and facilitator nodes. This implicitly assumed influencing factors were mutually exclusive. However, emergent themes within the included studies suggested a more nuanced reality. A similar observation might be made regarding the conceptual dichotomy between human and device factors. Indeed, one systematic review highlighted an interrelationship between these factors, reporting improved adherence in studies with longer monitoring durations [26]. The authors of the review posited that this could be attributed to increased user confidence over time. Consistent with this finding, studies included in the current analysis similarly indicated an interplay between motivation, technical integrity (eg, absence of defects, data accuracy), and adherence factors, suggesting that these elements are not isolated but rather interact synergistically in complex ways to influence outcomes. Studies included in the current analysis consistently indicated an interplay between motivation and adherence to PA.

Numerous theoretical frameworks have attempted to elucidate behavior change mechanisms through constructs such as self-efficacy (perceived confidence), decisional balance (weighing pros and cons), and processes of change (covert and overt activities facilitating progression) [42]. In the context of PA, self-efficacy specifically refers to an individual's confidence in identifying and achieving planned PA goals. This confidence is reinforced through mastery experiences, vicarious learning (ie, observing others' success), persuasion, and performance feedback [40]. While some behavioral goals are characterized by defined end states, others, such as increased PA, necessitate ongoing motivation for sustained maintenance. It has been suggested that individuals are more inclined to adopt healthy behaviors when confronted with a substantial threat and when their actions are perceived as effectively reducing the likelihood or severity of that threat [43]. This applies to patients with stroke concerned about secondary events, as well as individuals at risk of a primary stroke. However, the absence of universally agreed-upon construct measures complicates efforts to isolate which specific intervention components successfully drive behavior change and which do not.

The effectiveness of health care interventions and PA sensors is often complicated by social dynamics, as individuals' interactions can lead to unforeseen outcomes that alter the intended effects of the intervention [44]. For researchers, deciphering the complex evolution and adaptation of behaviors stemming from these interactions is a formidable task. This complexity is arguably amplified in PA sensor–based interventions, given the intricate interplay of human and device factors. The current study revealed prominent device-specific themes, with technical barriers featuring more significantly than psychological barriers related to motivation, support, adherence, or physiological limitations such as sensorimotor impairment.

While PA sensor–based devices offer objective measures of PA, potentially reducing biases inherent in self-report

XSL•FO
RenderX

instruments, themes related to perceived accuracy and trustworthiness were nonetheless evident in this synthesis [28]. The unregulated nature of the consumer market and clinometric quality of consumer-grade PA sensors warrant consideration in this context. A systematic review assessing consumer-grade PA sensors in older adults (mean age 70.2, SD 4.8 y) reported high accuracy for average daily step counts compared to research-grade reference PA sensors [41]. However, the reliability of daily step counts varied considerably across PA sensors, with gait, device placement, and walking speed influencing reliability. Several of the consumer-grade PA sensors contributing to the current thematic synthesis were also evaluated in the aforementioned review. While these findings offer some reassurance regarding accuracy, they simultaneously raise questions about public perceptions of consumer PA sensor accuracy and critical intervention design factors such as training and support. The level of support required for effective PA sensor use also emerged as a recurring major theme in the current study. The degree of intuitiveness and interactivity of the PA sensors may be contributing factors.

The synergistic factors identified in the current study suggest that future interventions should prioritize co-design methodologies, actively involving older patients with stroke in the development and refinement of PA sensors and health care interventions based on these technologies. This would ensure that PA sensors are not only functionally more robust but also intuitively usable, comfortable, and psychologically reinforcing for this specific cohort. For clinicians, these findings underscore the importance of tailored support, including training and goal setting, while addressing individual user concerns regarding PA sensor accuracy and usability when employing these devices in rehabilitation or preventive health care interventions. Future research should focus on developing and rigorously testing co-designed PA sensor–based interventions, employing mixed methods approaches to quantitatively validate the impact of the qualitative insights identified here on sustained levels of PA. Specific areas for investigation might include the optimal frequency and type of professional support, the most effective feedback mechanisms, and ergonomic design features critical in the context of stroke prevention and rehabilitation.

While the hypothesized advantages of PA sensors have garnered considerable scholarly attention, a notable gap exists in the literature regarding their application and, more critically, the lived experience of their use by stroke survivors and older adults at risk of stroke. The current study partially addresses that gap by synthesizing existing qualitative research concerning the utilization of PA sensors within this specific demographic. Through a rigorous qualitative synthesis, both major thematic elements and less predominant, yet illuminating, experiential aspects associated with PA sensor use were identified. The insights gleaned from these findings hold significant implications for the development of more efficacious interventions aimed at mitigating sedentary behavior and fostering increased PA in older adults at risk of primary or recurrent stroke.

Limitations

Despite a comprehensive search, only 2 included studies specifically addressed older stroke survivors: a qualitative study of 15 survivors and a systematic review incorporating one qualitative stroke study and 5 qualitative proxy population studies [25,26]. While limited stroke-specific data might traditionally constrain the generalizability of these findings, the methodology employed prioritized *conceptual transferability* over statistical representativeness [13]. By extending inclusion to proxy populations with analogous risk and functional profiles, this synthesis identified higher-level analytical constructs that are specifically relevant to older adults at risk of primary or recurrent stroke. These overarching themes provide a robust explanatory framework for PA sensor–based interventions that is theoretically relevant to the stroke experience, even as empirical qualitative data for this population are emerging. However, it is acknowledged that the inherent subjectivity of qualitative interpretation means this synthesis may represent one of several possible frameworks. Furthermore, the lack of detailed technical specifications across the diverse range of included PA sensors precluded an analysis of device-specific effects, such as wearability or discrete usability features. Future research should aim to validate these conceptual constructs through larger, stroke-specific cohorts and more granular investigations into device-specific factors.

Conclusion

By pooling existing qualitative research, this study contributes a novel and deeper understanding of the benefits and limitations of wearable PA sensors through the subjective experiential lens of older adults at risk of primary or recurrent stroke. This systematic review and thematic synthesis identified a synergistic interplay between human and device-specific factors that influence engagement and sustained increased PA. However, the precise nature of this relationship and its impact on objective PA levels would require verification through higher levels of evidence. These findings provide a framework for more effective PA sensor–based interventions in stroke prevention and rehabilitation, offering valuable insights for technologists designing PA sensors and therapists developing PA sensor–based health interventions for older stroke cohorts.

Acknowledgments

This study was based on a clinical research thesis written by PH under the supervision of A/Prof Anita Horvath from the Department of Medical Education, University of Melbourne. The coding structure and review process were jointly developed by IM and PH based on the thematic synthesis methodology. Dr Phillis Lau from the Department of General Practice, University of Melbourne, reviewed the methodological rigor of both the thesis and published protocol. Review comments for a preliminary analysis were also provided by Prof Kathleen Gray from the Centre for Digital Transformation of Health, University of Melbourne. All authors have read and approved the final version of the manuscript.

Abstract

Background: Wearable devices enabling remote monitoring by surgeons of their patients have gained prominence around total joint arthroplasty (TJA), offering continuous patient data to identify those not meeting postoperative goals, thereby facilitating timely interventions. While multiple studies highlight the utility of these devices in tracking postoperative progress, a standardized approach to their application is lacking. This review aims to synthesize existing literature on the use of wearable device-tracked activity for monitoring TJA outcomes.

Objective: We examined the current literature to evaluate how wearable devices are used in monitoring and improving patient rehabilitation and outcomes following TJA.

Methods: A systematic review was conducted following Cochrane methodology. A literature search of all available literature was performed in April 2024 and identified 102 studies to undergo full-text review. Systematic reviews, duplicate papers, and theoretical papers were excluded. Ultimately, 35 studies met the selection criteria.

Results: The review revealed that 32 of 35 (91.4%) studies used wearable devices to monitor step counts. A total of 21 (60%) studies incorporated joint-specific patient-reported outcome measures, though the specific measures varied. Further, 9 studies used standardized performance-based outcome measures, which also differed across studies. Finally, 7 (20%) studies collected sleep data; however, the methods and outcomes for sleep measurement were inconsistent among these studies.

Conclusions: Remote monitoring via wearable devices offers a novel approach to tracking outcomes in TJA patients. Although the use of these devices in perioperative care is expanding, significant variability exists in the data reported across studies. Wearable monitoring is often integrated with patient-reported outcome measures and standardized functional assessments, yet the optimal data parameters that best correlate with established outcome metrics remain undefined. Additionally, data collected by wearables has not yet been shown to predict patient recovery or satisfaction. Further research is essential to refine these data parameters and the development of postoperative protocols that leverage wearable devices to enhance patient compliance and improve clinical outcomes.

KEYWORDS

remote monitoring; wearable device; total joint arthroplasty recovery assessment; patient-reported outcome measures; mobility; osteoarthritis

Introduction

Total hip arthroplasty (THA) and total knee arthroplasty (TKA) are currently among the most commonly performed surgeries in the United States, with significant growth expected by 2030. The number of TKAs performed annually is projected to reach 1 million, and the number of THAs is projected to reach 600,000 by 2030 [1]. Despite high patient satisfaction rates, 10% to 20% of TKA patients and 5% to 15% of THA patients are not satisfied after surgery, suggesting that current recovery assessments may not adequately address all aspects of patient care [2,3]. The variability of current methods of assessing total

XSL•FO
RenderX

joint arthroplasty (TJA) recovery exists due to divergent guidelines, institutional policies, difficulty in obtaining data, and physician preferences. Most commonly, assessment of patient recovery has used patient-reported outcome measures (PROMs).

The adoption of wearable technology is on the rise, with 30% - 50% of adults in the United States using devices that track various health metrics [4,5]. Wearables can continuously monitor critical health parameters such as heart rate, physical activity, and sleep during the postoperative recovery phase, providing valuable data for assessing recovery outcomes in TJA patients. Wearable devices provide the opportunity to obtain data detailing the recovery of patients after TJA, improve patient compliance with rehabilitation programs, and enhance patient engagement through real-time feedback [6].

Previous studies demonstrate that wearable devices can enhance physical activity levels and offer insightful data throughout the postoperative recovery period [7-9]. Hameed et al found that remote monitoring of TKA patients improved outcomes in the early postoperative period [10].

Presently, there is a notable absence of standardized methods for interpreting the extensive data generated by wearable devices in the context of TJA outcomes. This systematic review aims to clarify how wearable devices can effectively measure TJA outcomes, focusing on metrics such as sleep quality, physical activity, and step counts. Data from both TKA and THA patients will be included to potentially yield more holistic insights into the application of wearable technology in joint replacement scenarios. The goal of this systematic review is to significantly contribute to ongoing discussions aimed at enhancing patient outcomes and satisfaction following TJA surgery by leveraging the innovative capabilities of wearable technology.

Methods

Search Strategy

A thorough systematic review was conducted according to the Cochrane methodology for systematic reviews as described in the Cochrane Handbook for Systematic Reviews of Interventions [11] (Multimedia Appendix 1). Our trial was registered with PROSPERO (registration number CRD420261346230). A literature search was conducted in Scopus, Medline, CINAHL, PubMed, CENTRAL, and Google Scholar databases in April 2024 using relevant search terms associated with the research question, “Can wearable device data be used to effectively augment postoperative patient-reported outcomes after total joint replacement?” (Multimedia Appendix 2). Literature searches were not limited by date of publication.

Screening and Assessment of Eligibility

A total of 471 papers were identified from the databases or registers used, as well as 7 studies from the reference lists of other papers. Selection criteria included availability in English and full-text accessibility. Systematic reviews and theoretical papers were excluded. After the removal of 100 duplicates, the abstracts of 371 studies were screened for compliance with the criteria. Further, 269 studies were excluded during abstract screening due to a lack of adherence to selection criteria, resulting in 102 studies to undergo full-text review. Finally, 35 studies were identified from the full-text review that satisfied the selection criteria for inclusion in this systematic review.

Data Extraction and Analysis

Data extraction of the 35 studies was performed on Covidence. Data extraction was originally performed independently by 2 reviewers, then reviewed for consensus. Extracted data included information regarding study identification, aims, study design and population, inclusion and exclusion criteria, data collection characteristics, interventions, accelerometer details and data, PROMs and quality of life assessments used, and study end points.

Risk of Bias Assessment

Study quality and bias risk were assessed using Cochrane’s Risk of Bias tool for randomized trials (RoB-2) [12] and the Risk of Bias in Nonrandomized Studies of Interventions (ROBINS-I) tool [13]. RoB-2 includes 5 domains: the randomization process, deviations from the intended intervention, missing outcomes data, measurement of the outcome, and selection of the reported result. ROBINS-I evaluates 7 domains: confounding, participant selection, intervention classification, deviations from intended interventions, missing data, outcome measurement, and selection of reported results. RoB-2 categorized bias as low risk, some concerns, high risk, or no information, while ROBINS-I classified risk as low, moderate, serious, critical, or no information. A total of 2 authors independently assessed the study quality of each paper and resolved any concerns with thorough discussion. Traffic light plots of domains regarding risk of bias were generated using the risk-of-bias visualization tool [14] (Multimedia Appendix 3). Notably, 5 studies were funded by Zimmer Biomet [15-19], in 1 study [20], 360 Knee Systems supplied the wearable device, and in 1 study [21], the lead author was a creator of the MoveUp Application that was used to assess patient recovery.

Study Quality

The quality of the studies was assessed using RoB-2 for the 5 randomized controlled trials (RCTs) and ROBINS-I for the 30 nonrandomized studies. RCT data are presented in Table 1, and nonrandomized data in Table 2. For overall risk of bias, 5 studies were characterized as low risk, 16 studies were ranked moderate risk or some concerns, 11 studies were ranked serious risk, and 3 studies were characterized as not enough information.

Systematic Review Procedure and Narrative Synthesis Process

The literature identified for review demonstrated considerable variability in variables collected via wearable devices as well as outcomes reported. As such, a meta-analysis was not performed. Rather, a systematic review was performed according to the Synthesis Without Meta-Analysis in systematic reviews guideline [49]. Studies were grouped according to outcomes reported, as demonstrated in Table 3. The results, limitations, and data presentation from our synthesis are also presented in Table 3.

XSL•FO

Table . Papers included in the systematic review grouped by measurements of interest.

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
Physical activity and PROMs[c]								
Bendich et al, 2019 [36]	Determine if perioperative patient-generated health data, such as steps and activity levels, are associated with early post-op PROMs.	22	Both	Fitbit Flex Google LLC; wrist)	Steps; physical activity; HR[d]	KOOS[e] or HOOS[f]	• Pre-op:[g] N/A[h] • Post-op[i]: ≤6 weeks	Changes from pre-op to 6-weeks post-op levels steps are associated with improvements in PROMs. Only a weak association between absolute sensor values and PROM values after TJA[j].
Bini et al, 2019 [37]	Predict early post-op TJA outcomes using wearable sensor data and machine learning.	22	Both	Fitbit Flex (wrist)	Steps; physical activity; HR; personalized activity intelligence; cadence; bounce	KOOS or HOOS, VR-12[k]	• Pre-op: ≤4 weeks • Post-op: ≤8 weeks	Moderate correlation between post-op activity levels (steps, minutes active, and metabolic output) and VR-12 PCS[l] scores. No correlation between preoperative steps and PROMs.
Brandes et al, 2011 [30]	Measure change in physical activity and the relationship between objective function data and pain post-TKA.	53	Total knee	SAM[m] step activity monitor (Cyma Corporation; ankle)	Steps	KSS[n], SF-36[o]	• Pre-op: N/A • Post-op: ≤12 mo	Post-op physical activity is influenced by pre-op physical activity, though post-op physical activity at 12 mo is not correlated with KSS or SF-36 scores pre-op or post-op.
Caliskan et al, 2020 [29]	Identify accelerometer-recorded physical activity patterns in patients undergoing TKA in addition to ROM[p], strength, and PROMs.	36	Total knee	ActiCal (Respironics Inc; wrist)	Steps; physical activity; energy expenditure	ROM; muscle strength; KSS, OKS[q]	• Pre-op: ≤1 week • Post-op: ≤6 mo	KSS, OKS, light and moderate physical activity, steps, and daily energy expenditure significantly improved from baseline to 6 months post-op, while knee flexion and extension strength and sedentary behavior did not improve.

RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
Christensen et al, 2023 [16]	Describe the trajectory of post-TKA recovery based on PROMs and smartwatch physical activity.	1005	Total knee	Apple Watch (Apple Inc; wrist)	Steps; stairs; gait speed; gait asymmetry	KOOS JR[r], EQ-5D	• Pre-op: N/A • Post-op: ≤12 mo	Perceived knee health and QoL[s] scores increased from pre-op to 12 months post-op while following a maximal recovery trajectory in the first 3 months. Steps per day increased to pre-op levels by 1 month and followed a maximal recovery trajectory in the first 3 months, while stairs per day returned to baseline by 3 months and continued to improve beyond 6 months.
Crizer et al, 2017 [28]	Track daily step count during pre-op and post-op periods and compare with PROMs.	589	Both	Smartphone (N/A)	Steps	LEFS[t]	• Pre-op: ≤4 weeks • Post-op: ≤12 weeks	LEFS scores only weakly correlated with objective step count, with increasingly weaker correlation with time post-op. No clear correlation at 12 weeks post-op suggests PROMs may only provide part of the story. Physical activity recovery is most rapid in THA patients, with most surpassing baseline step counts by 5 weeks compared to 9 in TKA.
Duong et al, 2023 [24]		102	Total knee	Fitbit Inspire (Google LLC; wrist)	Steps; physical activity; sleep		• Pre-op: N/A • Post-op: ≤12 mo	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
	Compare a digital technology package with usual care in reducing pain among participants post-TKA.					NRS[u], PDI[v], Sedentary Behavior Questionnaire, AQoL-8D, Patient Activation Measure, Modified Computer Self-Efficacy Scale, Change in pain intensity (Global Rating of Change)		Patient-reported physical activity (AAS[w]) significantly increases across all participants from baseline (10 days post-op) to 3, 6, and 12 months. Fitbit physical activity measures (ie, steps and sedentary time) do not see the same significant increases. Sleep duration and time in bed remain unchanged from 3 to 6 months, though they significantly decrease from 6 months post-op to 12 months. Digital technology group demonstrates reduced pain intensity and PDI scores and increased physical activity (step count and stepping time).
Fallahzadeh et al, 2023 [43]	Use wearable device data and immune profiling to quantify physical recovery in individuals following THA.	49	Total hip	ActiGraph (Amertis LLC; wrist)	Steps; physical activity; sleep	WOMAC[x], SRS[y]	• Pre-op: ≤5 days • Post-op: ≤40 days	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Activity capacity, sleep disruption, and sedentary activity are most predictive of time after surgery, while light, moderate, and overall activity are less predictive in the model. Objective physical recovery trajectory is significantly associated with SRS, but not WOMAC, suggesting that smartwatch data may be more associated with self-reported fatigue and ability to perform daily activities than pain and overall physical function. Preop activity levels are not associated with post-op recovery speed.
Frimpong et al, 2020 [31]	Assess whether changes in objectively measured physical activity were associated with PROMs before and after TKA.	89	Total knee	activPAL (PAL Technologies Ltd; thigh)	Steps; sleep; sedentary time; standing time; walking time	KOOS, OKS	• Pre-op: ≤2 weeks • Post-op: ≤6 mo	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Despite significant improvements in self-reported perceived knee pain and functional ability (KOOS and OKS) 6 months post-TKA, changes do not correlate with improvements in objectively measured (activPAL) light-intensity and sedentary activity behaviors. Average activity behaviors worsened 6 weeks post-op compared to pre-op, though by 6 months post-TKA, activity behaviors had improved to at or beyond pre-op levels.
Gibian et al, 2023 [19]	Measure patient sleep using a wearable device following TKA and compare with PROMs.	110	Total knee	Fitbit Inspire (wrist)	Sleep	PSQI[z], VAS[aa]	• Pre-op: N/A • Post-op: ≤90 days	Patient-reported sleep quality (very bad sleep) correlated well with 30-day VAS pain score, while sleep duration (monitored or patient-reported) did not correlate with any clinical measure and was not shown to be a useful metric in assessing TKA outcome.
Harada et al, 2024 [45]	Compare objective and subjective measurements of activity levels in patients undergoing THA pre-op and post-op.	42	Total hip	ActivPal3 (PAL Technologies Ltd; thigh)	Steps; upright time; sit-to-stand transitions	OHS[ab], UCLA[ac], FJS-12[ad]	• Pre-op: N/A • Post-op: ≤1 year	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Steps, OHS, and UCLA significantly improve from pre-op to 3 months and 1 year post-op, and age and hip abductor muscle volume are significant predictors of post-op step counts, while pre-op UCLA score does not predict postoperative objective activity data.
Harding et al, 2014 [35]	Measure physical activity pre-op and (6 months) postarthroplasty and examine the proportion of people meeting the American Physical Activity Guidelines.	44	Both	ActiGraph GT1M (Ametris LLC≈; wrist)	Physical activity	NPRS[ae], OHS/OKS, SF-12[af], UCLA	• Pre-op: N/A • Post-op: ≤6 mo	No change in objectively measured physical activity after arthroplasty, despite significant improvements in PROMs post-THA/TKA. There were significant improvements in self-reported pain during activity, physical function, QoL, and in physical activity measured by the UCLA activity score after arthroplasty.
Höll et al, 2018 [32]	Measure activity levels before and after THA.	46	Total hip	StepWatch 3 (Modus Health LLC; ankle)	Steps; physical activity	HHS[ag], WOMAC	• Pre-op: ≤1 week • Post-op: ≤3 mo	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Gait cycles (1 gait cycle =approximately 2 steps) and time in moderate to vigorous physical activity did not increase from pre-op to 6 weeks, but did increase at 3 mo follow-up, while PROMs increased at both follow-up time points. Gait cycles per day did not correlate with PROMs at any time point.
Karas et al, 2020 [44]	Use patient-generated health data from a wearable device to predict recovery trajectories from lower limb surgeries.	196		Fitbit (Google LLC; wrist)	Steps; HR; sleep	Self-reported recovery time	• Pre-op: ≤26 weeks • Post-op: ≤26 weeks	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Daily steps return to baseline in ≈12 weeks post-op, while 95th percentile HR returns to baseline in roughly 4 weeks. Sleep efficiency does not follow a specific trajectory pre-op or post-op, though there are significant reductions in sleep efficiency from baseline up to 24 weeks post-op. Long-term recovery can be accurately predicted on an individual level 1 month after surgery. Further, 12 weeks pre-op and 26 weeks post-op trajectories of daily behavioral measurements (steps sum, HR, and sleep efficiency score) can capture activity changes relative to an individual's baseline.
Komann et al, 2024 [33]	Assess the relationship between postoperative physical activity and PROMs.	55 (TKA)	Total knee	ActiGraph wGT3X (Amertis LLC; wrist)	Steps	BPI[ah], IPO[ai] Questionnaire	• Pre-op: N/A • Post-op: ≤7 days	There is no statistically significant correlation between steps and average pain intensity post-op.
Lebleu et al, 2021 [40]		146	Both	Nokia Go (Nokia Corporation; wrist)	Steps	KOOS or HOOS	• Pre-op: ≤1 week • Post-op: ≤3 mo	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
	Assess physical activity recovery post-op and determine perioperative features that could help predict physical activity recovery at 3 mo with telerehabilitation intervention.							Patients receiving telerehabilitation reached pre-op step count at 7 weeks post-op. Change in step counts post-op at 3, 6, and 11 weeks could be predicted by pre-op step count and post-op length of time on crutches. Further, 3-month step increases are additionally associated with pre-op symptoms level, while early (3 - 6 weeks) step count improvements are associated with pre-op QoL.
Lyman et al, 2020 [47]	Investigate the feasibility of mobile technology to collect daily step data and biweekly PROMs to track TJA recovery: (1) what proportion of patients provided full 6-month follow-up step and PROMs information, (2) whether THA and TKA patients recovered differently, (3) if new patterns of recovery could be discovered, and (4) how well step counts and PROMs scores were correlated.	267	Both	Smartphone accelerometer (N/A)	Steps	NRS, HOOS JR or KOOS JR	• Pre-op:≥2 days • Post-op: ≤6 mo	Recovery was faster by all metrics in THA than in TKA patients, correlations between step counts and PROMs were modest, and 2 distinct clusters of recovery could be described using step counts.
Pasqualini et al, 2024 [18]		2333	Total knee	Apple Watch (Apple Inc; wrist)	Steps; stairs	KOOS JR, NRS	• Pre-op:≥14 days • Post-op: ≤3 mo	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
	Investigate the correlation between pain and KOOS JR with step and stair flight counts in patients undergoing TKA.							Step count is correlated with NRS and KOOS JR, both pre-op and at 1 and 3 mo post-op in TKA patients, while stair flight count is significantly correlated with PROMs pre-op and at 1 month, though no longer associated at 3 months.
Redfern et al, 2023 [15]	Investigate objective measures and PROMs as a function of preoperative PA[aj] levels in TKA patients.	1941	Total knee	Apple Watch (Apple Inc; wrist)	Steps; physical activity	EQ-5D-5L, EQ-VAS, KOOS JR, KSS, NRS	• Pre-op: ≤2 weeks • Post-op: ≤12 mo	Patients in the 2 middle quartiles of wearable device-measured pre-op step counts recovered activity with a modest increase in step counts 1 year after surgery, while those in the highest quartile of activity did not return to preoperative levels at any interval through 1 year. The lowest-activity participants reported greater improvements in joint function, pain, and health-related QoL. Despite this, satisfaction scores did not vary between groups.
Sato et al, 2023 [17]	Identify the trajectory of physical activity and PROMs after THA.	1898	Total hip	Apple Watch (Apple Inc; wrist)	Steps; stairs; walking asymmetry; gait speed	HOOS JR, EQ-5D	• Pre-op: N/A • Post-op: ≤1 year	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								At all post-op time points, THA patients see statistically significant increases in steps, stair flights, walking asymmetry, and gait speed, though only steps and stair flights were clinically significant at 3, 6, and 12 months. Meanwhile, PROM improvements are clinically significant at all time points. Greatest PROM improvements were reached by 1 mo and physical activity by 3 months.
Shah et al, 2019 [38]	Determine the frequency and timeline of wearable device activity data that correlate with early PROMs following TJA.	22	Both	Lumo Lift (Lumo Inc, ND[ak])	Steps; bounce; braking; drop or roll; pelvic rotation or yaw; or pelvic tilt or pitch	VR-12 PCS, HOOS or KOOS	• Pre-op: N/A • Post-op: 42 days	Raw wearable device data predicts 6-week post-op outcomes significantly better than 24-hour summarized data does, and clinical outcomes may be predictable by wearable device data as early as 1 - 2 weeks post-op. Increasing sampling frequency above the standard 24-hour average provided by consumer-grade activity sensors improves the ability of machine learning algorithms to predict 6-week PROMs.
Surmacz et al, 2024 [46]		327	Both			HOOS or KOOS JR

RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
	Determine the association between pain and PROMs or objective mobility data.			Apple Watch (Apple Inc; wrist)	Steps; gait speed; gait asymmetry		• Pre-op: ≤30 days • Post-op: ≤90 days	Pain scores are associated with gait speed at all 3 time points, whereas step count was not significantly associated with pain at any time point.
Tang et al, 2021 [27]	Compare accelerometer-measured physical activity and sleep to PROMs following THA.	41	Total hip	Fitbit Flex (wrist)	Steps; sleep	HOOS JR	• Pre-op: N/A • Post-op: ≤3 mo	No correlation between accelerometry-measured activity level nor sleep and functional PROM scores in the early follow-up period (within 3 months) following THA. Average daily steps and minutes slept pre-op were similar to average daily steps and minutes slept 3 months post-op. Weak negative correlation between average steps pre-op and pre-op HOOS JR. Significant improvement in patients' average daily sleep occurs between 1 - 2 weeks and 1 month post-op.
Twiggs et al, 2018 [20]	Assess pre-op and early post-op physical activity in TKA patients and determine benchmarks for expected activity.	91	Total knee	Fitbit Flex (wrist)	Steps	SF-12, KOOS	• Pre-op: ≤2 weeks • Post-op: ≤6 weeks	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								SF-12 PCS and KOOS ADL were significantly correlated with step counts at all 3 time points. KOOS QoL was significantly associated with post-op 6-week step count, while KOOS pain was significantly associated with post-op day 2 - 4 step count and pre-op step count. Pre-op step count is both strongly significantly correlated to and not statistically different from 6-weeks post-op step count. BMI and SF-12 PCS scores may also be predictive of post-op recovery.
Van der Walt et al, 2018 [23]	Determine if feedback from a wearable device improves activity levels over 6 weeks post-op following TJA.	163	Both	Garmin Vivofit 2 (Garmin Ltd; wrist)	Steps	KOOS, EQ-5D	• Pre-op: ≤2 weeks • Post-op: ≤6 mo

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Feedback from wearable activity trackers increases daily activity in the acute post-op phase and at 6 months. The greatest increase in average daily steps post-op for both groups occurs during the 1 - to 2-week period. Most patients surpass their pre-op step counts after 6 weeks post-op. Patients who received feedback from a commercial wearable device activity tracker with a daily step goal had significantly higher activity levels after hip or knee arthroplasty over 6 weeks and 6 months than those who did not receive feedback.
Vitale et al, 2021 [50]	Assess the objective physical activity and rest-activity daily rhythm in TJA patients.	20	Both	Actiwatch 2 (Amertis LLC; wrist)	Physical activity; RAR[al]	FIM, Barthel Index	• Pre-op: 1 day • Post-op: 10 days	Patients restored and maintained a significant and physiological RAR beginning 2 days post-op. Improvements can be seen in physical activity, BI[am], FIM[an], TUG[ao], pain, and 10MWT[ap] as early as 10 days post-op.

Physical activity and performance-based measures

								Cadence measurements (ie, P6MC[as] and P1M[at]) may offer more stable indicators of gross motor function compared to the number of steps per day. Patients typically resumed their pre-op activity levels 6 - 10 weeks after undergoing surgery. Age significantly affects steps per day and cadence in TKA/THA. Patients who met MCID[au] for FJS at 3 months surpassed baseline physical activity metrics, particularly light intensity activity, between 25 and 50 days post-op. Patients who did not meet the MCID for FJS were less likely to surpass baseline PA.
Mehta et al, 2020 [25]	Evaluate the effect of activity monitoring and bidirectional text messaging on the rate of discharge to home and clinical outcomes in TJA patients.	242	Both	Withings (Apple Inc, ND)	Steps	TUG, rehospitalizations, ED[av] visits, PT visits, pain scale	• Pre-op: N/A • Post-op: ≤6 weeks

RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Activity capacity, sleep disruption, and sedentary activity are most predictive of time after surgery, while light, moderate, and overall activity are less predictive in the model. Objective physical recovery trajectory is significantly associated with SRS, but not WOMAC, suggesting that smartwatch-derived data may be more associated with self-reported fatigue and ability to perform daily activities than pain and overall physical function. Pre-op activity levels are not associated with postoperative recovery speed.
Frimpong et al, 2020 [31]	Assess whether changes in objectively measured physical activity were associated with PROMs before and after TKA.	89	Total knee	activPAL (thigh)	Steps; sleep; sedentary time; standing time; walking time	KOOS, OKS	• Pre-op: ≤2 weeks • Post-op: ≤6 mo	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
								Despite significant improvements in self-reported perceived knee pain and functional ability 6 months post-TKA, these changes do not correlate with improvements in objectively measured (using activPAL) light-intensity and sedentary activity behaviors. On average, activity behaviors worsened 6 weeks after surgery compared to preoperative levels, though by 6 months post-TKA, activity behaviors either were similar to pre-op levels or had improved beyond pre-op levels, such as in the case of step measures.
Gibian et al, 2023 [19]	Measure patient sleep using a wearable device following TKA and compare with PROMs.	110	Total knee	Fitbit Inspire (wrist)	Sleep	PSQI, VAS	• Pre-op: N/A • Post-op: ≤90 days	Patient-reported sleep quality (very bad sleep) correlated well with VAS pain score at 30 days, while sleep duration (monitored or patient-reported) did not correlate with any clinical measure and was not shown to be a useful metric in assessing TKA outcome.
Karas et al, 2020 [44]		196		Fitbit (wrist)	Steps; HR; sleep	Self-reported recovery time	• Pre-op: ≤26 weeks • Post-op: ≤26 weeks	

XSL•FO
RenderX

Study ID	Aim of the study	Participants (n)	TKA?[a] THA?[b] both?	Device (placement)	Accelerometer data collected or assessed	Recovery assessments	Timeline	Summary of findings
	Use patient-generated health data from a wearable device to predict recovery trajectories from lower limb surgeries.							Daily steps return to baseline in ≈12 weeks post-op, while 95th percentile HR returns to baseline in roughly 4 weeks. Sleep efficiency does not follow a specific trajectory pre-op or post-op, though there are significant reductions in sleep efficiency from baseline up to 24 weeks post-op. Long-term recovery can be accurately predicted on an individual level 1 month after surgery. Further, 12 weeks pre-op and 26 weeks post-op trajectories of daily behavioral measurements (steps sum, HR, and sleep efficiency score) can capture activity changes relative to an individual's baseline.
Tang et al, 2021 [27]	Compare accelerometer-measured physical activity and sleep to PROMs following THA.	41	Total hip	Fitbit Flex (wrist)	Steps; sleep	HOOS JR	• Pre-op: N/A • Post-op: ≤3 mo	

XSL•FO

Results

Overview

This systematic review analyzed 35 studies that used wearable devices to assist with patient monitoring in the TJA perioperative period. These papers detail how monitoring with wearables is used in conjunction with PROMs and functional metrics in the recovery of patients undergoing TJA. The final analysis included 35 papers, including 5 RCTs and 30 nonrandomized papers (Figure 1).

XSL•FO
RenderX

Figure 1. PRISMA flow diagram. PRISMA: Preferred Reporting Items for Systematic Reviews and Meta-Analyses.

Physical Activity and Performance-Based Functional Outcomes

Of the 35 papers included in this study, 32 collected step count, making it the most common data point reported (Table 3). Another component of assessing functional outcomes in TJA is performance-based tests, such as the 6-minute walking test (6MWT), range-of-motion, or timed-up-and-go (TUG; Table 3). A total of 9 studies used both wearable device data and standardized performance-based functional outcomes in their assessments (Table 3).

Physical Activity and PROMs

Physical activity and PROMs used were not consistent among studies (Table 3). Joint-specific PROMs, including Knee Society Score, Knee Injury and Osteoarthritis Outcome Score (KOOS), Oxford Knee Score, Hip Disability and Osteoarthritis Outcome Score (HOOS), and Harris Hip Score, were used in 21 studies. Virtual Analog Scale (VAS) was used in 4 studies [15,19,34,41] and Numerical Rating Scale for pain was used in 4 studies [15,18,24,47]. EQ-5D scores were examined in 4 studies [15,16,21,23], and 3 used Western Ontario and McMaster Universities Arthritis Index (WOMAC) [32,39,43]. The Lower Extremity Functional Scale (LEFS) was used in 2 studies [48,51]. The Veterans Rand 12-Item Health Survey was used in 2 studies [37,38], and 1 used SF-36 (36-Item Short Form Health Survey) [30].

Sleep

Sleep as recorded by wearable devices was reported in 7 of the included studies (Table 3). Gibian et al [19] recorded sleep duration and reported a negative correlation with VAS pain scores [35]. A total of 2 additional studies [17,20,24] also report sleep duration as recorded by wearable devices. Frimpong et al [31] use a validated algorithm to report sleep data as recorded by wearables. Karas et al [44] report “sleep efficacy,” which is

XSL•FO
RenderX

the proportion of minutes asleep to the total time in bed. Finally, Fallahzadeh et al [43] and Vitale et al [41] focused on multiple components of sleep, with the former including overall sleep and sleep quality and the latter recording 9 components of sleep.

Rehabilitation Workflow

Interestingly, only 1 study used a novel application to assess patients [28]. This study demonstrated that step counts as recorded in the MoveUp application correlated with LEFS following TJA. However, the authors did not mention how this application can be used to create tailored rehabilitation protocols.

Discussion

Principal Findings

This systematic review found that most of the literature regarding the utility of wearable devices to monitor TJA outcomes includes step count. In addition to recording step count, these devices can record data regarding gait speed and asymmetry as well. Assessment of such metrics allows providers to evaluate gait comprehensively. Nevertheless, few studies used this capability of wearables [16,17,22,46]. Further, there is a large variability in how wearable device data is used in conjunction with other outcome measures in the current literature. Further, while ample studies include PROMs in addition to wearable data, many different PROMs are used. As demonstrated in Table 3, wearable devices have the capability of measuring multiple objective metrics. While this capability has the potential to allow holistic assessment of patient recovery, there is currently no consensus on which metrics are most valuable to record and assess in the perioperative setting. Further, the studies reviewed are not uniform in when patients are assessed, with certain groups analyzing patients days to weeks after surgery, while others continue for 6 to 12 months. The heterogeneity among these studies demonstrates that the ideal manner in which surgeons can use wearable devices for remote monitoring requires further research. We suggest that stratification regarding the reporting of perioperative data obtained by wearables, and that coupling this data with a unified PROM, will maximize the utility of wearable devices as a tool for assessing patient recovery.

The relationship between wearable-derived physical activity and PROMs, such as pain, quality of life, and self-reported function scores, was explored by 21 studies. The most common PROMs reported were joint-specific. Multiple studies found a correlation between change in step count and KOOS, KOOS JR (KOOS-joint replacement), HOOS, or HOOS JR [15,18,20,36,38,42,47,48]. Both the KOOS and HOOS were developed particularly for patients with osteoarthritis and have long been used to track progress following TJA. Such studies support the use of wearable devices as another component of comprehensive monitoring of TJA recovery, particularly since such devices allow continuous monitoring. However, the current literature does not yet suggest a data point obtained via remote wearables that necessitates intervention or that intervention improves KOOS or HOOS.

Contrastingly, some groups found that steps did not correlate with other joint-specific PROMs. Frimpong et al 2020 [31] report that there is no correlation between KOOS and an increase in physical activity. Additionally, Tang et al [27] reported that there is no correlation between accelerometry-measured activity level and HOOS JR within 3 months of TJA. Multiple studies found no correlation between step count and WOMAC [31,43] or UCLA (University of California, Los Angeles Activity Scale) activity index [35,45]. It is unclear why many studies found that step count correlated with KOOS and HOOS, but not WOMAC or UCLA activity index. One suggestion is that HOOS and KOOS have been shown to better detect changes over time, while WOMAC and UCLA are more adapted for more active populations [52,53]. Regarding the UCLA activity index, it is possible to have large increases in step number but not have an increase in activity level on this scale.

In addition to joint-specific PROMs, other measures were used. Notably, 3 studies [28,43,48] found relationships between perioperative physical activity and patients' ability to perform everyday tasks as measured by the LEFS and Surgical Recovery Scale. Others [20,36-38] found a positive correlation between wearable device reported step count and general health and physical functioning, as measured by the Veterans Rand 12-Item Health Survey PCS (Physical Composite Score) or SF-12 (12-Item Short Form Health Survey) PCS scores.

Further, some of the reviewed studies include functional outcome measures. Performance-based tests, such as the 6MWT and TUG, allow standardized assessment of patients. These tests are normally used immediately following surgery, before patient discharge, and then repeated at certain intervals in the clinic. As such, these tests allow serial, objective evaluation of patient recovery. Paxton found that both 6MWT and step count increased 20% from baseline at 12 weeks post-TKA, while TUG improvements are present but less robust [22]. Similarly, Pechstein et al [26] found a dose-response relationship between 6MWT and device-measured physical activity. Improvements in physical activity and TUG can be seen as early as 10 days postoperatively [41], and van Diemen et al [42] found a significant correlation between activity and TUG. Step count and 6MWT both measure endurance in walking, while TUG focuses on mobility. This correlation suggests that data collected by wearable devices might serve as a surrogate for these objective assessments. In contrast to TUG and 6MWT, wearable devices allow assessments to be performed continuously and remotely. As such, patients can be assessed in between clinic visits. When patients deviate from expected progress or demonstrate setbacks, tailored protocols can be developed.

While this review found that most wearable device literature includes step count, many wearable devices have the capacity to monitor additional variables, such as balance, as well. Further investigation could examine how such parameters correlate with TUG and other performance measures.

Further, because wearable devices are used during the preoperative period, they allow providers to obtain a patient baseline before TJA. The collection of this data allows recovery trajectories to be crafted. Patients demonstrate decreases in activity, balance, and gait speed acutely postoperatively, but then return to or surpass their baseline postoperatively. In the acute postoperative setting, knowledge of patient deviation from

XSL•FO
RenderX

baseline can inform discharge protocols to allow patients to return to benchmarks. As patients progress in their recovery, comparison of metrics to preoperative and immediate postoperative data informs the multidisciplinary team about patient recovery. If a patient is not meeting a step count goal, therapy can be tailored toward endurance. Contrastingly, if a patient is struggling with balance, therapy can be adjusted to focus on improving this deficit. As the number of patients who have data collected increases, there is also potential to create expected recovery trajectories for patients based on baseline preoperative data, allowing providers to provide realistic and individualized recovery expectations.

In addition to papers that focus on activity, 7 of the included studies use wearable devices to monitor sleep in the TJA perioperative period. It has been well established that sleep and pain are closely associated, and it has been further shown that higher sleep quality is associated with better acute pain relief following TKA [28,29]. Wearable devices were shown to both increase physical activity on the Active Australia Survey and reduce time in bed and sleep duration [24]. This study did not report on sleep quality as reported by the wearable device. Another study found that both daily steps and minutes slept returned to preoperative levels 3 months post THA. Again, sleep quality as measured by wearable was not reported. Karas et al [44] report a "sleep efficacy score," which is the proportion of minutes asleep to the total time in bed. They find that reductions in sleep efficiency from baseline up to 24 weeks postoperatively, but that daily steps return to baseline 12 weeks after surgery.

Gibian et al [19] found that patient-reported sleep quality, particularly poor-quality sleep as defined by the Pittsburgh Sleep Quality Index, correlated well with VAS pain score at 30 days postoperatively. However, they found no relationship between device-recorded sleep duration and VAS. Further, they found no correlation between overall Pittsburgh Sleep Quality Index scores and device-recorded hours of sleep at 30, 60, or 90 days postoperatively. Finally, 1 study used wearable devices to monitor multiple components of sleep, including overall sleep, sleep onset, and sleep disruption. Sleep disruption increased after surgery, but overall sleep did not. Sleep duration as an isolated metric may lack sensitivity in predicting changes in a patient's recovery timeline following TJA, but fortunately, smartwatches and activity trackers can collect more advanced measurements of sleep. Taken together, the current literature that uses wearable devices to monitor sleep in TJA is heterogeneous. Different groups report an array of variables. This underscores the immense capacity of wearable devices to track multiple domains and also highlights the fact that more uniform outcomes reporting would allow studies to be more easily compared. Further, despite sleep data being collected and reported, current literature does not report on intervening on patients with altered sleep components as reported by wearables.

Notably, 5 of the 35 reviewed studies were sponsored by Zimmer Biomet [15-19], 1 study used a mobile application the lead author created [21], and 1 study used a wearable supplied by 360 Knee Systems [20]. Redfern et al [15] report that patients in the lowest preoperative step count group have lower KOOS JR scores and demonstrate greater postoperative improvement in KOOS JR. Similarly, Pasqualini et al [18] demonstrate that step counts correlate with HOOS JR both preoperatively and at 1- and 3-month follow-up. Further, 2 industry-funded studies [16,17] suggest that PROM surpasses minimal clinically important difference earlier in recovery than activity as measured by wearables. Twiggs et al [20] found a positive correlation between postoperative step count and KOOS activities of daily living subscore. Lebleu et al [21] perform an analysis using the MoveUp application the lead author created. They find that peak cadence improved beyond minimal clinically important difference more quickly than step count in both TJA and TKA recovery. Taken together, the industry-funded studies suggest that PROMs may improve faster than wearable device measurements and that some PROMs correlate with step counts or other measures of physical activity. Further, this research demonstrates the heterogeneity in the types of wearable data reported and the PROMs used among different studies.

The major strength of this study is the comprehensive examination of existing literature. Multiple databases were searched to ensure a comprehensive review of the literature. Further, 2 authors independently extracted data and then collaborated for consensus regarding study eligibility. There was also an agreement between reviewers regarding bias assessment according to the RoB-2 or ROBINS-I tools. This review reports on the vast capabilities of wearable devices, ranging from tracking step counts and sleep to more sophisticated measures. Moreover, we report how wearable device data correlates with validated PROMs and outcome measures, emphasizing their potential to revolutionize postoperative outcome monitoring. Wearable devices also encourage patient participation in rehabilitation protocols and offer patients objective data by which to monitor their postoperative progress. The studies included for review demonstrate high patient participation and compliance.

There are several limitations to this review. As with all reviews, the quality of the reviewed studies is a limitation. Our review included only 5 RCTs, with 30 studies representing nonrandomized trials, and these have lower levels of evidence. As discussed, the heterogeneity among study methods makes direct comparisons difficult. Different wearables have different capabilities. Further, different groups collected data at different time points or had patients wear devices in different locations. While the included studies provided patients with the wearable devices, requiring patients to use a wearable is a source of bias. Patients who are familiar with these devices may have higher technological literacy, socioeconomic status, or ability to care for themselves. As such, certain populations may be excluded from these studies. Additionally, the use of a wearable device on the wrist immediately postoperatively can result in falsely low recordings if patients are using an assistive device such as a walker or cane.

Finally, we propose that remote monitoring via wearable devices provides a practical method for tracking recovery, supporting patient engagement, and detecting deviations from expected progress. Current literature does not agree on the optimal data that wearables provide or when data collection should be performed. Despite this, the studies included in this review demonstrate that variables collected via wearable devices correlate with certain PROMs, pain measures, and objective

XSL•FO
RenderX

postoperative tests. As such, monitoring patients with wearables may allow a more holistic assessment of patient recovery. Further, wearable devices have the potential to allow analysis informed by baseline preoperative activity, which can enhance preoperative counseling and personalize recovery expectations. Lastly, continuous monitoring may also allow early identification of delayed recovery, enabling timely intervention and tailored rehabilitation. Further studies can explore the ideal time in recovery, variables to assess, and the combination of data collected with additional outcome measures that allow wearable devices to most effectively assess outcomes following TJA.

Conclusions

The increasing prevalence of wearable devices presents significant opportunities for advancing postoperative care through continuous health monitoring and data collection. Remote monitoring using these devices allows surgeons to gather extensive and continuous data, which can be crucial for assessing outcomes following TJA. When integrated with a collection of PROMs and objective assessments, data from wearable devices facilitates more comprehensive patient surveillance and enables tailored interventions during the perioperative period. Early monitoring of patients in the postoperative phase enhances the timely identification of adverse events and complications, thereby allowing prompt intervention. Additionally, remote monitoring of patients has been demonstrated to improve compliance with postoperative protocols and instructions. Through rigorous evaluation and standardization of data collected, remote monitoring has the potential to elevate the quality of care and enhance the recovery experience for TJA patients, ultimately leading to improved patient outcomes and satisfaction. However, further research is needed to delineate which specific remote data points are most effective in facilitating the early identification of adverse events and in optimizing patient outcomes and satisfaction after TJA. Future studies can focus on which data provides the most valuable and complete assessment of patient recovery. As our knowledge of how wearables can be best used to assess outcomes increases, there is potential to use data provided to tailor continuous patient assessment and individualized rehabilitation protocols, customized postoperative evaluation, and early detection of deviation from norms in recovery.

The Use of 3D Printing Technology in Rehabilitation for Adults Living With Neurological Conditions: Scoping Review

Salena Aggerwal[1], BHS; Zahra Lalani[1], BHS; Jennifer O'Neil[1,2], PT, PhD

Abstract

Background: Neurorehabilitation plays a key role in improving motor recovery for people with neurological conditions. Although 3D printing has emerged as a promising rehabilitation tool, little is known on how it is used for the rehabilitation of adults living with neurological conditions worldwide.

Objective: We aimed to provide a comprehensive overview of 3D printing in neurorehabilitation and precisely explore how it is used to improve motor recovery for adults with neurological conditions living in higher- and lower-middle–income countries.

Methods: We conducted a scoping review following the Joanna Briggs Institute guidelines. After searching 3 databases (MEDLINE, Web of Science, and Nursing and Allied Health Premium), 2 independent reviewers screened and selected English-language studies involving adults (≥18 years) published between 2019 and 2024 to capture the most recent advancements in this field. We extracted relevant information on neurological conditions, motor recovery outcomes, and types of 3D printing and offered a comparative analysis of 3D printing in physical neurorehabilitation from the perspective of national income levels using a modified Joanna Briggs Institute extraction form. We synthesized the findings narratively with tabular support.

Results: After screening 2752 titles and abstracts and 103 (3.7%) full texts, we included 13 (0.5%) studies based on our inclusion criteria. All included studies were conducted in upper-middle–income or high-income countries, and most studies (9/13, 69.2%) focused on stroke, followed by spinal cord injury (2/13, 15.4%), Parkinson disease (1/13, 7.7%), and central nerve disease (1/13, 7.7%). The 3D-printed rehabilitation tools included orthotics (7/13, 53.8% for the upper extremities [UEs]; 3/13, 23.1% for the lower extremities [LEs]), an exoskeleton (1/13, 7.7%; UEs), a modular assistive hand device (1/13, 7.7%; UEs), and an insole (1/13, 7.7%; LEs). In total, 69.2% (9/13) of the studies targeted UE rehabilitation, measured using the Action Research Arm Test, active range of motion, the box and block test, the Fugl-Meyer Assessment, the Modified Ashworth Scale, the manual function test, range of motion, and the Toronto Rehabilitation Institute Hand Function Test, and 30.8% (4/13) targeted LE rehabilitation, measured using the 10-m walk test, anteroposterior ground reaction force analysis, the Barthel index, the Tinetti scale, the RehaWatch system, and the GaitWatch system.

Conclusions: Used as a rehabilitation tool, 3D printing technology has demonstrated significant potential in improving upper and lower motor recovery for people with certain neurological conditions in high-middle–income countries. Future research should explore the implementation feasibility and effectiveness of these technologies across different neurological conditions and income settings, particularly in low- and lower-middle–income countries.

Introduction

Background

Neurological conditions encompass a broad spectrum of central and peripheral conditions caused by damage to the brain, spinal cord, or peripheral nerves that interfere with brain development or result in impaired motor functions [1]. According to a 2021 report published in *The Lancet Neurology* by the World Health Organization (WHO), over 3 billion people in the world are living with a neurological condition [2,3]. Neurological conditions such as stroke, traumatic brain injury, spinal cord injury, cerebral palsy, Parkinson disease, and cognitive disorders are some of the leading causes of illness and disability worldwide [2,4,5]. Disability-adjusted life years, which measure the overall burden of disease, including disability, sickness, and premature death due to neurological conditions, have increased by 18% since 1990 [1-3]. Moreover, care disparities persist across demographics. Higher-income countries possess greater access to specialized care, with 70 times more health

XSL•FO
RenderX

professionals specializing in neurological conditions per 100,000 individuals compared to lower-middle–income countries [1]. In the United States alone, the financial and public health burden of neurological conditions is estimated to cost US $1.7 trillion annually [1]. Given the global prevalence of neurological conditions, and with over 80% of neurological-related deaths and health losses occurring in low- and middle-income countries (LMICs), there is a need for effective treatment strategies to improve patient health outcomes and reduce associated burdens worldwide [1-7]. Neurorehabilitation is an interdisciplinary clinical process designed to assess disabilities and provide rehabilitation interventions to enhance functions affected by damage to the nervous system [8,9]. The WHO defines neurorehabilitation as enabling individuals to acquire the knowledge, skills, and resources necessary to achieve optimal physical, psychological, social, and economic functioning [2,3,8]. Many interventions, including assistive devices, therapeutic exercises, and cognitive behavioral therapies, are used in the provision of rehabilitation services for individuals with neurological conditions [5,10,11]. For motor recovery, one promising rehabilitation tool is the use of 3D printing technology.

This is an emerging technology that creates 3D objects out of melting materials into thin layers printed layer by layer based on computer-programmed designs [12]. A range of materials can be used, including nylon, biodegradable plastic filament, polylactic acid, and acrylonitrile butadiene styrene plastic [12,13]. Worldwide, 3D printing has the potential to improve access to rehabilitation devices in lower-middle–income countries where traditional manufacturing processes can be both costly and time-consuming [14,15]. Currently, in health care, 3D printing has been widely adopted beyond rehabilitation, including applications in surgical planning, dental restorations, and the production of anatomical models for medical education and preoperative simulation [16]. In the rehabilitation field, 3D printing is being used to produce a variety of highly customized, patient-specific devices, such as orthotics, prosthetics, and assistive tools [6,12,14]. Many of these designs are low cost, customizable, and easy to assemble, making them well suited for resource-limited settings [12,15]. Specific to neurorehabilitation, 3D printing technologies have gained increasing attention for their potential to deliver personalized, cost-effective, and accessible therapeutic solutions [17]. Despite growing interest, there remains limited synthesis of how these technologies are being applied worldwide, particularly in relation to their use in supporting motor recovery in adults living with neurological conditions. As the scope of neurorehabilitation extends across multiple professions (ie, physiotherapy, occupational therapy, audiology, speech-language pathology, social work, and nursing), focusing on motor recovery specific to physiotherapy or physical rehabilitation is a first step toward understanding 3D printing use in neurorehabilitation.

Research Objectives

To address this gap, the objective of our scoping review was to provide a comprehensive overview of how 3D printing technologies have recently been used in neurorehabilitation for adults. We aimed to document and compare their applications across high-income, upper-middle–income, lower-middle–income, and low-income countries and identify the types of assessments used to evaluate motor recovery outcomes when using 3D-printed rehabilitation tools, including standardized clinical scales, functional performance tests, and biomechanical measurements. To our knowledge, this study is the first to offer a comparative analysis of 3D printing in physical neurorehabilitation from the perspective of national income levels.

Methods

We conducted this scoping review in accordance with the Joanna Briggs Institute (JBI) methodology for scoping reviews [17] and aimed to answer the following question: how is 3D printing used to improve motor recovery for adults with neurological conditions in higher- and lower-middle–income countries?

Population, Concept, and Context Framework

We used the population, concept, and context framework as recommended by the JBI guidelines [17]. We included studies involving adult participants (18 years and older) with neurological conditions who received rehabilitation interventions aimed at improving or restoring motor function. Participants under 18 years of age were excluded as pediatric populations have different developmental trajectories and rehabilitation needs, which fall outside the scope of this review [18]. Eligible conditions included acquired brain injuries, neurodegenerative disorders, and traumatic brain or spinal cord injuries [19].

The concept for this review focused on the application of 3D printing technology in improving motor recovery for adults with neurological conditions. Studies exploring the use of 3D printing rehabilitation interventions or 3D-printed tools to enhance motor function in adults within multiple rehabilitation settings were considered. Rehabilitation interventions included physiotherapy or physical rehabilitation strategies designed to enhance motor abilities. Physiotherapy referred to evidence-based treatments delivered by trained professionals to restore movement and function, often through targeted exercises, manual techniques, and assistive devices. Physical rehabilitation strategies more broadly included any structured interventions aimed at improving motor control, strength, or mobility, particularly after neurological injury. Settings included clinical environments (eg, hospitals, rehabilitation centers, and outpatient clinics), home-based rehabilitation programs, and laboratory-based rehabilitation programs. Studies that focused on 3D printing for surgical planning, medical pharmaceutics, bioengineering, or any interventions that did not report clinical or functional motor recovery outcomes (ie, purely descriptive studies) were excluded as they did not reflect the rehabilitation objective of this review [16].

This scoping review considered studies conducted in contexts of higher-income, upper-middle–income, lower-middle–income, and low-income countries as defined by the World Bank based on gross national income per capita for 2023 (Multimedia Appendix 1) [20]. The geographical and socioeconomic context was explored in terms of access to 3D printing technologies as well as how this impacts the effectiveness of these interventions.

XSL•FO

No limitations were placed on the gender, ethnicity, or religion of the participants included in the studies.

Developing a Search Strategy

We developed a rigorous search strategy in 3 steps. First, we conducted a preliminary search of MEDLINE (PubMed) to identify articles on the topic and define main keywords. In this preliminary search, we used the keywords "3D printing" and "rehabilitation" to capture as many articles on the topic as possible, thus providing insights into existing literature. We then reviewed keywords contained in titles and abstracts and the indexing terms used to describe potentially included articles (reviewing keywords and indexing terms from relevant titles and abstracts), which was then used to refine our search strategy. Second, we developed a refined search strategy incorporating additional keywords: "physiotherapy," "physical therapy," or "physical rehabilitation" (Multimedia Appendix 2). This refined search strategy incorporated both MeSH (Medical Subject Headings) terms and text word searches in MEDLINE (PubMed) and was adapted using equivalent text word strategies in 2 other databases (Web of Science and Nursing and Allied Health Premium). In this step, a filter for English-language publications was applied across all databases to maintain consistency (Multimedia Appendix 2). Third, the reference lists of all articles included in the review were manually screened for additional relevant papers. This step aimed to capture any pertinent studies that may not have been identified through the database searches.

Study Screening and Evidence Selection

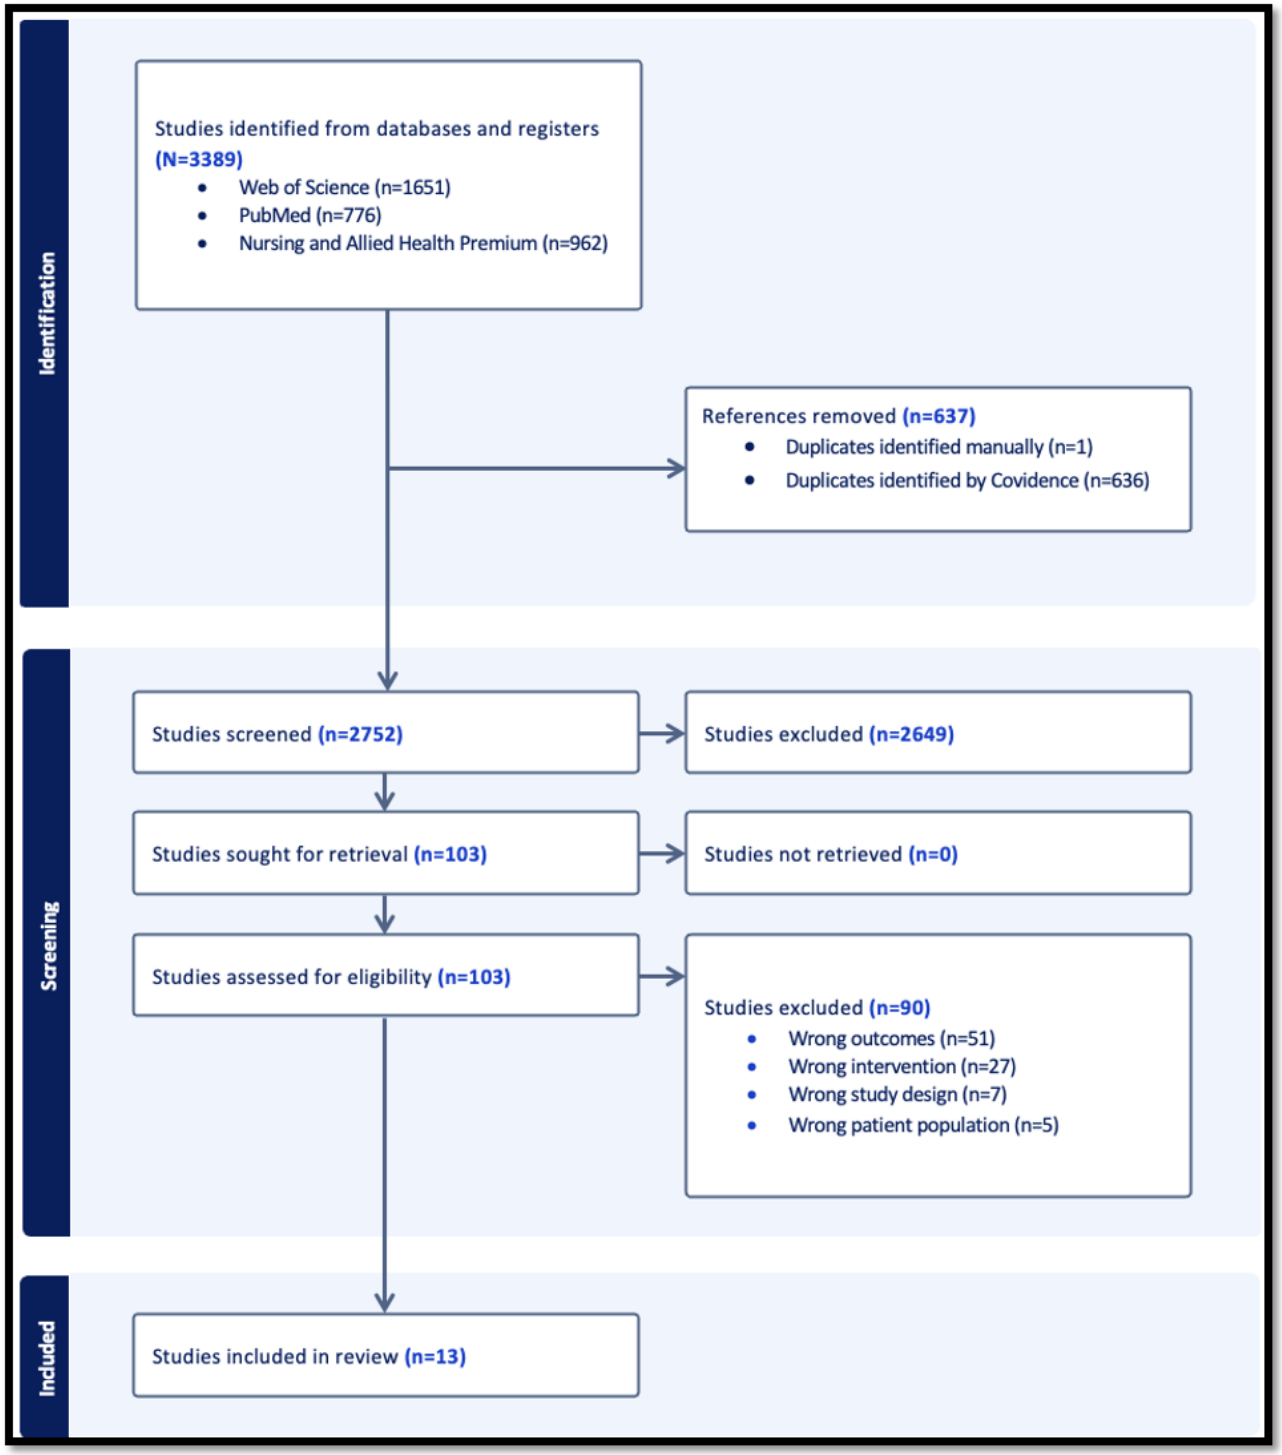
Following the 3-database search, we collated all identified studies and used Mendeley Reference Manager (version 2.51.0; Elsevier) and Covidence (Veritas Health Innovation) for citation management and removal of duplicates. Titles and abstracts were screened by 2 independent reviewers (SA and ZL) for assessment against the inclusion and exclusion criteria. We screened studies published from 2019 onward, with the final search completed on November 21, 2024, to capture the most recent advancements in 3D printing technologies for neurorehabilitation. We included a variety of study designs (ie, randomized controlled trials [RCTs], nonrandomized experimental studies, pilot and feasibility studies, case studies, and systematic reviews) in our search to capture both the effectiveness of the interventions and the practical considerations surrounding their implementation. RCTs and non-RCTs were included to assess potential causal relationships between 3D printing interventions and motor recovery outcomes [21]. Pilot and feasibility studies were eligible if they examined the usability, acceptability, or logistical feasibility of 3D-printed devices in rehabilitation contexts [22]. Case studies were included if they provided detailed examples of individualized application [23]. Systematic reviews were considered if they synthesized primary research aligned with our inclusion criteria [24]. Opinion pieces, editorials, commentaries, and protocols without full-text availability were excluded as they did not contribute to the empirical evidence required for conclusions. When the inclusion criteria were met at the title and abstract screening stage, the full texts were screened through the same 2-reviewer screening method. Any disagreements were resolved through consensus with a third reviewer (JON) when necessary.

Data Extraction

We extracted relevant data from the included full-text studies. We used a data extraction form that was developed based on the JBI guidelines (Multimedia Appendix 3) to ensure completeness of data extraction. The extraction form included (1) general study characteristics, including authors, title, year of publication, date of data collection, study type, country, and study aim; (2) population details, such as sample size, age, gender, and the health condition being addressed; (3) intervention details, including setting (eg, clinical, home based, or laboratory) and duration of the intervention, type of 3D-printed technology used (eg, orthosis or insole), stiffness and type of polymer, neurological condition (eg, stroke or Parkinson disease), and motor area focus (upper extremities [UEs] or lower extremities [LEs]); and (4) outcomes, including the types of assessments used to evaluate motor recovery, such as standardized clinical scales, functional performance tests, and biomechanical measurements.

Data Analysis and Interpretation

We analyzed the data using descriptive qualitative content analysis and synthesized the extracted data from a geographical perspective. Data were systematically mapped based on the objectives of our scoping review to capture study characteristics, (authors, title, and publication year), the type of 3D-printing technology used, the associated neurological condition and rehabilitation goal, outcome measures, and country of implementation. A comparative approach was applied to assess differences between high-income and lower-middle–income countries, documenting disparities in access (as reported through the availability of 3D printing technology, affordability considerations, descriptions of infrastructure, and integration into clinical practice) and effectiveness. Findings were synthesized into thematic categories, providing a comprehensive overview of how 3D-printed technologies have been used to support motor recovery in different health care contexts.



Results

Overview

A total of 2752 titles and abstracts were screened. Of these 2752 articles, after removing 637 (23.1%) duplicates, 103 (3.7%) full-text articles were assessed for eligibility, and 90 (3.3%) were excluded (Figure 1). We included 13 studies [25-37], with sample sizes ranging from single case reports (N=1 individual) to small trials (N=31 individuals) (Table 1). The reported participant ages ranged from 23 to 83 years, aligning with the inclusion criterion of adult participants (18 years and older).

Table . Technologies used in neurological rehabilitation for upper- and lower-extremity impairments, including the country in which the technology was implemented, the associated neurological condition, the type of technology, 3D printing materials and processes, the outcome summary, and the outcome measures used to assess effectiveness.

Study and country	Neurological condition	Assistive device	3D printing details (device; stiffness and type of polymer) and process	Outcome summary	Outcome measures
Upper-extremity impairments					
Chen et al [25], 2022, China	Stroke	Hand splint	PLA[a]; 3D printing method and process not specified	Improved grip and lateral pinch strength; no significant change in palmar pinch and gross movement	ARAT[b] and pinch force tests[c]
Demeco et al [26], 2023, country not specified	Stroke	Hand splint	Not specified	Improved upper-limb ROM[d], hand dexterity, and pinch strength (palmar and lateral); reduced spasticity	ROM, BBT[e], pinch force tests, FMA[f], and MAS[g]
Dudley et al [27], 2021, United States	Stroke	Exoskeleton	PLA+1% copper additive (PLACTIVE); FDM[h] (Ultimaker 2+ Extended); infill: 35% - 40%; layer height: 0.15 - 0.25 mm; bed: 50 °C; shell: 0.8 mm; print speed: 60 - 100 mm/s	Improved finger flexion and extension, grasp function, and hand dexterity	FMA and BBT
Huber et al [28], 2023, United States	Stroke	Hand splint	Variable-stiffness TPU[i] powder; SLS[j] 3D printing; printer and parameters not reported	Improved hand dexterity and pincer force; no significant change in pincer aperture	Pincer force test, pincer aperture test, and BBT
Kuo et al [29], 2024, China	Neurological central nerve injury	Modular assistive hand technology device	TPU filament (1.75 mm); FDM (Original Prusa i3 MK3S+); CAD[k] designed (SolidWorks, DesignSpark Mechanical, and Meshmixer)	Improved shoulder AROM[l] and functional hand tasks; no significant change in hand dexterity or grip strength	AROM, BBT, Jamar dynamometer, and functional hand tasks
Yeh et al [30], 2023, China	Spinal cord injury	Hand splint	Material not specified; FDM (FlashForge Finder); layer height: 0.2 mm; infill: 15%; speed: 60 - 80 mm/s; print temperature: 200 °C; nonprinted components: silicone finger cots; acrylic linkages (3 mm) laser cut	Improved pinch force and hand dexterity	Pinch force test and BBT
Toth et al [31], 2020, Hungary	Stroke	Hand splint	PA[m] 2200 (nylon) framework; TPU sheets; nitinol SMA[n]+Kapton heating elements; SLS (EOS Formiga P 110); 110 µm layers; FDM; integrated heating elements	Improved pencil holding, handle and tool grasp, vertical handle grasp, cup holding, door handle operation, and device assembly; no significant improvement in eraser holding	MFT[o]

XSL•FO
RenderX

Study and country	Neurological condition	Assistive device	3D printing details (device; stiffness and type of polymer) and process	Outcome summary	Outcome measures
Yang et al [32], 2021, China	Stroke	Hand splint	ABS[p] filament; FDM (UP Box); layer thickness: 0.2 mm; infill: 20%; nozzle temperature: 230 °C; print speed: 60 mm/s	Improved upper-extremity motor function; reduced spasticity	MAS and FMA
Yoo et al [33], 2019, South Korea	Spinal cord injury	Hand splint	PLA; FDM (Moment 2); CAD designed (SolidWorks); postprint heat reshaping; nonprinted components: self-adhesive padding, Velcro, and nylon thread	Improved grasp, lift, and object manipulation	TRI-HFT[q]
Lower-extremity impairments					
Brognara et al [34], 2020, Spain	Parkinson disease	Insole	Material not specified; 3D foot scan (3D Sense); CAD designed (Rhinoceros 3D); FDM (Delta WASP 4070); custom insole with 2 blunted cones (plantar stimulation)	Improved balance; no significant change in daily activities	Barthel index and Tinetti scale
Hsu et al [35], 2020, China	Stroke	Ankle-foot orthoses	Nylon (4611); 3D scan (Structure Sensor; OBJ[r]→STL[s]); FDM (Ultimaker); approximately 3-mm wall thickness	Improved gait parameters; no significant change in walking speed	RehaWatch system and 10MWT[t]
Kwon et al [36], 2019, China	Stroke	Ankle-foot orthoses	TPU filament; VeroBlackPlus (rigid components); FDM (Cubicon Single Plus); PolyJet (Objet 30 Prime)	Improved paretic propulsion; no significant change in walking speed	Anteroposterior ground reaction force analysis and 10MWT

Study and country	Neurological condition	Assistive device	3D printing details (device; stiffness and type of polymer) and process	Outcome summary	Outcome measures
Liu et al [37], 2019, South Korea	Stroke	Ankle-foot orthoses	PA-12; 3D scan (EinScan-Pro); model modification (Geomagic Studio); MJF[u]	Increased gait velocity and stride length; no significant changes in cadence and step symmetry	GaitWatch system

[a]PLA: polylactic acid.

[b]ARAT: Action Research Arm Test.

[c]"Pinch force test" is used as a standardized term across studies measuring pinch strength except for the study by Huber et al [28], which specifically used "pincer force test" based on a defined protocol.

[d]ROM: range of motion.

[e]BBT: box and block test.

[f]FMA: Fugl-Meyer Assessment.

[g]MAS: Modified Ashworth Scale.

[h]FDM: fused deposition modeling.

[i]TPU: thermoplastic polyurethane.

[j]SLS: selective laser sintering.

[k]CAD: computer-aided design.

[l]AROM: active ROM.

[m]PA: polyamide.

[n]SMA: shape-memory alloy.

[o]MFT: manual function test.

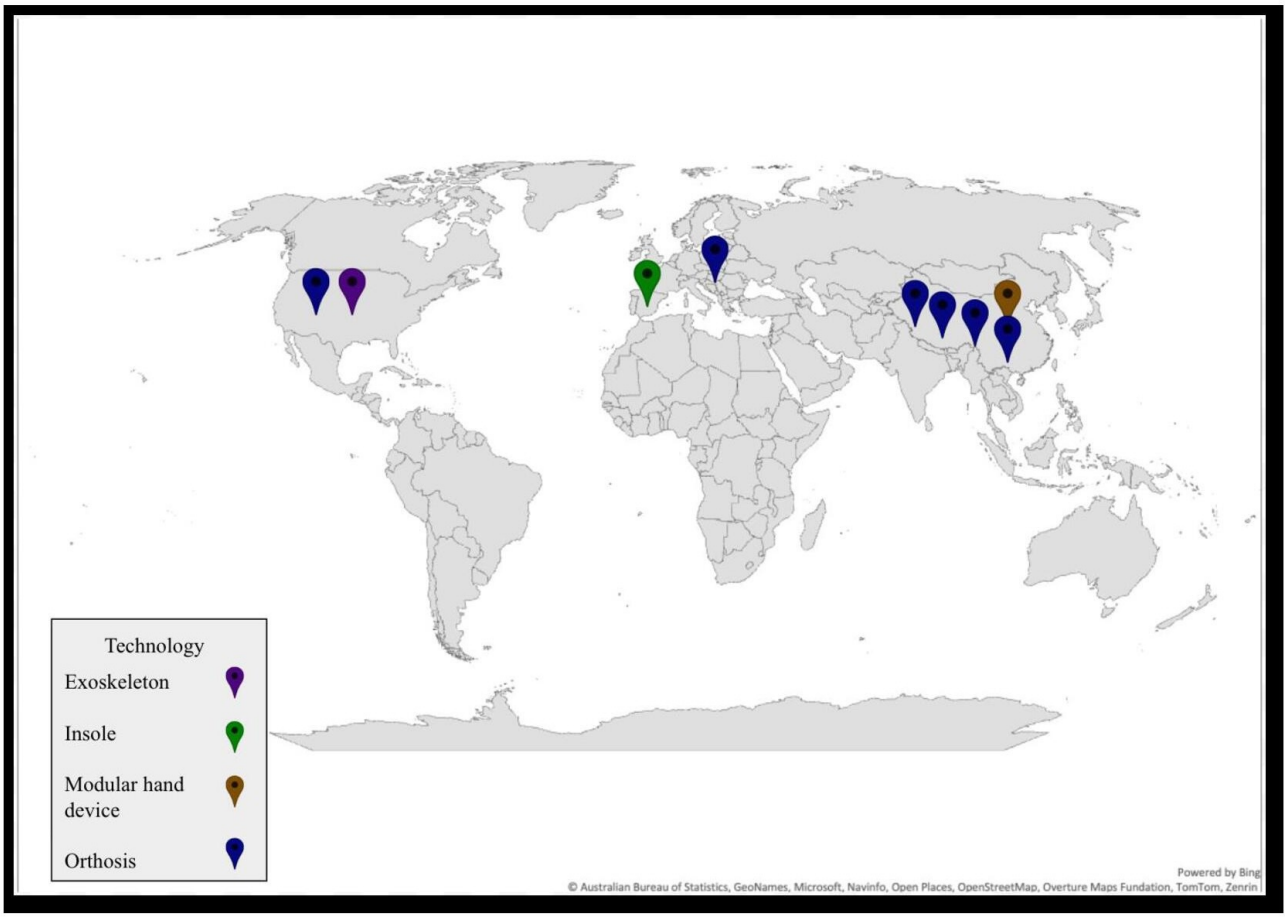
[p]ABS: acrylonitrile butadiene styrene.

[q]TRI-HFT: Toronto Rehabilitation Institute Hand Function Test.

[r]OBJ: Wavefront Technologies file format.

[s]STL: stereolithography.

[t]10MWT: 10-m walk test.



[u]MJF: multijet fusion.

Overview of 3D-Printed Rehabilitation Tools Used in Neurorehabilitation per Country

All included studies [25-37] were conducted in upper-middle–income or high-income countries (ie, China, South Korea, the United States, Spain, and Hungary; Figure 2). While 4 different types of neurorehabilitation tools were designed using 3D printing—orthotics (10/13, 76.9%) [25,26,28,30-33,35-37], an exoskeleton (1/13, 7.7%) [27], a modular assistive hand technology device (1/13, 7.7%) [29], and an insole (1/13, 7.7%) [34] (Multimedia Appendix 4)—most included studies (8/13, 61.5%) primarily focused on orthoses for stroke rehabilitation [25,26,28,30-32,35-37].

XSL•FO
RenderX

Figure 2. Geographical distribution of 3D-printed rehabilitation tools by country and technology type. Map created using Microsoft Excel and Google Drawings.

In total, 69.2% (9/13) of the included studies focused on rehabilitation of UE function, and 30.8% (4/13) focused on LE rehabilitation [25,27-33]. For UE rehabilitation, 5 of the studies used 3D printing technology to design hand splints for stroke-related impairments [25,26,28,31,32], 2 of the studies focused on hand splints for individuals with spinal cord injury [30,33], 1 study included a 3D-printed modular assistive hand device for patients with central nerve injuries [29], and 1 study investigated the use of a 3D-printed upper-limb exoskeleton to support hand rehabilitation for individuals after stroke [27]. For LE rehabilitation, 3 of the studies explored the use of 3D-printed ankle-foot orthoses for gait impairment rehabilitation after stroke [35-37], and 1 study used a 3D-printed insole for people living with Parkinson disease [34].

Types of Assessments

Across studies, outcome measures were predominantly used in pretest-posttest designs to assess changes in motor performance before and after the application of 3D-printed rehabilitation tools. The most frequently used standardized outcome measures for UEs were the pinch force test (4/13, 30.8%) [25,26,28,30] and the box and block test (5/13, 38.5%) [26-30]. For LEs, a commonly used outcome measure was the 10-m walk test (10MWT; 2/13, 15.4%) [35,36].

Discussion

Principal Findings

To our knowledge, this scoping review is the first to explore the application of 3D printing rehabilitation interventions for adults with neurological conditions from a geographical perspective. We selected a geographical perspective and the World Bank national income classification to reflect the socioeconomic and structural determinants of adoption that may influence whether 3D-printed neurorehabilitation devices can be implemented across international health systems. Our geographical analysis showed that rehabilitation research on 3D printing technologies is primarily concentrated in higher- and upper-middle–income countries (ie, China, the United States, South Korea, Spain, and Hungary). This distribution reflects broader economic trends and access to infrastructure and materials. In contrast to this technological growth in higher-income countries, rehabilitation-specific data remain limited in lower- and lower-middle–income countries. No studies were identified in our review from lower-middle– or low-income countries, highlighting the current gap in implementation within resource-constrained health systems.

As outlined in the WHO *Global strategy on digital health 2020 - 2025*, such disparities reflect systemic barriers in low-resource settings, including underdeveloped infrastructure, limited digital capacity, and inadequate financing models that constrain the adoption of digital health technologies [38].

XSL•FO
RenderX

Potential barriers also include the cost of medical-grade 3D printers, which can be substantial depending on material capabilities; infrastructure limitations such as unreliable electricity, insufficient internet connectivity, and shortages of trained personnel [14,39]; sociocultural factors such as potential stigma associated with 3D-printed assistive technologies; and if rehabilitation is not widely used in some regions, this may further affect the uptake of 3D-printed devices for rehabilitation [14,40]. The technical compatibility of 3D printing in lower-middle– or low-income countries may also be limited by gaps in the broader fabrication ecosystem required for clinical device production. This includes unreliable access to printing materials (eg, filament or resin), supplementary assistive device components (eg, straps or Velcro and padding or foam), and the software and digital infrastructure needed for the design process [12,14,40]. Even when 3D printers are available, limited capacity for postprocessing (eg, curing and edge finishing), routine maintenance (eg, calibration and replacement of wear parts), and training of clinicians may hinder sustained implementation in resource-constrained settings [12,14,40]. While barriers must be considered, investigating the use of emerging technologies in LMIC settings is crucial to understanding adoption, adaptation, and implementation in various and diverse contexts. The feasibility and long-term sustainability of 3D printing in low-resource settings remain critical areas for future investigation [14,40].

3D Printing Technology in Neurorehabilitation

Integrating 3D printing technologies into neurorehabilitation represents a paradigm shift in delivering innovative, personalized, clinically relevant interventions for individuals with neurological conditions. Our scoping review synthesized evidence on the application of novel technology, including 3D-printed orthotics, exoskeletons, modular assistive hand devices, and insoles, supporting motor rehabilitation for individuals who have experienced a stroke or spinal cord injury or been diagnosed with Parkinson disease or central nerve injury. We recognize that these are not representative of all neurological conditions, and we consider that our findings suggest a potential shift characterized by the ability to use emerging technologies such as 3D printing to rapidly design and produce patient-specific rehabilitation tools tailored to individual needs and functional impairments [12]. Among the technologies reviewed, orthotic devices emerged as the most widely studied, primarily addressing lower motor impairments for persons who experienced a stroke. This focus is particularly important in both upper-middle– and lower-income countries as stroke remains a leading cause of morbidity and mortality worldwide. Gait impairments after stroke are extensively researched and prevalent in neurological rehabilitation, so investigating cost- and resource-effective tools tailored to these impairments is imperative [41]. Unlike conventional rehabilitation tools, 3D-printed solutions may offer greater flexibility and adaptive adjustments based on the patient, faster production timelines, and affordability [12,14]. Therefore, 3D-printed rehabilitation tools may improve fit, comfort, and usability to enhance motor recovery outcomes and support greater independence in daily activities. Their application across clinical and home-based settings could further broaden access to care, particularly in LMICs. Given this emphasis and the growing potential of 3D printing in neurorehabilitation, it is essential that future research not only continue to refine orthotic solutions but also explore a broader range of technologies and document their effectiveness within neurorehabilitation contexts.

Our findings offer a comprehensive overview of measurements used to evaluate motor recovery outcomes (ie, standardized clinical, functional, and biomechanical measurements). Gold-standard rehabilitation assessments are those that are widely validated, clinically reliable, and consistently used across diverse populations to measure functional outcomes with high sensitivity and specificity. Results from our scoping review identified 4 gold-standard outcome measures being used for assessing the impact of 3D printing technologies on UE rehabilitation: the Fugl-Meyer Assessment (FMA), the Action Research Arm Test (ARAT), the Jamar dynamometer, and the Barthel index. For LE rehabilitation, the 10MWT was the only gold-standard outcome measure identified. The frequent use of the FMA across our included studies reflects its widespread acceptance as an outcome measure, particularly for people after stroke. Its strong psychometric properties, such as high interrater reliability, responsiveness to change, and internal consistency, make it a clinically relevant tool for capturing motor function in the UEs [42-44]. Within the context of 3D printing interventions, the FMA's emphasis on voluntary movement patterns, coordination, and reflex activity aligns well with the types of impairments that these technologies aim to address [42-44]. Its application in studies examining customized orthoses and exoskeletons suggests that researchers prioritize outcome measures that can accommodate the complexity of stroke-related motor deficits and individualized recovery trajectories [42-45].

The Jamar dynamometer was used in 7.7% (1/13) of the studies [29] and serves as a recognized gold-standard tool for objectively quantifying grip strength. In neurorehabilitation, grip strength is a meaningful proxy for upper-limb recovery and is often correlated with broader indicators of functional independence and quality of life in individuals with neurological impairments [46,47]. The Jamar dynamometer is particularly important for evaluating 3D printing interventions as it can provide precise, quantifiable feedback on how assistive devices, such as modular assistive hand devices, can enhance grip function and hand strength for adults with neurological conditions [46,47]. These objective data strengthen the clinical evidence supporting the functional efficacy of 3D-printed devices and enable more informed design refinements for 3D-printed technologies. In resource-limited settings, where comprehensive neurological assessments may not be feasible, dynamometers can offer practical and scalable solutions for tracking fine motor outcomes in response to 3D printing interventions [48].

The Barthel index was used in 7.7% (1/13) of the studies [34] as a gold-standard tool and captures independence in essential activities of daily living, including feeding, grooming, bathing, mobility, and toileting [43,49]. Its relevance lies in its ability to assess the effectiveness of 3D-printed insoles by monitoring changes in self-care and mobility over time, thereby capturing the progressive nature of degenerative neurological conditions such as Parkinson disease [50]. Its ease of administration, low

XSL•FO
RenderX

cost, and global familiarity make it especially well suited for integration into 3D printing rehabilitation protocols in settings with limited infrastructure or personnel [49].

The ARAT was reported in 7.7% (1/13) of the studies [25] as a gold-standard measure to evaluate upper-limb performance across 4 domains: grip, grasp, pinch, and gross movement [51]. The ARAT has widely excellent interrater reliability, high test-retest reliability, and good construct validity, particularly for people after stroke [51]. By assessing both fine and gross components of upper-limb function, it is well suited for evaluating 3D-printed devices targeting grasp and release, dexterity, and functional hand use [25,51].

The 10MWT was used in 15.4% (2/13) of the studies [35,36] as a gold-standard measure of short-distance walking performance. Its relevance to 3D-printed ankle-foot orthoses lies in its ability to quantify clinically meaningful changes in gait capacity through walking speed, a core functional indicator of mobility and community ambulation after neurological injury [52,53]. The 10MWT is particularly well suited for integration into 3D printing rehabilitation protocols in resource-limited settings because it is rapid to administer and requires minimal equipment and training for clinicians and patients [52,53].

The systematic use of gold-standard rehabilitation assessments within studies investigating 3D printing interventions is particularly significant as they provide an important framework for objectively evaluating the efficacy of these technologies, ensuring that observed improvements in motor function are both measurable and clinically meaningful across various neurological populations. Therefore, by aligning 3D printing research with gold-standard tools, clinicians and researchers can ensure more accurate, comparable, and clinically meaningful assessments of motor recovery and functional gains.

Strengths and Limitations

A strength of this scoping review lies in its rigorous methodology, which included a comprehensive search strategy, clear inclusion criteria, and a structured data extraction form. By synthesizing evidence across diverse neurological conditions and outcome measures, this review provides a detailed understanding of how 3D-printed technologies contribute to motor recovery.

Although previous research has demonstrated improvements in motor recovery outcomes through 3D-printed rehabilitation technologies, several limitations remain. Studies included in this review had small sample sizes and heterogeneous intervention protocols, limiting the ability to draw generalizable conclusions. Additionally, the search strategy may have inadvertently excluded relevant studies by not expanding the keywords to include other discipline-specific terminology (eg, “occupational therapy,” “audiology,” and “nursing”). Not indexing these terms potentially narrowed the scope of the findings. Moreover, restricting inclusion to English-language publications may have introduced a language bias and limited the generalizability of the results.

All eligible studies were conducted in high- or middle-income countries, which limited comparisons across income groups and may have contributed to heterogeneity as the effectiveness and feasibility of 3D-printed neurorehabilitation devices may differ in infrastructure-constrained settings. Printer type, printing materials, and fabrication processes were inconsistently reported across the included studies. We reported available details descriptively (Table 1) but were unable to synthesize fabrication methods across studies or provide implementation guidance.

Conclusions

This scoping review highlights the growing interest in 3D-printed rehabilitation technologies within neurorehabilitation, particularly in the development of orthoses for motor recovery [12,14]. While preliminary findings suggest that 3D printing may offer a flexible and cost-effective means of delivering personalized interventions, the current evidence base remains limited by small sample sizes and heterogeneous study designs [14]. To strengthen the field, future research should prioritize larger and more diverse populations; standardized protocols; and consistent use of validated, clinically meaningful outcome measures [54]. These efforts are essential to better assess the functional impact and real-world applicability of 3D-printed technologies in neurorehabilitation [54].

Abstract

Background: Knee exoskeletons represent a significant advancement in wearable robotic technology, developed to enhance gait assistance and facilitate rehabilitation processes. These devices are increasingly used in clinical and research environments worldwide. Nonetheless, the existing empirical evidence supporting their biomechanical and functional outcomes lacks both breadth and clarity. Further investigation is essential to elucidate the specific effects of knee exoskeletons on gait dynamics and rehabilitation efficacy.

Objective: This study aims to systematically review the clinical and biomechanical evidence on knee exoskeletons used for gait assistance and rehabilitation.

Methods: A systematic search of databases—PubMed, Web of Science, IEEE Xplore, and Scopus—was conducted to identify eligible studies published between January 2015 and March 2025. Studies were included if they investigated knee exoskeleton systems in human participants for gait assistance and rehabilitation. Randomized controlled trials, observational studies, and experimental investigations were eligible. Exclusion criteria were multijoint exoskeletons, nonhuman studies, and simulation-based analyses. Two reviewers independently extracted study characteristics, participant demographics, device features, intervention protocols, and clinical and biomechanical outcomes. Risk of bias was assessed using RoB-2 (Cochrane Risk of Bias 2) for randomized controlled trials and ROBINS-I (Risk of Bias in Nonrandomized Studies of Interventions) for nonrandomized studies.

Results: Thirty-two studies met the inclusion criteria. Most investigations involved healthy adults in feasibility or pilot settings, while a smaller subset included individuals with stroke, spinal cord injury, or orthopedic conditions or pediatric movement disorders. Across studies, knee exoskeletons demonstrated short-term improvements in spatiotemporal gait parameters, including increased gait speed and step length, improved knee joint kinematics, and reductions in muscular effort or metabolic demand. However, substantial heterogeneity in device design, outcome metrics, and intervention duration limits comparability across studies. Sample sizes were typically small, and follow-up outcomes were rarely reported, restricting the interpretation of the long-term clinical efficacy of these devices.

Conclusions: Knee exoskeletons demonstrate promising short-term functional and biomechanical benefits and are increasingly feasible within structured rehabilitation settings. While current evidence is limited by small sample sizes and brief follow-up periods, emerging data suggest potential for enhancing task-specific gait training. Larger, well-designed trials are needed to determine sustained clinical impact and integration into routine rehabilitation practice.

Introduction

Gait disorders and knee joint dysfunction are the most common consequences of neurological and orthopedic diseases, including postoperative conditions such as total knee replacement [1]. Neurological gait disorders are commonly associated with stroke, spinal cord injury, cerebral palsy, and degenerative conditions. At the same time, orthopedic pathologies such as osteoarthritis, joint degeneration, and skeletal deformities of the lower extremities also contribute to gait disorders and progressive disability [2,3]. Knee disorders impose a substantial and growing global burden across all populations. Osteoarthritis of the knee is especially prevalent, affecting approximately 4% - 5% of people worldwide (365 million in 2019) [4] and, by some estimates, about 16% of adults aged >40 years (654 million) [5]. Traumatic knee injuries (eg, sports or accident injuries) also contribute significant morbidity, especially in younger and athletic populations, often precipitating earlier osteoarthritis [6]. Even after surgical treatment (eg, total knee arthroplasty), many patients remain disabled: roughly 15% - 30% report persistent pain or functional limitation postoperatively [7,8]. Economic costs are correspondingly high: one systematic review found mean annual costs of €11,100 (€1=US $1.16 as of March 10, 2026) per knee/hip patient with osteoarthritis [9], and national expenditures reflect this trend. For example, osteoarthritis-related costs in Germany rose from €8.6 billion in 2015 to €12.1 billion in 2020 [10]. These impairments significantly affect mobility, functional independence, and quality of life across adult and pediatric populations.

The knee joint plays a central role in shock absorption, load transfer, and movement during walking and functional loads [11]. Several technology-enhanced modalities have been investigated as adjuncts to conventional knee rehabilitation, except for robotic exoskeletons. Virtual reality–based training has demonstrated clinically meaningful improvements in pain, strength, and function. In patients undergoing anterior cruciate ligament reconstruction, a meta-analysis of 9 randomized controlled trials reported significant reductions in pain and improvements in knee function, quadriceps strength, and knee flexion range of motion compared with standard therapy [12]. Similarly, pooled evidence from studies of rehabilitation in total knee arthroplasty (TKA) showed modest but significant improvements in pain, balance, and knee-specific function with virtual reality interventions [13]. Telerehabilitation and app-guided programs have also demonstrated outcomes comparable to face-to-face therapy, including improved pain relief, knee flexion, and quadriceps strength after TKA [14]. Wearable biofeedback systems further support functional recovery, with faster Timed Up and Go performance and higher patient satisfaction reported following TKA rehabilitation [15].

Despite these benefits, most nonrobotic technologies rely on feedback-based strategies and do not provide direct mechanical assistance to the knee joint during functional tasks.

Wearable knee exoskeletons offer a complementary approach by delivering task-specific, assist-as-needed mechanical support during gait, enabling high-repetition training while reducing physical demand and discomfort [16,17]. Exoskeleton-assisted rehabilitation has been associated with improved gait performance, muscle activation, and functional independence in neurological and orthopedic populations [18,19]. Emerging evidence also suggests that robotic gait training may promote central neuroplastic adaptations, supporting recovery beyond peripheral biomechanics [20]. In addition, knee exoskeletons are increasingly explored for fall prevention, with integrated recovery assistance shown to improve swing-limb kinematics and reduce fall risk in mobility-impaired populations [21]. This highlights the growing use of exoskeletons as both therapeutic and protective devices.

A wide range of technology-based interventions, including virtual reality, telerehabilitation, neuromuscular stimulation, and sensor-driven feedback systems, have been implemented in orthopedic and neurological knee rehabilitation [22-26]. Among these approaches, robotic knee exoskeletons have attracted increasing interest due to their capacity to provide biomechanical support and task-specific training. Despite growing evidence of their potential benefits, substantial gaps remain regarding consistency, affordability, and comparative effectiveness across technologies. With a focus on clinical outcomes, implementation challenges, and integration into rehabilitation care pathways, this systematic review examines knee exoskeletons for gait assistance and rehabilitation, with particular attention to their clinical applications and mechanical components.

This systematic review aimed to critically evaluate knee exoskeletons used for gait assistance and rehabilitation. The objectives were to identify the types of knee exoskeleton systems investigated, the clinical conditions and patient populations in which these devices have been applied, and the reported clinical and biomechanical outcomes associated with their use. In addition, the review identifies key gaps in the existing literature and proposes directions for future research to support the safe, effective, and scalable adoption of advanced rehabilitation technologies.

Methods

Protocol and Registration

This systematic review was registered on PROSPERO (International Prospective Register of Systematic Reviews) under registration number CRD420261285256. The review was conducted and reported in accordance with the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) 2020 guidelines (Checklist 1). Minor methodological changes were made during full-text screening to align the risk-of-bias assessment tools with the final included study designs. These refinements did not affect the overall objectives, eligibility criteria, or review conclusions.

Search Strategy

A comprehensive literature search was conducted across 4 electronic databases: PubMed, Scopus, Web of Science, and IEEE Xplore. The search covered studies published between January 2015 and March 2025, with the final search performed in March 2025. These databases were selected to ensure

XSL•FO
RenderX

coverage of biomedical, rehabilitation, engineering, robotics, and wearable technology literature.

To improve sensitivity and minimize the risk of missing relevant studies, the search strategy combined keywords and synonyms related to exoskeleton technologies and the knee joint. These included terms such as “exoskeleton,” “robotic exoskeleton,” “wearable robot,” “powered orthosis,” and “robotic orthosis,” combined with “knee” or “knee joint,” and terms related to human or clinical testing (eg, “human,” “patient,” “clinical,” “trial,” and “experiment”). Studies that focus solely on simulation, musculoskeletal modeling, finite element analysis, or in silico approaches were excluded at the search level where possible.

Database-specific Boolean search strings were developed and adapted for each platform. The full reproducible search strategies for all databases are provided in Multimedia Appendix 1.

The search was limited to English-language publications due to feasibility constraints in screening and data extraction. Gray literature, trial registries, and industry- or manufacturer-reported studies were excluded because this review focused on peer-reviewed scientific evidence. These decisions may introduce language and publication bias, and this is acknowledged in the limitations.

Eligibility Criteria

Inclusion Criteria

Studies were included if they met the following criteria:

- Investigated knee-focused exoskeletons or robotic knee orthoses designed for gait assistance, rehabilitation, or functional lower-limb activities.
- Involved human participants, including healthy individuals, pediatric populations, or clinical populations with neurological or orthopedic impairments.
- Reported original experimental, observational, feasibility, or clinical trial data and were published as peer-reviewed full-text articles.
- Were published between 2015 and 2025.
- Were available in English.

Exclusion Criteria

Studies were excluded if they:

- Articles, systematic reviews, meta-analyses, editorials, protocols, conference abstracts, or opinion papers were reviewed.
- Investigated multijoint exoskeleton (hip-knee, knee-ankle, or full lower-limb exoskeletons) where knee-specific outcomes could not be isolated.
- Focused solely on simulation, finite element modeling, musculoskeletal modeling, or in silico analysis without human validation.
- Investigated devices not related to knee function or gait rehabilitation (eg, upper-limb exoskeletons).
- Lacked sufficient methodological or outcome data for extraction and evaluation.

Study Process

Following the initial database search, 71 duplicate records were removed, resulting in 2418 unique articles. Study selection was performed in multiple stages.

First, an AI-assisted abstract screening was applied to articles retrieved from Web of Science, IEEE Xplore, PubMed, and Scopus. Screening was performed using the GPT-4 large language model accessed through the OpenAI API. The model was not additionally trained on domain-specific datasets and relied on its pretrained language understanding capabilities. The filtering prompt and classification code were developed by reviewer AZ and applied prior to manual screening (provided in Multimedia Appendix 2). The AI-assisted screening used a prompt-based binary classification approach in which each abstract was evaluated to determine whether the study focused exclusively on knee exoskeletons. The model was instructed to retain studies by default and to exclude articles only when the abstract explicitly involved joints other than the knee (eg, hip, ankle, foot, or multijoint lower-limb systems). In ambiguous cases, studies were retained for further manual evaluation. This conservative filtering strategy was intentionally designed to prioritize sensitivity and minimize false exclusions.

Of the 2418 unique records, 1089 were excluded solely through AI-assisted abstract screening. To validate the performance of the AI-assisted filtering process, a random subset of AI-excluded records was manually reviewed by the authors. This validation confirmed that the majority of excluded studies involved multijoint or non–knee-focused exoskeleton systems. After AI-assisted screening, 71 articles from Web of Science, 21 from IEEE Xplore, 29 from PubMed, and 997 from Scopus remained eligible for subsequent manual screening.

Second, articles retained after AI-assisted screening underwent manual review to confirm eligibility and ensure that the studies focused exclusively on knee exoskeletons and represented original research rather than review articles. Manual screening was performed independently by 4 reviewers (DK, Zeeshan, AN, and ARK). Following AI-assisted and manual screening, 1166 articles were retained for full-text assessment. Full-text screening further evaluated eligibility based on the predefined inclusion and exclusion criteria, resulting in 112 studies selected for data extraction.

Data Extraction and Quality Assessment

Data extraction was performed for all eligible studies following full-text screening. For each study, the following information was systematically extracted and organized into structured tables: author name and DOI, article title, database source, device name, weight, mechanism type, control system, actuators, range of motion, clinical testing details, and patient type. These data formed the basis for qualitative and comparative analysis of knee exoskeleton technologies and applications.

Risk of Bias Assessment

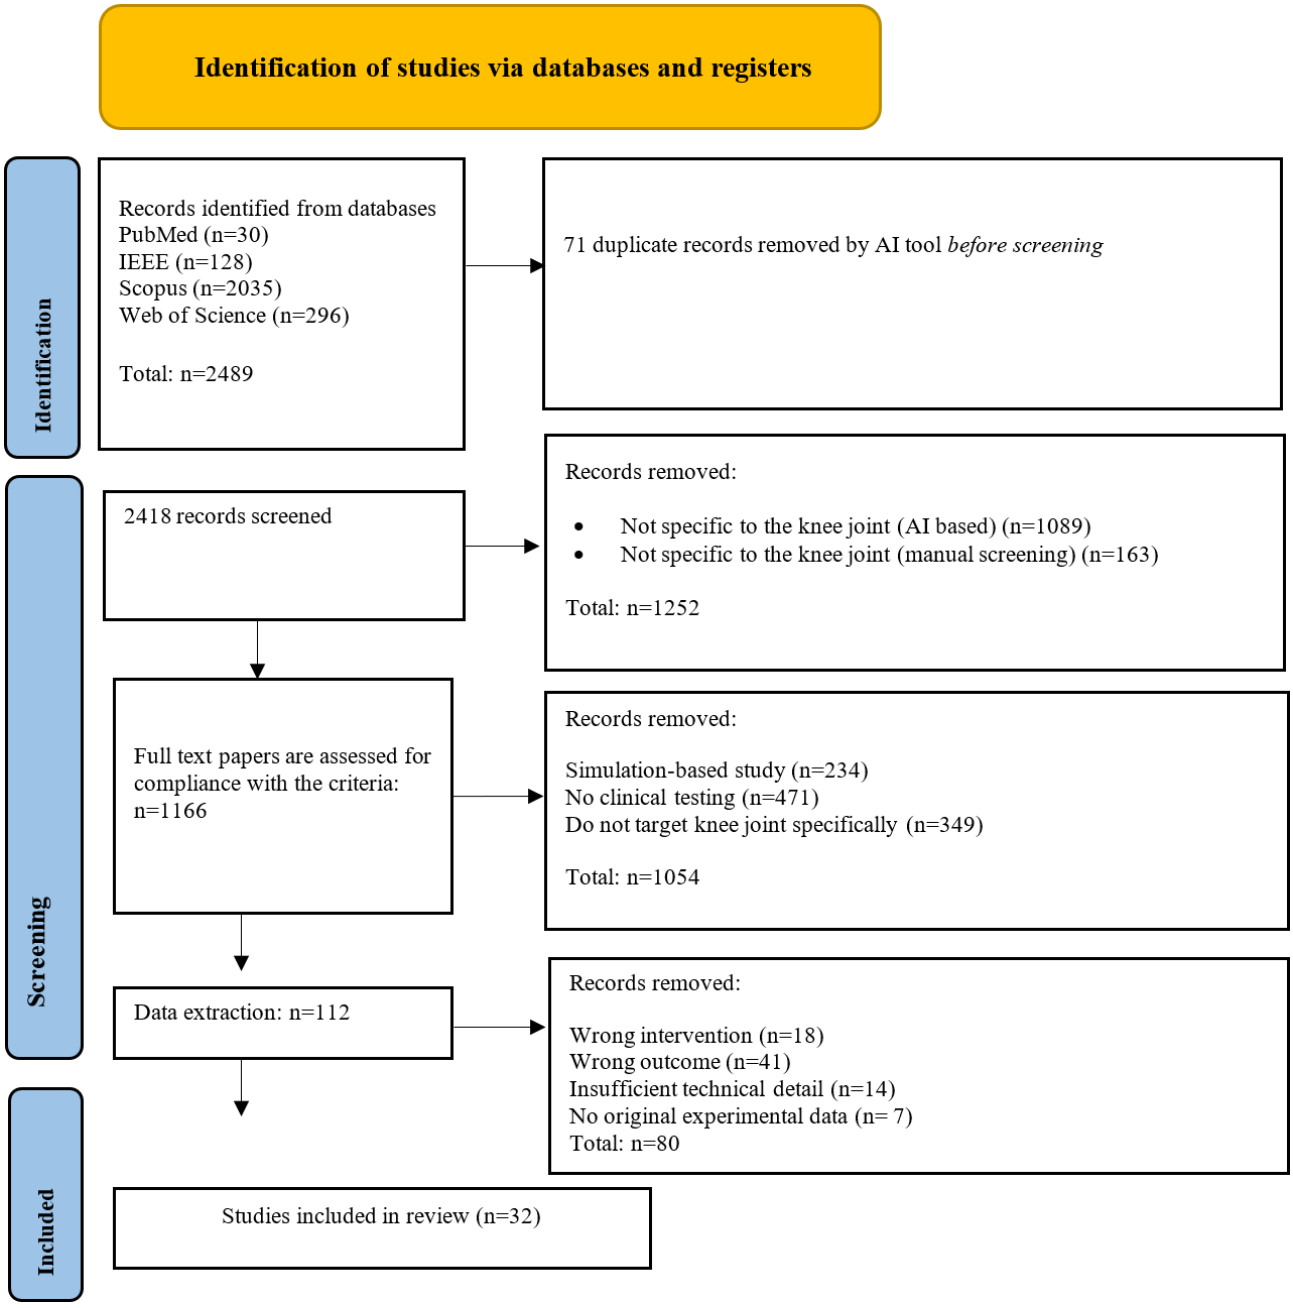
The risk of bias was assessed based on the design and methodological characteristics of the included studies. This approach was adopted because the reviewed literature included randomized clinical trials, nonrandomized clinical studies,

XSL•FO
RenderX

experimental feasibility studies involving healthy participants, and technical validation studies. Risk of bias was assessed according to the study design: randomized controlled trials were evaluated using the RoB-2 tool. Nonrandomized clinical studies involving patient populations were assessed using the ROBINS-I (Risk of Bias in Nonrandomized Studies of Interventions) tool, which evaluates bias due to confounding, participant selection, intervention classification, deviations from intended interventions, missing data, outcome measurement, and selective reporting. Experimental and feasibility studies conducted in healthy participants were assessed using a modified Downs and Black checklist, as these studies typically focus on technical feasibility, biomechanical performance, usability, or short-term functional outcomes rather than clinical efficacy. Risk-of-bias assessment was independently performed by 3 reviewers (DK, PKJ, and Zeeshan), and disagreements were resolved through discussion. Nonhuman validation studies were not assessed using clinical risk-of-bias tools, as they do not evaluate health outcomes, and were analyzed descriptively with emphasis on device architecture, actuation strategy, sensing configuration, control method, and technical validation outcomes.

Risk-of-bias assessments were incorporated into the narrative synthesis, with greater emphasis placed on findings from studies demonstrating lower risk of bias or higher methodological quality.

Results



Study Selection

A total of 32 articles met all inclusion criteria and were included in the final review.

Figure 1 illustrates the overall study selection process, detailing the reasons for excluding certain articles and their corresponding numbers.

RenderX

Figure 1. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flowchart on the selection of papers.

To reflect the multidisciplinary nature of this field and to ensure clarity in synthesizing the evidence, the Results section was divided into two complementary parts. The first part focuses on the engineering perspective, summarizing design concepts, actuation strategies, and control approaches that enable the functionality of knee exoskeletons (Table 1). The second part addresses the clinical perspective, highlighting patient populations, rehabilitation goals, and functional outcomes associated with the use of knee exostheses (Table 1). This structured approach highlights the importance of integrating engineering advances with clinically relevant outcomes to ensure effective rehabilitation.

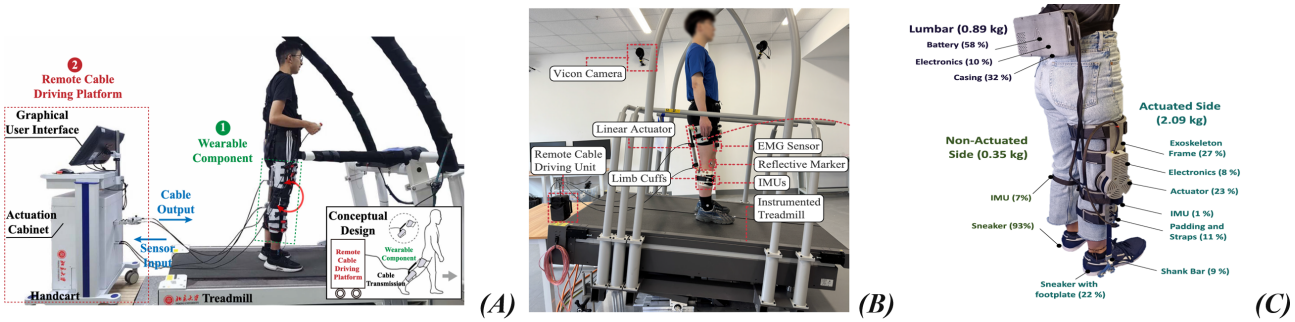
Part 1: Engineering Perspective

Actuation Systems



The choice of actuator in knee exoskeletons is constrained by the trade-off between high-fidelity torque control and the penalties of increased mass, complexity, and reduced portability. Three prevailing actuation paradigms can be identified within this design space: motor-driven rigid joints, compliant or distributed actuation systems, and passive elastic mechanisms.

The most common solution has been electric motor-driven actuation for rehabilitation-focused devices and gait-assist, one of which is shown in Figure 2A. In such systems, direct current or brushless direct current motors are typically used, with gear reductions used to provide repeatable, controllable knee torques, which can be used in closed-loop torque or impedance control

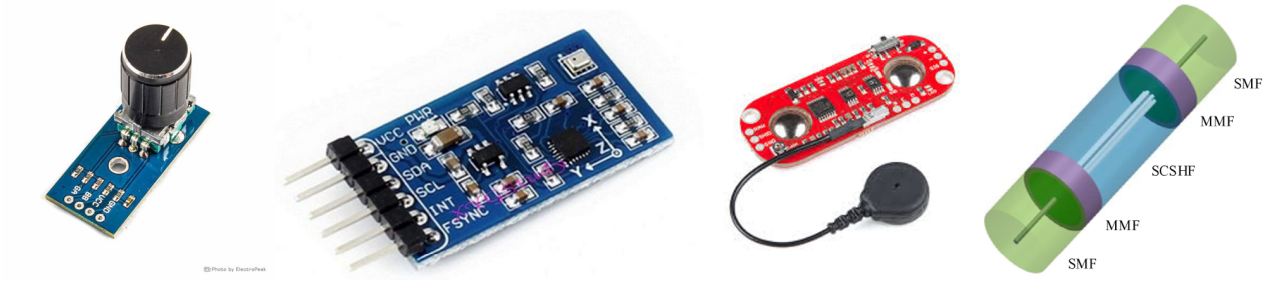
XSL•FO
RenderX

structures [29,34,38,42,56]. It provides accurate command tracking and can be easily combined with sensor-based feedback required for safe interactions during rehabilitation activities. In the reviewed literature, assistive torques typically range from 5 to 30 Nm, which is consistent with the mechanical loads of level walking and early rehabilitation [29,31,36,44,56]. Stair-climbing or perturbation-recovery devices are designed for more challenging tasks that require much higher torque capability, with peak assistive torques of nearly 40 Nm [21,33]. They usually accept larger actuators, higher transmission gears, and external power. To dampen interaction forces in high-impedance motorized joints, several papers have added compliance to the actuation chain, either in series-elastic or mechanically compliant form. This was done to enhance shock resistance and the accuracy of torque regulation [45,54].

Figure 2. Representatives of different actuation architectures in knee exoskeletons: (A) a rigid motor-driven powered exoskeleton using electric motor actuation with gearbox transmission for precise torque control [56], (B) a rigid-soft hybrid exoskeleton combining a rigid frame with compliant elements to improve comfort and reduce joint misalignment [31], and (C) a passive knee exoskeleton using coil-spring mechanisms to store and return elastic energy during gait without external power [52]. EMG: electromyography; IMU: inertial measurement unit.

By contrast, a second design focuses on interaction quality and wearability with compliant or distributed actuation. Examples of such solutions include hybrid rigid-soft exoskeletons and hinge-free textile-based exosuits, which redistribute mass closer to the interface, as shown in Figure 2B [31]. The objects of these systems maintain natural knee kinematics and reduce discomfort associated with joint misalignment. Although compliant actuation is less disruptive and less damaging, it presents engineering challenges, including transmission and friction losses and a more complex calibration process.

The third paradigm comprises passive knee exoskeletons that store and recover elastic energy without external power or closed-loop control. Assistance during certain stages of motion is provided by coil springs and compliant mechanisms, as shown in Figure 2C, thereby reducing device mass and simplifying the mechanism [32,49,52]. These systems have the benefit of being portable and low-complexity, but do not offer flexibility across users and tasks.



The smaller group of papers investigated hydraulic artificial muscles as an alternate actuation concept, also driven by their high force density and natural compliance, especially when a high torque is needed in large knee flexion angles [33,43]. Given these merits, fluidic actuation systems introduce considerable complexity in pressure and power control. They can only be applied to tethered concept prototypes, thereby hampering translational scalability.

Sensor Design and Engineering Integration

All powered knee exoskeletons have joint-level kinematic sensing as the basic sensing layer. Rotary encoders, as shown in Figure 3A, in the actuation or transmission system can provide high-resolution knee angle measurements needed to control closed-loop torque, knee position, or impedance [34,38,39,54]. In engineering terms, encoder-based sensing operates in a high-bandwidth, low-latency range, but its accuracy also depends on mechanical alignment. Various studies underscore that encoder measurements reflect device joint motion rather than the actual motion of the anatomy, making them susceptible to joint-axis misalignment and soft-tissue deformation.

XSL•FO
RenderX

Figure 3. Examples of sensor modalities integrated into knee rehabilitation exoskeletons: (A) rotary encoder mounted at the joint axis for high-resolution knee angle measurement [58], (B) inertial measurement unit (IMU) attached to the leg segment for gait-phase detection and swing-stance classification [59], (C) surface electromyography (sEMG) electrodes placed over the quadriceps for real-time motor intention estimation [60], and (D) polymer optical fiber (POF) embedded in a textile sleeve for nonrigid kinematic sensing [61]. MMF: multimode fiber; SCSHF: single-core six-hole microstructure optical fiber; SMF: single-mode fiber.

(A) Rotary encoder *(B) IMU sensor* *(C) EMG sensor* *(D) Optic fiber*

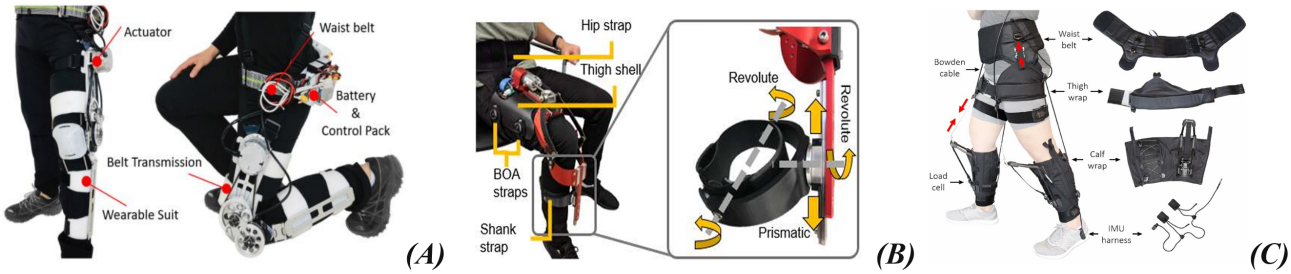
Most systems use gait-phase detectors based on inertial measurement units (IMUs), shown in Figure 3B, and plantar pressure sensors to provide task-oriented support, particularly while walking. IMUs provide the segment's angular velocity and orientation, thereby supporting the detection of swing-stance transitions across different walking speeds [29,31,46,56]. Plantar pressure sensors or foot switches provide temporally accurate event information, for example, heel strike and toe-off, and are often used with IMU data to enhance robustness and minimize false state changes [35,46]. The current success of multimodal gait sensing has been a companion to recognition throughout the field due to the limited reliability of single-sensor modalities across conditions, particularly for impaired gait patterns.

A smaller body of related work uses surface electromyography (EMG) to infer purpose and control assistance in real time [36,48,50]. In engineering terms, EMG, shown in Figure 3C, provides an entirely new control signal that occurs before joint motion and, in theory, may enable predictive assistance. There are some practical difficulties identified with the implementation of EMG, such as electrode placement sensitivity, signal variability due to fatigue or perspiration, and susceptibility to motion artifacts. These properties require complex signal-processing pipelines and frequent recalibration, thereby restricting the use of EMG-based sensing to a laboratory setting.

The third way is an emerging technique in nonrigid, textile-based sensing technologies to overcome the comfort and alignment constraints of solid sensor attachment. The use of polymer optical fiber-based strain sensors, shown in Figure 3D, in wearable sleeves indicates that it is possible to measure knee kinematics without placing mechanical limits on the joint [27]. Although these methods make wearable objects less sensitive to alignment and motion tracking, they are currently used predominantly for motion detection rather than for closed-loop actuation.

Control Strategies and Algorithms

The control strategies for knee exoskeletons have been designed to balance accuracy in assistance timing, stability in interactions, and computational viability against real-time requirements. In the literature reviewed, control architectures are always hierarchical, with high-level task or gait-state estimation.



A finite-state machine (FSM)–controlled walking aid is most often implemented for gait-phase-driven control. FSMs allow deterministic, phase-specific assistance modulation in stance and swing, and conform control output to the gait cyclic pattern, with minimal computational cost [29,31,42,46,48]. The method is quite appealing for rehabilitation because the duration of assistance can be predicted. However, FSM-based control is very sensitive to both the correctness and precision of state transitions; misclassifying the gait phase will cause assistance at the wrong time and result in poor-quality interaction.

Some studies use assist-as-needed control strategies, in which the level of assistance is regulated based on the user's interaction forces or task execution [37,39,57]. From an engineering perspective, these solutions are based on the localization of control complexity. That is, a way of state timing, which necessitates stable low-level controllers and robust sensing. Although assist-as-needed paradigms provide enhanced customization, they are mostly done in a heuristic manner, and few formal reports on stability indicators have been described in the studies reviewed.

Knee exoskeletons are dominated by low-level torque- and impedance-based control. Torque monitoring enables direct regulation of assistive moments and is applicable to systems with built-in torque sensors or series compliance [34,45]. Instead, we use impedance control, which is commonly used to reduce interaction forces caused by joint misalignment and to maintain back drivability, particularly in comfort-based designs as depicted in Figure 4A,B [38,54]. As illustrated in Figure 4C, the hinge-free exosuit redistributes actuation forces through Bowden cable routing anchored to textile thigh and calf wraps, with a load cell and IMU harness enabling force and kinematic sensing without imposing any rigid constraint on the knee joint axis. Though it has less control bandwidth, it offers the benefit of perceived transparency, at the cost of achievable responsiveness in high-torque or high-speed processes.

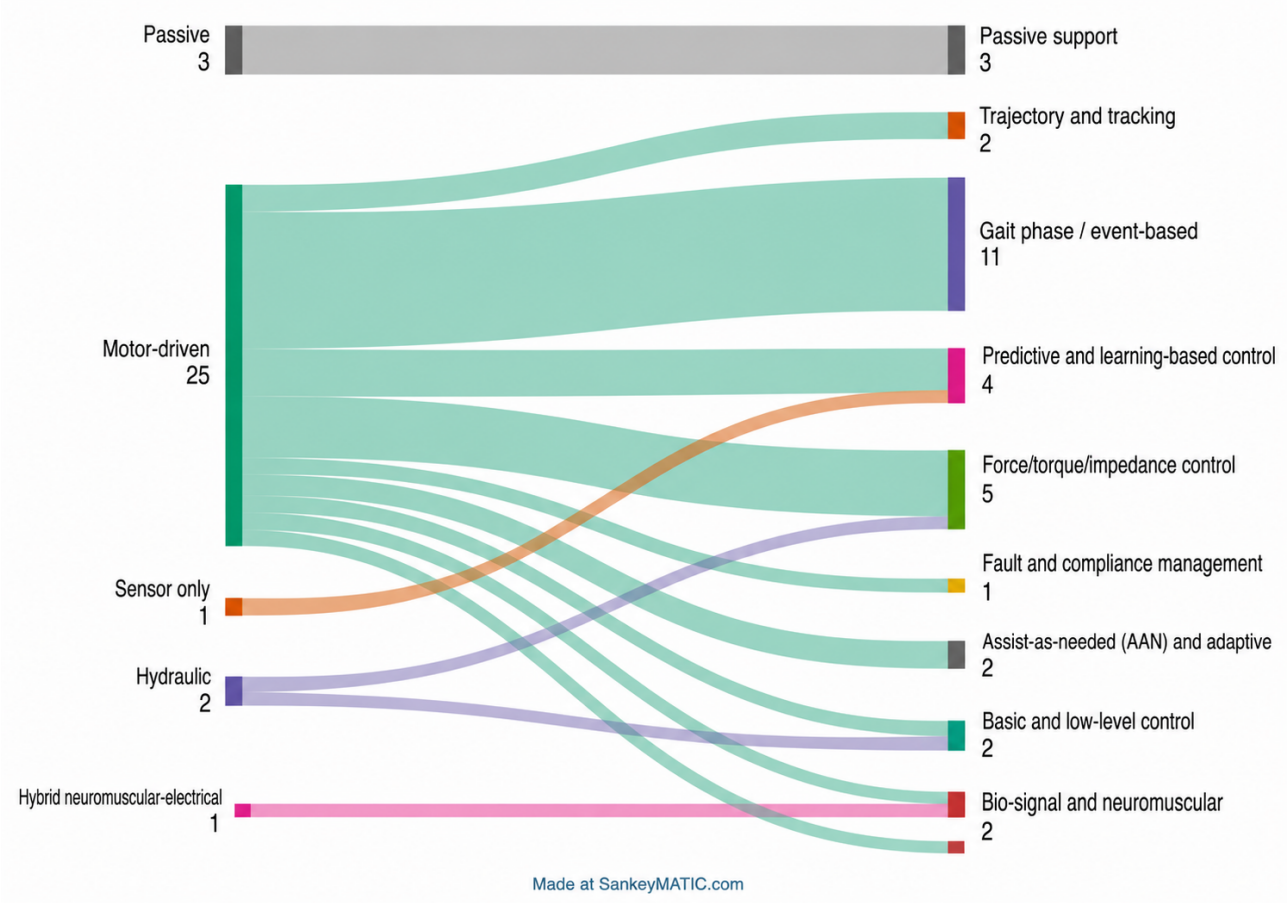
XSL•FO
RenderX

Figure 4. Representatives of different structural design and alignment strategies in knee exoskeletons: (A) a lightweight, back drivable knee exoskeleton featuring a low-ratio transmission for improved transparency and reduced distal inertia [38], (B) a powered knee exoskeleton with a self-aligning mechanism designed to accommodate anatomical variation and reduce parasitic joint forces [54], and (C) a hinge-free tethered exosuit that replaces rigid linkages with textile-based cable routing, preserving natural knee kinematics [40]. BOA: BOA system straps; IMU: inertial measurement unit.

More complex control techniques, such as explicit model predictive control, human-in-the-loop optimization, and machine-learning-based controllers, are reported in fewer studies [30,39,48]. The same strategies are expected to enhance adaptability by incorporating predictive models and iterative optimization. They have shown promising results in controlled experiments but are only practical when model-dependent, computationally expensive, and require large amounts of calibration or training data.

Engineering Limitations and Challenges

Although substantial advances have been made in developing knee exoskeletons, the reviewed articles indicate a range of inherent engineering issues that limit their effectiveness, wearability, and translational appropriateness. Such restrictions are not limited to designs but are repeated as systems of the subsystems of actuation, sensing, control, and human-robot interface.



One of the major limitations is the mechanical misalignment between the exoskeleton joint and the anatomical knee axis, which increases discomfort and reduces the efficacy of assistance. In systems with tuned joint-level sensory and torque control, the error is due to soft-tissue deformity and anatomical differences in residual limbs. Multiple attempts to reduce these effects include self-aligning or compliant interfaces, but these solutions introduce additional mechanical complexity and mass and represent an open-ended trade-off between alignment strength and structural simplicity [54].

Another prevailing challenge is the mass and inertia of devices. Exoskeletons with motorized knees usually require greater mass and battery capacity, leading to higher distal inertia and reduced user acceptance. To deliver mass in proximity and enhance wearability, hybrid rigorous-soft architecture and remote actuation strategies are currently being explored, but these methods have their own problems: transmission friction, hysteresis, and sensitivity to environmental conditions make repeatable torque delivery difficult to achieve [31,40,56].

Among other observations, one major finding is that the choice of actuation implicitly limits the entire system architecture. Figure 5 demonstrates that motor-driven systems prevail in the field, and the most diverse control strategies are supported. This is an indication of the predictability and controllability of the electric motors, as well as an indicator that designers are willing to trade the added mass, inertia, and alignment sensitivity to gain the ability to predict the torque generation. Other actuation ideas, such as compliant, passive, or hydraulic actuation, are much less common because they introduce new issues related to controllability, scalability, or power control [34,42]. This implies that the design of knee exoskeletons is constrained by the challenge of achieving both high torque authority and wearability within a single system.

XSL•FO
RenderX

Figure 5. Sankey diagram illustrating the relationship between actuation mechanisms and control architectures across the included knee exoskeleton studies. Arrow width is proportional to the number of studies using each combination. Motor-driven actuation is linked to the widest range of control strategies, reflecting its prevalence and versatility in the reviewed literature. Diagram created using SankeyMATIC [62].

Limitations about sensing also limit the reliability of control. Encoder-based joint sensing quantifies device motion rather than anatomy motion and is thus sensitive to alignment errors, whereas IMU-based gait phase estimation is prone to errors in abnormal gait patterns. All these concerns are part of the problem of the absence of standard benchmarks for sensing accuracy, latency, and durability under realistic operating conditions.

These sensing and mechanical constraints are closely linked to control challenges. FSM-based gait controllers offer robustness and simplicity but lack flexibility when gait patterns deviate from nominal cycles. On the other hand, adaptive and learning-based controllers impose additional computational and modeling constraints that are likely to compromise real-time reliability and safety. It is worth noting that there is limited research on formal stability assessment or long-term assessment, and there remains an open question regarding the performance of controllers when fatigued, affected by sensor drift, or used over long periods of the day [30,39,48].

Lastly, the absence of engineering standards impedes meaningful comparisons across studies. Measures such as energy efficiency, long-term functionality, and durability are not commonly addressed, even though they directly affect practical use. In the absence of regular evaluation of these factors, it remains difficult to estimate the effectiveness of these design trade-offs in nonexperimental settings.

To conclude, engineering issues include energy efficiency and long-term operability. Battery capacity, power consumption, and thermal management are rarely measured in standardized units, even though they directly influence portability and user compliance.

Risk of Bias Quality

Risk of bias and methodological quality were assessed according to study design using the Cochrane RoB-2 tool [63] for randomized controlled trials, ROBINS-I [64] for nonrandomized clinical studies, and a modified Downs and Black checklist [65] for experimental and feasibility studies (Figures 6 and 7, Table 2). Among the nonrandomized clinical studies assessed using ROBINS-I, most were rated as having a moderate risk of bias [28,29,44,51,57] (Figure 6). The most common sources of bias were confounding, participant selection, and lack of blinding during intervention delivery and outcome assessment. One study was classified as having a serious risk of bias due to substantial methodological limitations and potential confounding [33]. The randomized crossover clinical trial by Rodríguez-Fernández et al [42] was rated as having an overall low risk of bias according to the RoB-2 tool (Figure 7). However, some concerns were identified regarding deviations from intended interventions, as participant blinding was not feasible in wearable exoskeleton studies.

RenderX

Experimental and feasibility studies evaluated using the modified Downs and Black checklist generally demonstrated fair-to-good methodological quality. Total scores ranged from 15 to 19 points (Table 2). Three studies achieved "good" (19 points) quality ratings [30,31,52], whereas the remaining studies were classified as "fair." Overall, studies consistently provided detailed descriptions of exoskeleton architecture, control strategies, sensor integration, and outcome measures. However, important methodological limitations were identified. External validity was often limited because most studies used small convenience samples, healthy participants, or single-subject feasibility designs, thereby reducing generalizability to broader clinical populations. Randomization and blinding were generally not feasible. In addition, none of the included experimental studies reported formal power calculations or sample-size justification, indicating a persistent risk of bias in the statistical power domain.

Two studies involving benchtop or no human-validation experiments were not assessed using formal clinical risk-of-bias tools because they did not evaluate patient outcomes or clinical interventions [37,38]. Instead, these studies were analyzed descriptively with emphasis on technical reporting quality, actuator validation, sensor integration, and controller performance. Both studies provided detailed engineering descriptions and reproducible experimental protocols; however, their findings remain limited to laboratory validation settings and cannot be generalized to clinical rehabilitation outcomes.

Part 2: Clinical Perspective

Study Populations and Clinical Settings

This section summarizes the clinical, biomechanical, and user-oriented outcomes of knee exoskeletons for gait improvement and rehabilitation. The presented studies span orthopedic, neurological, pediatric, and healthy populations and investigate both powered and passive knee exoskeleton systems across laboratory, clinical, and real-world settings.

Among the included studies, 22 studies were conducted in healthy adult participants, primarily to evaluate feasibility, safety, biomechanical effects, and control strategies. Clinical populations were investigated in 8 studies: neurological populations represented the largest clinical subgroup and included individuals with stroke, multiple sclerosis, spinal cord injury, and hemiplegic paralysis [29,42,44,46,57]. Orthopedic applications were limited to patients in the early postoperative phase after total knee arthroplasty [28], whereas pediatric populations included children and adolescents with cerebral palsy, crouch gait, or knee-extension deficits [50,51]. In addition, two studies were conducted without human participants [37,38].

Neurological Rehabilitation Outcomes

Knee exoskeletons were most frequently used in neurological gait rehabilitation. In stroke and multiple sclerosis populations, portable, powered knee exoskeletons have been shown to be feasible and safe, with participants able to complete overground walking tasks without major adverse events [29]. Improvements were reported in spatiotemporal gait parameters and walking performance, although responses varied across individuals and control strategies.

In a randomized crossover clinical trial involving individuals with spinal cord injury, a knee-powered exoskeleton demonstrated improved walking efficiency compared with conventional knee-ankle-foot orthoses, highlighting the potential of active knee assistance to reduce ambulatory effort [42]. Poststroke clinical trials have reported improvements in gait control and adaptability when assistance levels are adjusted to task demands or individual user characteristics, particularly during the stance and swing phases of gait [44,57]. Swing phase–specific assistance was associated with increased knee flexion and improved foot clearance during walking in patients with hemiplegic stroke [17].

Orthopedic and Postsurgical Applications

Orthopedic applications were primarily represented by a clinical trial involving patients undergoing early rehabilitation following total knee arthroplasty. In this study, the integration of a robotic knee device within 48 hours postsurgery was reported to be safe and well-tolerated [28]. Participants successfully completed assisted exercises, including passive mobilization, sit-to-stand transitions, and gait training, with no significant adverse events reported. Patient satisfaction was high, and clinical outcomes were comparable to those achieved with conventional rehabilitation protocols, suggesting that knee exoskeletons may serve as a feasible adjunct during early postoperative recovery. However, despite these promising preliminary findings, validated clinical evidence for orthopedic and postsurgical applications of knee exoskeletons remains extremely limited. Most of the currently available studies are feasibility-focused, involve small sample sizes, and lack long-term follow-up or controlled, comparative designs. In addition, there remains insufficient data on other orthopedic conditions, indicating a significant gap in the current literature and a need for larger clinical trials for specific conditions.

Pediatric Rehabilitation and Gait Correction

Pediatric studies primarily addressed pathological gait patterns, particularly crouch gait and impaired knee extension in children and adolescents with cerebral palsy. Powered knee exoskeletons were associated with clinically meaningful improvements in knee extension during stance and reductions in crouch gait severity [51]. In a case-based study, combining mechanical knee assistance with noninvasive neuromuscular electrical stimulation led to greater improvements in knee extension than exoskeleton assistance alone, highlighting the potential benefits of multimodal rehabilitation strategies in pediatric populations [50].

Functional Tasks and Outcome Domains

Across the included studies, level walking was the most assessed functional task, evaluated in both healthy and clinical populations [29,42]. Additional tasks included stair ascent [33], sit-to-stand transitions [28], squatting [49], stumble recovery [21], jumping [52], and community ambulation in outdoor environments [53].

Clinical outcome measures clustered into four main domains:

XSL•FO
RenderX

1. Gait performance and biomechanics, including walking speed, knee range of motion, joint moments, and stance- and swing-phase characteristics [29,31,51].
2. Neuromuscular outcomes, such as muscle activation amplitude, coordination, and interaction torque, reflecting reductions in muscular demand during assisted walking [36,41,50].
3. Physiological and effort-related outcomes, including metabolic cost and fatigue, with several studies reporting reduced energetic demand during exoskeleton-assisted gait [30,40,49].
4. User-centered outcomes, including comfort, safety, stability, alignment, and perceived trust, are particularly emphasized in studies addressing interface design and migration resistance [45,54].

Relationship Between Engineering Design and Clinical Outcomes

Clinical and biomechanical outcomes were frequently associated with specific engineering design characteristics across the included studies, as shown in Table 3. Motor-driven exoskeletons with gait-phase-based control were among the most commonly investigated systems in neurological rehabilitation and were associated with improvements in gait coordination, swing-phase assistance, and walking support in individuals with stroke and spinal cord injury [29,42,44,57]. Similarly, assist-as-needed and adaptive control strategies were developed to modulate assistance in response to user performance and task demands, thereby supporting individualized rehabilitation approaches [48,57].

Table . Relationship between engineering design features and reported clinical or biomechanical outcomes.

Engineering feature or technical configuration	Reported clinical or biomechanical outcome	Representative studies
Gait-phase-based motor control	Improved gait timing, coordination, and assistive synchronization	Kim et al, 2015 [35]; Wang et al, 2023 [55]
Assist-as-needed and adaptive control	Personalized rehabilitation and task-specific gait assistance	Zhang et al, 2023 [48], de Miguel Fernández et al, 2023 [57]
Passive elastic actuation	Reduced muscular effort and assistance during repetitive movement	Hidayah et al, 2021 [49], Ben-David et al, 2022 [52]
High-torque motor-driven systems	Improved support during rehabilitation and pathological gait assistance	Kittisares et al, 2020 [43], Rodríguez-Fernández et al, 2022 [42]
Hybrid rigid-soft structures	Reduced joint misalignment and improved comfort during walking	Wang et al, 2023 [56]
Self-aligning and polycentric knee mechanisms	Improved biomechanical alignment and preservation of physiological knee kinematics	Sarkisian et al, 2021 [54], Olinski et al, 2025 [47]
EMG[a]-driven intention recognition	Improved synchronization between user intention and robotic assistance	Villa-Parra et al, 2018 [36], Zhang et al, 2023 [48]
NMES/FES[b]-triggered robotic assistance	Increased voluntary muscle activation and enhanced motor relearning potential	Shideler et al, 2020 [50]
Assistance/resistance multimodal training	Improved peak knee flexion and gait endurance after stroke rehabilitation	de Miguel Fernández et al, 2023 [57]
IMU[c]-based outdoor gait monitoring	Improved evaluation of community ambulation and ecological walking behavior	Goffredo et al, 2022 [53]
Cable-driven lightweight exoskeleton systems	Improved comfort and reduced restriction of natural gait motion	Wang et al, 2023 [56]
Adaptive oscillator-based gait prediction	Improved real-time gait synchronization and assistive timing	Wang et al, 2023 [55]

[a]EMG: electromyography.

[b]NMES/FES: neuromuscular electrical stimulation/functional electrical stimulation.

[c]IMU: inertial measurement unit.

Passive and compliant exoskeleton systems have been commonly investigated for repetitive movement assistance and the reduction of muscular effort in healthy individuals [40,49,52]. However, these systems generally provided lower torque output and limited adaptability for pathological gait correction. In contrast, higher-torque motorized systems (10 - 40 Nm) were more frequently used for stair climbing, perturbation recovery, and poststroke rehabilitation tasks that require greater movement support and stabilization [21,33,43].

Several studies also emphasized the importance of wearable comfort, joint alignment, and interface compliance for user acceptance and stability during assisted gait [45,54]. Hybrid rigid-soft architectures, self-aligning mechanisms, and hinge-free exosuit designs were specifically developed to reduce joint misalignment and preserve more physiological gait kinematics while maintaining assistive functionality [31,40,54,56]. Overall, the reviewed studies demonstrated that rehabilitation outcomes were influenced not only by torque generation capacity but also

XSL•FO
RenderX

by sensing modalities, control strategies, biomechanical alignment, and human-robot interaction design.

Discussion

Bridging Engineering Innovation and Clinical Reality

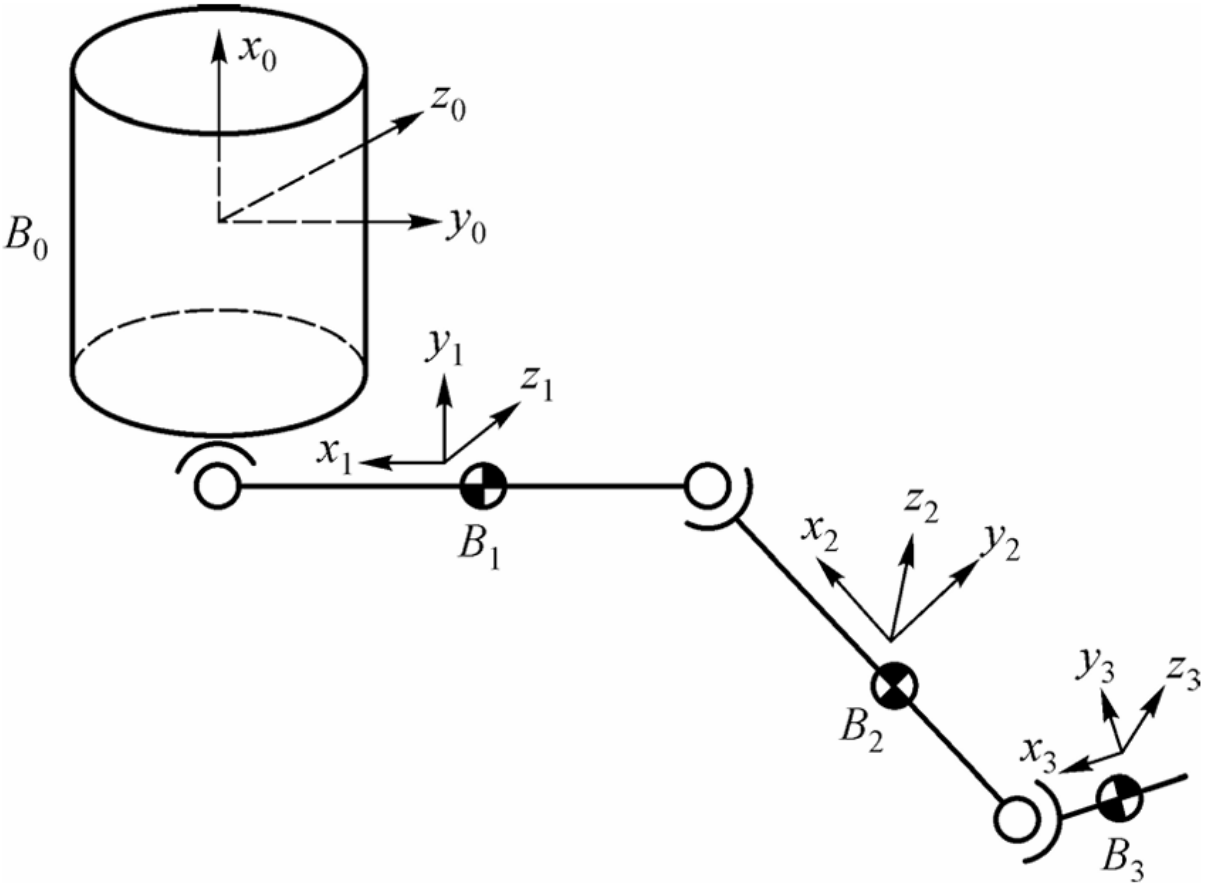
Over the last 10 years, significant progress has been made in knee exoskeleton research, particularly in actuator design, sensor integration, and control system development [38,39,48,54,56]. From an engineering perspective, the domain has evolved significantly in complexity. Nevertheless, a closer look at the literature reveals that clinical validation has not kept up with this advancement. The risk-of-bias assessment indicates that current evidence supporting knee exoskeletons is methodologically heterogeneous. Although engineering reporting and technical characterization are generally robust, clinical evidence remains constrained by small sample sizes and the moderate risk of bias. Therefore, the strength and generalizability of the current evidence regarding long-term clinical efficacy should be interpreted with caution.

Many published studies continue to be conducted in laboratory settings, primarily involving healthy subjects rather than those with neurological or orthopedic conditions [29,32,45,48-50,55]. Although these investigations are essential for confirming feasibility and safety, they fail to fully address the intricacies of rehabilitation in practice.

Motor-driven exoskeletons remain the leading technology in this area due to their ability to accurately adjust assistive torque and their effective integration with control frameworks that use torque and impedance principles [31,34,42,54,56]. In structured walking activities, these systems can consistently provide assistance that varies with the gait cycle phase. Nevertheless, achieving greater torque capability often requires larger actuators and transmission mechanisms, thereby increasing distal mass and inertia [31,40,42,54]. These mechanical additions may influence natural gait mechanics and metabolic demand, yet these effects are not consistently quantified. In rehabilitation settings, the trade-off between torque capacity and wearability becomes particularly relevant, as long-term use depends on comfort and tolerance rather than peak output.

Passive and hybrid systems have emerged as attempts to address these limitations by emphasizing transparency and reduced mechanical burden [32,40,49,52]. Passive elastic devices have demonstrated measurable biomechanical effects during controlled tasks such as squatting and jumping [49,52]. However, their assistance profiles are inherently task-specific and less adaptable to the variability observed in pathological gait. Hybrid rigid-soft architectures seek to preserve torque capability while improving interface compliance and load distribution [31,54,56]. Although conceptually promising, comparative data demonstrating superior long-term outcomes are still limited. Taken together, the current evidence suggests that future progress may depend less on maximizing mechanical output and more on refining the balance between assistance magnitude, comfort, and adaptability to individual impairment.

The review demonstrated that rehabilitation outcomes were strongly influenced by engineering characteristics such as actuation type, control architecture, and interface compliance, highlighting the importance of biomechanically aligned and task-specific exoskeleton design.



Knee Biomechanics

The observed results in clinical and biomechanical parameters can be directly interpreted using fundamental knee biomechanics. When walking on a flat surface, knee biomechanics are characterized by coordinated changes in joint kinematics and kinetics, particularly during the initial stance phase, in which knee flexion and extension moments regulate shock absorption and stability [66,67]. During daily activities, tibiofemoral forces can reach 2 - 4 times body weight during level walking and up to 5 times body weight during stair descent, highlighting the substantial mechanical demands placed on the joint [68,69]. These biomechanical requirements emphasize the need to develop an exoskeleton adaptable to various tasks.

Figure 8 shows a biomechanical model of the human lower limb, representing the femur and tibia as rigid bodies interconnected by ligamentous and contact elements, used to estimate knee joint kinematics and loading. This framework provides a physiological basis for designing knee exoskeletons that deliver assistive torques aligned with natural joint motion and internal force distributions.

XSL•FO
RenderX

Figure 8. Mechanical model of human lower limbs. The figure illustrates the mechanical representation of the human lower limb modeled as a kinematic chain of rigid segments (pelvis, thigh, leg, and foot), each assigned a local coordinate system to define joint orientations and interactions [68].

Clinical data show that altered knee mechanics lead to pain and functional disorders. Although the peak moment of external knee adduction shows a weak overall correlation with knee pain in osteoarthritis, dynamic anomalies, such as varus deformity, are associated with pain, underscoring the importance of frontal-plane stability [70]. After total knee replacement, knee extension moments decrease in patients, and joint load increases during downhill walking, indicating continued biomechanical vulnerability in the early stages of rehabilitation [71]. Similarly, patients after anterior cruciate ligament reconstruction exhibit altered kinematics during rehabilitation [72]. Overall, knee exoskeletons must integrate accurate anatomical sensing, adaptive control, and compliant actuation to modulate joint moments without disrupting natural movement, underscoring the critical need to align engineering design with clinical biomechanics.

Human-Robot Interface: A Determinant of Clinical Viability

Across studies, the quality of the human-robot interface consistently influences system performance, even when not explicitly analyzed. Mechanical misalignment between the anatomical knee axis and the exoskeleton joint can introduce parasitic torques and increase soft tissue stress [40,42,43,51,54]. Several groups have proposed self-aligning mechanisms, polycentric linkages, and improved suspension strategies to address this issue [33,42,54]. These refinements have been associated with improved user comfort and perceived naturalness of movement.

Despite these advances, many clinical investigations do not systematically report alignment errors, device migration, or long-duration wear tolerance [31,44,52,57]. This omission is clinically meaningful. Rehabilitation depends on repetition and sustained engagement; even minor discomfort or instability may alter neuromuscular activation patterns or reduce adherence over time. Emerging work examining embodiment and user perception suggests that when assistance feels mechanically coherent with voluntary movement, users integrate the device more effectively [44,57]. For this reason, interface optimization should be considered central to rehabilitation efficacy rather than an accessory design feature.

Control Strategies: Reliability vs Personalization

Control architecture remains a defining feature of knee exoskeleton systems. FSM-based controllers remain widely used in clinical contexts for their deterministic phase segmentation and predictable assistance timing [21,31,33,38,39,41,45-47,51]. In patient populations where safety is paramount, this reliability provides practical advantages.

XSL•FO
RenderX

More advanced strategies, including impedance control [38,54], model predictive control [39], human-in-the-loop optimization [30], EMG-driven assistance [36,50], and neuromusculoskeletal model-informed machine learning [48], have demonstrated promising personalization capabilities in controlled environments. For example, human-in-the-loop optimization has reduced metabolic costs in healthy participants [30], and EMG-based systems enable modulation of assistance based on muscle activation signals [36,50]. However, these approaches are rarely evaluated in larger or clinically heterogeneous cohorts [44,57].

Furthermore, few studies report performance under fatigue, uneven terrain, prolonged daily use, or sensor drift [30,39,48]. Without such validation, it is difficult to determine whether algorithmic complexity yields meaningful clinical benefit. At present, clinical implementation appears to favor robustness and predictability over adaptive sophistication.

Assistance Timing and Implications for Motor Learning

Across the reviewed literature, phase-specific assistance consistently contributes to functional improvement. Systems that target swing-phase knee flexion or stance-phase extension tend to improve toe clearance, knee extension, and gait symmetry while preserving voluntary muscle contribution [46,50,51,53]. This observation suggests that the timing of assistance may be more critical than continuous torque magnitude.

In contrast, trajectory-enforced systems may risk reducing active neuromuscular participation [42,44]. Since rehabilitation aims to facilitate motor relearning rather than to replicate passive movements, this distinction is important. Studies in pediatric cerebral palsy populations demonstrate that appropriately timed extension assistance can reduce crouch gait severity without suppressing voluntary engagement [50,51], supporting the concept of deficit-targeted assistance.

However, most outcome assessments are performed during active device use [31,44,57]. Postintervention follow-up is uncommon, making it difficult to determine whether improvements represent true motor adaptation or temporary mechanical augmentation. Longitudinal retention studies remain necessary to clarify this distinction.

Clinical Interpretation and Functional Relevance

Short-term improvements in knee kinematics, gait symmetry, and metabolic efficiency were consistently reported across studies. However, these findings were predominantly derived from studies conducted in healthy participants under controlled laboratory conditions [30,31,40,49].

Evidence from clinical populations, including individuals with stroke, spinal cord injury, and cerebral palsy, remains comparatively limited and heterogeneous [29,42,44,51,57]. While some studies reported improvements in gait parameters and walking efficiency, these findings are based on small sample sizes, short-duration interventions, and variable study designs. Therefore, the strength of evidence supporting clinical effectiveness is substantially lower than that observed in healthy populations.

Importantly, most reported improvements occurred during active exoskeleton use, with limited assessment of retention or transfer of gains after device removal [31,44,57]. This raises uncertainty about whether the observed improvement represents true motor rehabilitation or temporary performance augmentation driven by mechanical assistance.

Short-term improvements in knee extension, step symmetry, and metabolic efficiency have been reported in stroke, spinal cord injury, pediatric cerebral palsy, and postsurgical populations [28,31,36,38,42,44,46,50,51]. In spinal cord injury, powered assistance reduced ambulatory effort compared to orthotic support [42]. Early postoperative implementation after total knee arthroplasty has been reported to be feasible and safe [28].

Nevertheless, most studies involve small cohorts and brief intervention periods [29,44,57]. Outcome measures frequently emphasize kinematic and biomechanical metrics, whereas participation-level outcomes and quality-of-life indicators are less consistently reported [35,37,53]. While biomechanical improvements confirm device functionality, sustained functional independence and integration into daily activities remain the ultimate rehabilitation goals.

The available evidence therefore supports short-term performance enhancement, but durable rehabilitation benefit has not yet been conclusively demonstrated. Larger randomized trials with extended follow-up are required to determine whether knee exoskeleton–assisted training yields meaningful, lasting functional gains.

State of the Field and Translational Challenges

Collectively, the literature indicates that knee exoskeleton technology has achieved a high degree of mechanical and algorithmic sophistication [39,48,54,56]. However, clinical validation remains comparatively early in development [31,44,57]. The field appears technologically advanced yet still consolidating in terms of rehabilitation evidence.

Future progress will likely depend on closer integration between biomechanical analysis, interface refinement, control robustness, and longitudinal clinical evaluation. Demonstrating sustainable functional outcomes in real-world contexts will ultimately determine whether knee exoskeletons transition from promising prototypes to established rehabilitation tools.

Study Limitations

This review is limited by substantial heterogeneity in device design, control strategies, populations, and outcome measures, which precluded quantitative meta-analysis. Many included studies were exploratory or feasibility-focused and frequently involved healthy participants, limiting generalizability to clinical populations. Reporting of mechanical specifications, adverse events, and long-term follow-up was inconsistent, constraining cross-study comparison. Additionally, most studies assessed outcomes only during device use, providing limited insight into retention or neuroplastic effects.

XSL•FO
RenderX

Furthermore, a substantial proportion of included studies were conducted in healthy participants or involved early-stage feasibility or prototype validation, limiting the direct clinical applicability of the findings.

Future Research Directions

Future research should more explicitly align mechanical design and control strategies with specific rehabilitation objectives. Mechanical parameters such as torque capacity, range of motion, and assistance timing should be justified based on task demands and population needs rather than maximized by default. Adaptive and uncertainty-aware control approaches that show promise in healthy users should be systematically evaluated in clinical populations with attention to safety, usability, and interindividual variability.

Most importantly, future studies should move beyond short-term feasibility testing and controlled laboratory demonstrations. Well-designed, multicenter randomized controlled trials are needed, with larger, clinically representative samples, predefined primary outcomes, and standardized intervention protocols. Longer follow-up periods should be included to determine whether improvements persist after device removal and whether observed gains reflect true rehabilitation effects rather than temporary device-assisted performance.

Future trials should include patient-important outcomes, not only biomechanical parameters. These should include functional independence, walking, endurance, fall risk, participation in daily activities, quality of life, and user satisfaction. Greater standardization of outcome measures that integrate biomechanical, functional, and participation-level domains would strengthen cross-study comparisons and improve clinical interpretation. This would help determine whether knee exoskeletons can provide meaningful rehabilitation benefits beyond short-term improvements observed during assisted use.

Conclusions

In summary, knee exoskeleton devices demonstrated consistent short-term improvements in biomechanical and performance-related outcomes, particularly under controlled laboratory conditions [30,31,40,49]. However, the current evidence is largely derived from small-scale studies, frequently involving healthy participants or short-duration feasibility trials [29,44,57].

Evidence from clinical populations remains limited and heterogeneous, with insufficient high-quality data to support routine clinical implementation in physical therapy and rehabilitation practice. While preliminary findings suggest potential benefits for gait rehabilitation, these results should be interpreted cautiously due to methodological limitations, including small sample sizes, lack of long-term follow-up, and variability in outcome measures [29,42,44,57].

Future research should prioritize well-designed, multicenter randomized controlled trials with clearly defined primary outcomes, longer intervention and follow-up periods, and inclusion of patient-centered outcomes such as functional independence, fall risk, and participation. These factors are critical for establishing the true clinical value and translational potential of knee exoskeleton-assisted rehabilitation.

Abstract

Background: Serious games have become an alternative support for traditional physical therapy. However, many of these games do not address the emotional needs of patients. People with disabilities often experience emotions such as sadness, frustration, and even anger, which can create a barrier to their rehabilitation treatment.

Objective: This review presents a comprehensive overview of technologies, techniques, and methods in affective computing as applied to serious games for physical rehabilitation and identifies key gaps to guide future research in this field.

Methods: A scoping review was conducted following PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines, using the databases PubMed, ScienceDirect, IEEE Xplore, ACM Digital Library, PEDro, Springer, and Google Scholar.

Results: The initial search yielded 5293 records, of which 9 papers met the inclusion criteria. Data were systematically extracted from these papers based on predefined research questions. Notably, engagement, tiredness, and pain were the most identified emotions, reported in 4 of 9 (50%) studies. Only 3 studies applied theoretical frameworks for emotion classification. Facial expression analysis and gesture recognition were the most frequently used affective computing techniques, yet only 2 studies implemented adaptive gameplay based on affective feedback.

Conclusions: The integration of affective computing into serious games represents a promising approach for detecting affective states in patients undergoing rehabilitation. However, the limited number of primary studies, methodological limitations, and potential selection and reference-standard biases limit the reliability and generalizability of the current findings. Future research should prioritize rigorous multicenter designs, standardized evaluation protocols, and multidisciplinary collaboration. Developing these areas is essential to establishing clinical effectiveness.

Introduction

Overview of Serious Games for Physical Rehabilitation

Physical rehabilitation is a therapeutic approach aimed at improving the quality of life for individuals who have lost mobility in one or more body parts. Rehabilitation typically involves a series of repetitive exercises using the affected limb to gradually regain mobility. However, the repetitive nature of these exercises often becomes monotonous, leading to patient boredom and, in many cases, therapy discontinuation [1].

To address these challenges, alternative interventions such as serious games have been developed. Serious games are video

XSL•FO
RenderX

games designed to be both entertaining and educational [2]. They have great potential for training, motivation, and entertainment. One of their key features is the ability to simulate reality in a virtual environment, enhancing user immersion and concentration. These types of games have been used in various fields, including health, education, politics, and engineering. Specifically, serious games designed for physical rehabilitation aim to provide a more motivating environment, enhance treatment adherence, and make repetitive exercises more engaging. They provide a different context within therapeutic interventions to help patients reacquire, recover, and maintain physical capabilities, thereby improving quality of life [3]. Applications include motor recovery following stroke, gait rehabilitation, Parkinson disease, multiple sclerosis, orthopedic recovery, and physical stimulation for individuals with cerebral palsy [4,5]. These interventions have gained considerable attention among researchers and health care professionals due to their potential to address complex rehabilitation needs through innovative technologies [6].

A wide range of serious games has been developed for physical rehabilitation [7,8], which have shown positive results compared to conventional rehabilitation therapies. For instance, these games enhance the quality, enjoyment, and effectiveness of rehabilitation by providing an engaging environment and varying levels of difficulty based on injury severity. They can also overcome logistical limitations by enabling patients to engage in therapy remotely, attending clinical sessions only when necessary [5,9]. However, literature reviews show that most existing platforms focus on motor metrics, such as range of motion and kinematics, and often overlook the patients' affective state, including frustration from pain and feelings of sadness, depression, or anxiety [9,10]. Consequently, there are significant gaps in achieving an optimal balance between game challenge and emotional engagement.

One approach to improving interaction between patients and serious games is affective computing, a type of human-computer interaction that enables systems to recognize and adapt to users' affective states [11]. Evidence suggests that dynamic adaptation based on affective states in serious games can enhance rehabilitation outcomes by improving motivation, performance, and treatment adherence [12]. Additionally, affective computing offers real-time diagnostic capabilities that allow for personalized adjustments in gameplay in response to detected emotional cues [13].

Theoretical Background

Affective Computing

Picard [11] introduced the term "affective computing," defining it as "computing that relates to, arises from, or deliberately influences emotion." This definition highlights 3 key elements: (1) recognition, for detecting and classifying affective states; (2) expression, for displaying affective states through interaction media such as avatars; and (3) influencing affect, by using emotional models to guide behavior and decision-making.

Affective computing integrates input recognition to create an affective loop, a dynamic process in which the user's emotional states and the system's responses continuously interact through perception, interpretation, and emotional feedback [14]. Ideally, the system should not only detect or model emotions but also actively influence the user's affective experience, forming a closed loop in which the user's emotional state shapes the system's behavior and, in turn, the user's emotional experience.

Affective computing enables a more interactive and personalized experience by considering users' affective states. Several studies have focused on patient care. For example, Maj et al [15] developed a system that enhances care for individuals with chronic conditions or those in rehabilitation by continuously monitoring their affective state. This system also provides real-time affective feedback and virtual companionship through a personal assistant module, offering emotional support and helping to reduce loneliness and isolation. The benefits of affective computing have been demonstrated in digital mental health interventions [16,17], adaptive systems that adjust difficulty based on users' cognitive or emotional states [18], human-robot interactions with real-time emotion recognition and task adaptation [19], and adaptive systems with real-time feedback [20]. When combined with serious games, affective computing allows adaptive systems to modify game parameters in response to users' emotions, such as reducing difficulty during stress or sadness and increasing it when users are motivated or engaged.

Emotion Recognition Techniques

According to Hurst et al [21], affective recognition techniques can be categorized into invisible and visible inputs. Invisible inputs detect physiological signals imperceptible to the human eye, such as electrodermal activity or heart rate variability. Conversely, visible inputs include observable behaviors such as facial expressions and body movements.

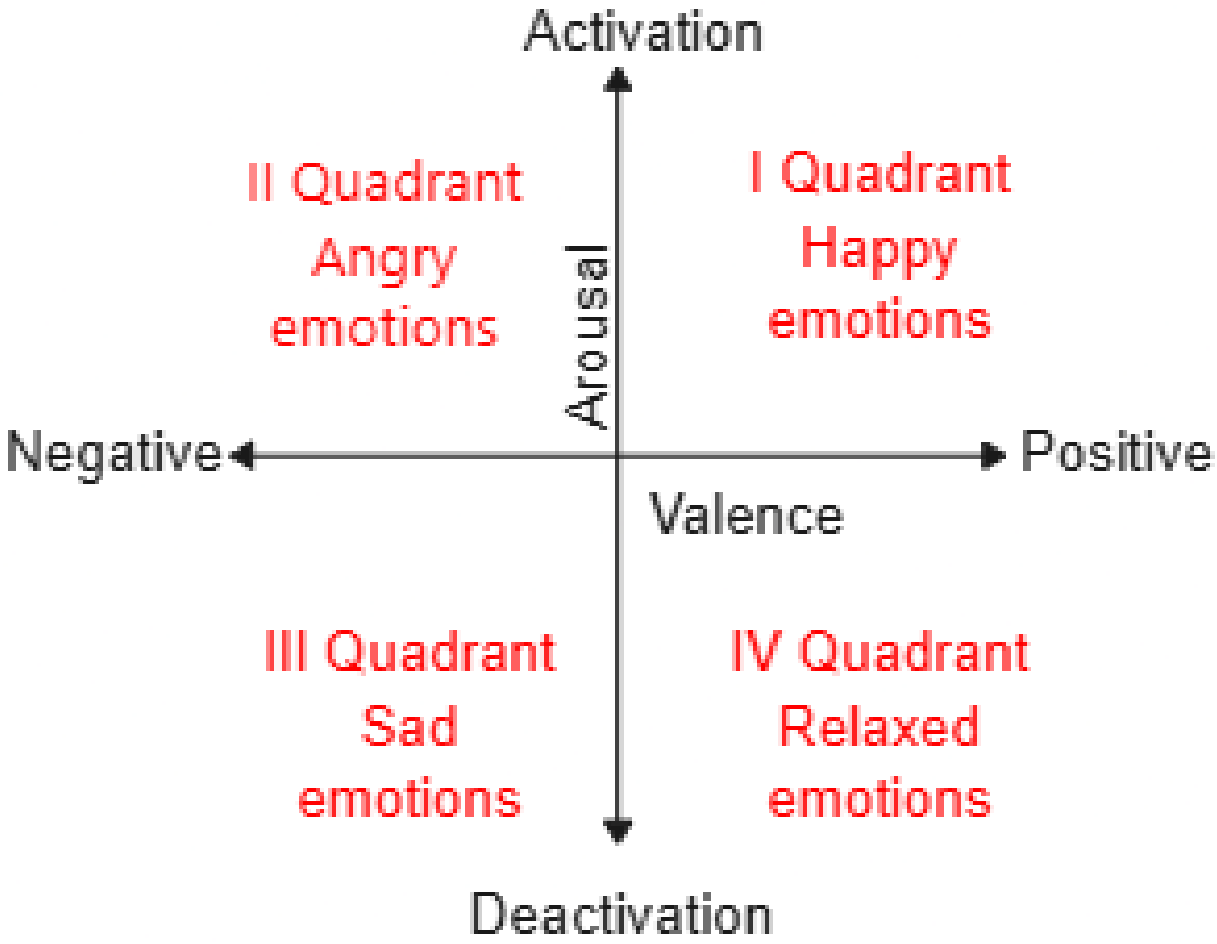
Techniques based on invisible inputs generally use sensors that are placed on a part of the body. However, these techniques may present some challenges, such as mild discomfort for the individual when sensors are attached to the body. The most commonly used techniques are based on electrocardiogram and electroencephalogram (EEG). The electrocardiogram is an electrical tracing of the heart and is recorded noninvasively by electrodes placed on the body. EEG is a test that measures the brain's electrical activity by placing electrodes, which are small metal discs, on the scalp.

Techniques based on visible inputs do not require the user to be in direct contact with a sensor. Examples include facial expression analysis, user behavior monitoring, and gesture recognition. Facial expression techniques gather information about affective states from facial cues, even at rest. As a result, many studies have explored the link between facial movements and affective states [22]. User behavior techniques infer emotional states based on interaction with the system, including task performance, time spent on tasks, number of clicks, and mouse movement [23]. Gesture recognition techniques infer emotions from motor responses such as body movement, hand movement, or finger pressure [24].

Emotions are difficult to identify. According to Gonçalves et al [25], emotions are triggered by interrelated changes in 5 components: cognitive appraisals, behavioral tendencies, motor

XSL•FO
RenderX

expressions, physiological reactions, and subjective feelings. To detect emotions efficiently, it is necessary to use a combination of tests that include as many components as possible. Therefore, no single emotion recognition technique is sufficient on its own.



Models for Classifying Affective States

The classification of affective states varies across studies; however, 2 principal models are predominantly used in affective computing: the discrete emotion model and the dimensional emotion model [26].

One discrete model is that proposed by Ekman [27], which conceptualizes emotions as discrete, measurable, and linked to physiological responses. Ekman identified 6 basic emotions considered to be universal: happiness, sadness, anger, fear, surprise, and disgust. In contrast, Plutchik [28] proposed a model comprising 8 basic emotions: joy, fear, surprise, trust, sadness, anger, disgust, and anticipation, organized in a wheel-like structure. This model suggests that more intense emotions are located at the center of the wheel, while less intense emotions are found at the periphery.

Dimensional models were introduced to overcome the limitations of discrete models by acknowledging the complexity and fluidity of emotional experiences [29-32]. For instance, Russell [30] developed the circumplex model based on valence and arousal to represent complex emotions, in which emotions are classified within quadrants. The model proposes a 2-axis plane, where the x-axis represents valence, indicating the degree of pleasure or displeasure (positive or negative), and the y-axis represents arousal, symbolizing the level of activation or deactivation. The first quadrant represents emotions associated with happiness, the second encompasses emotions related to anger, the third includes sadness, and the fourth is associated with calm emotions. The circumplex model is illustrated in Figure 1.

Figure 1. Illustration of the valence-arousal model proposed by Russell [30].

Related Works

Recent advances in affective computing focus on developing techniques to detect affective states and integrating real-time affective feedback within adaptive systems. This is especially relevant in digital health, human-computer interaction, and intelligent rehabilitation. For instance, one study shows that emotion-sensitive adaptive approaches can promote task persistence and enhance in-game performance [33]. Another review finds that machine learning models support real-time personalization of psychological treatments by including behavioral and affective signals [34]. A systematic review by Leong et al [35] focused on facial emotion recognition, evaluating classification techniques and technologies used,

XSL•FO
RenderX

while emphasizing the increasing use of deep learning. Despite its contributions, the review is limited to 2 emotion recognition techniques and does not examine adaptive mechanisms within the software.

These studies do not focus specifically on physical rehabilitation, where emotional engagement is essential for treatment adherence. Therefore, there is a critical need to explore how affective computing can support empathetic interactions in rehabilitation contexts, through either the adaptation of gameplay elements or the application of novel emotion detection techniques.

Objective

This paper presents a scoping review of affective computing technologies, techniques, and methods used in serious games for physical rehabilitation, following the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) guidelines. It offers a comprehensive overview of the current research and highlights key gaps for future developments in this field.

Research Questions

To assess the current landscape of research in affective computing within serious games for physical rehabilitation, the following research questions were formulated:

RQ1: What theoretical approaches to emotion were applied in the studies, and which emotions were recognized?

RQ2: What techniques, including sensors and algorithms, were used for emotion recognition?

RQ3: Which game elements were adapted in response to affective state detection?

RQ4: What specific hardware was used to support the rehabilitation process?

Methods

Study Design

Given the objective of providing a broad overview of the literature and the diverse nature of the research questions, a scoping review was determined to be the most appropriate methodological approach. Scoping reviews are particularly suitable when the volume of publications or the heterogeneity of the topic precludes more focused methodologies such as systematic reviews [36].

This study adhered to the reporting standards outlined in the PRISMA protocols extension for scoping reviews [37] (Checklist 1).

Inclusion and Exclusion Criteria

Due to the limited available literature on this particular topic and to ensure the inclusion of all relevant contributions, studies with varied designs and outcome measures were considered. The inclusion criteria were as follows: papers published in English, regardless of publication date; studies that used affective computing within a serious game for physical rehabilitation; and studies that involved at least 1 patient in the evaluation process. Participants in the included studies were required to have a condition necessitating physical rehabilitation.

Review papers (eg, systematic reviews, scoping reviews, and literature reviews) were excluded to focus on primary empirical evidence.

Information Sources and Search Strategy

A comprehensive literature search was carried out in March 2024 and updated in February 2025 across the following databases: Google Scholar, PubMed, ScienceDirect, IEEE Xplore, ACM Digital Library, SpringerLink, and PEDro (Physiotherapy Evidence Database). The search strategy used the following keywords: “(affective OR emotional) AND serious (game OR games) AND rehabilitation.” The number of results retrieved from each database is presented in Table 1.

Table . Databases used.

Database	Results, n
Google Scholar	4370
PubMed	38
ScienceDirect	453
IEEE Xplore	5
ACM Digital Library	41
SpringerLink	354
PEDro	32

Selection of Sources of Evidence

Three authors independently reviewed the records obtained through the search. Duplicate entries were removed using Mendeley Desktop (version 2.122.0) Reference Manager. Studies that met the inclusion criteria based on the title and abstract were retrieved in full text for further evaluation. Any disagreements among the reviewers were resolved by a fourth reviewer, who made the final decision.

Data Charting Process and Data Items

Once the primary papers were identified, each was analyzed by at least 2 reviewers. These reviewers were responsible for extracting essential information from each study. Subsequently,

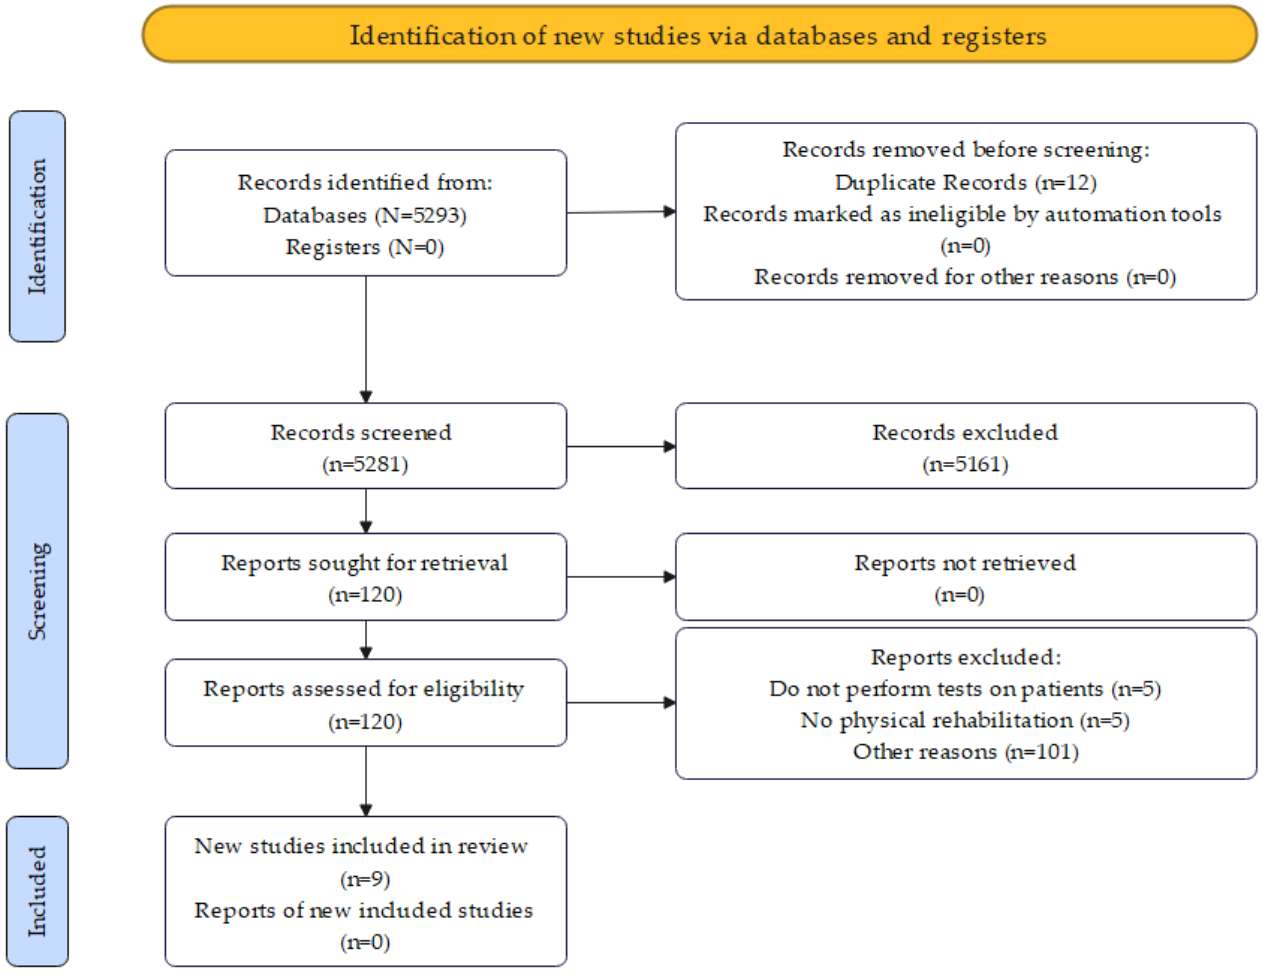
XSL•FO
RenderX

the reviewers met to reach a consensus on the extracted data. The following data items were identified per paper: study, citation, affective computing technique, sensor or device used to detect affective states, population characteristics (age and sex), type of disease, type of rehabilitation, game elements adapted in response to affective states, affective states detected, machine learning algorithms or software used for affective state detection, and theoretical approaches to affective states.

Assessment of the Quality of the Included Studies

The methodological quality of the selected studies was evaluated using the QUADAS-2 (Quality Assessment of Diagnostic Accuracy Studies) tool [38], which assesses 5 domains: sample selection, index test, reference standard, flow, and timing (Multimedia Appendix 1). Risk of bias and overall study quality were reviewed by 2 authors. Any disagreements in the assessment process were resolved through discussion and consensus within the research team. Question 1 in domain 3 was modified to require at least 2 tests to validate the target condition. The question was modified because, although there is no gold standard for validating emotions, Gonçalves et al [25] suggest that 5 components should be considered: cognitive appraisals, behavioral tendencies, motor expression, physiological reactions, and subjective feelings. Although validating the emotion using the 5 components would be more effective, it is also more complex. For this reason, it was expected that at least 2 tests would be used.

Synthesis of Results



A formal narrative synthesis was conducted to evaluate the influence of affective computing on the rehabilitation process.

Results

Selection and Characteristics of Sources of Evidence

A total of 5293 records were identified through database searching. After removing 12 duplicate records, 5281 records were screened based on title and abstract, of which 5161 were excluded. As a result of this screening process, the full texts of 120 reports were sought for retrieval, all of which were successfully obtained and assessed for eligibility. Of these, 111 reports were excluded for various reasons, including interventions involving healthy individuals, games not involving physical rehabilitation, or review papers. Finally, 9 studies were included in the systematic review (Figure 2).

Figure 2. PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) flow diagram illustrating the selection process of the included studies.

RenderX

Results From Individual Sources of Evidence

Analysis of the Research Questions

RQ1: What theoretical approaches to emotion were applied in the studies, and which emotions were recognized?

As shown in Table 2, 3 of the analyzed studies used the dimensional model [39-41], while the others did not specify the emotion model applied. The authors noted that affective states were classified as discrete (eg, pain and fatigue), enabling researchers to address these states as events requiring immediate intervention by therapists or the rehabilitation systems. Additionally, psychophysiological states were identified as having a direct impact on patients' motor performance.

Overall, the studies address affective states with direct clinical relevance to patient progress: (1) pain and anxiety are the main barriers to motor recovery, as they may lead patients to discontinue therapy; (2) physical and psychological fatigue are critical to monitor to prevent overexertion and frustration; and (3) engagement and motivation are essential for long-term treatment adherence. Studies such as those by Rivas et al [42,43] also highlight the interdependence among these states. For example, pain often coexists with anxiety, while engagement rarely occurs alongside extreme fatigue.

RQ2: What techniques, including sensors and algorithms, were used for emotion recognition?

Analysis of the 9 studies indicates that affective computing in virtual rehabilitation uses sensor-based techniques, artificial intelligence (AI) algorithms and models, and data integration to assess patients' affective states.

Sensor-Based Techniques

The reviewed studies classify sensors into 3 primary categories based on their nature and degree of intrusiveness.

- Movement-based and force-based systems: A notable trend in the field is the adoption of low-cost devices that integrate 3D position and pressure sensors to capture hand location and grip strength [42-46]. This nonintrusive approach allows affective states to be inferred directly from rehabilitation platform data, eliminating the need for additional sensors on the patient.
- Physiological and neurophysiological signals: Neurophysiological signals, especially EEG, are used to capture brain activity for the direct interpretation of affective states. Some approaches classify basic emotional valence (positive or negative) [41], while others use wearable devices to monitor complex states such as engagement, boredom, or frustration. These methods are also applied in areas such as gait rehabilitation [40].
- Computer vision and posture capture: The application of visual sensors has evolved from specific limb tracking, such as hand position analysis by Funabashi et al [47], to more robust multimodal approaches. Recent studies integrate conventional webcams for simultaneous analysis of facial expressions and body posture [42-45]. This integration enables a more comprehensive, contextually informed interpretation of the user's affective state.

[b]Games perform dynamic adaptation.

Algorithms and AI Models

The evolution of algorithms in this field has progressed from simple classifiers to architectures capable of addressing the complexity and interdependence of affective states: (1) probabilistic and Bayesian models, such as Semi-Naive Bayesian classifiers, have been used by Rivas et al [42,43,45,46] to support patients who have experienced stroke during upper-limb rehabilitation exercises; (2) dependency models, including multilabel approaches such as Circular Classifier Chains, have been implemented to simultaneously recognize multiple affective states (eg, pain, anxiety, and fatigue) [42,43]. These algorithms are critical because they account for the correlation among affective states; (3) fuzzy logic has been used in the Emphatic Virtual Caregiver system developed by Tironi et al [39], which applies fuzzy inference to process patient performance and affective state, thereby enabling smooth, natural transitions in the virtual caregiver's responses; (4) traditional machine learning techniques, such as support vector machines [44], have been documented in preliminary stages for classifying affective states, including tiredness, tension, pain, and satisfaction, based on descriptors of 3D hand movement and finger pressure.

Data Integration and Fusion

A trend in the papers is the adoption of multiple techniques for detecting affective states. Rather than relying on a single sensor, the systems proposed by Rivas et al [42-45] combine data from limb movements, facial expressions, and finger pressure. This integration permits the fusion algorithm to function as a higher-level layer, weighting information from each source to generate a more robust final emotional label that is resilient to noise and variability among different motion-sensing devices.

RQ3: Which game elements were adapted in response to affective state detection?

This research question seeks to determine which elements of serious games are adapted or modified in response to users' affective states. Four categories of adaptation were identified: auditory, visual, difficulty, and no adaptation.

Auditory Adaptation

Auditory adaptation is primarily used to regulate negative emotions and increase user engagement in serious games for rehabilitation, generally through background music and sound effects. This approach is frequently implemented when users display negative emotions despite correct task performance, indicating that auditory feedback serves as a compensatory mechanism to improve mood without changing the task structure, as observed in Hou and Sourina [41].

Visual Adaptation

Visual adaptation is a flexible approach to addressing users' affective states by modifying graphical user interface elements, such as avatars, environments, lighting, and in-game objects. These adaptations occur at expressive and environmental levels, involving modifications in facial expressions, gestures, object configurations, color schemes, and visual complexity.

At the expressive level, systems dynamically adjust avatar behavior to reflect users' emotional states, enabling empathetic responses through facial expressions and body movements, as implemented in Tironi et al [39]. At the environmental level, visual properties of the game—such as object shapes, colors, and scene configuration—are modified in response to users' affective states, particularly when negative emotions are detected despite adequate performance, as reported by Hou and Sourina [41].

Overall, visual adaptation works as both a reactive mechanism and a tool for modulating the user's emotional experience. This dual capacity highlights its potential to reflect and influence affective states in rehabilitation contexts.

XSL•FO
RenderX

Difficulty Adaptation

Difficulty adaptation is based on flow theory [48], which highlights the need to balance task challenge with the user's ability to maintain engagement. This balance is especially important in rehabilitation, where tasks must be adjusted to avoid both frustration and disengagement.

Hou and Sourina [41] found that task difficulty increases when users perform successfully and show positive affect. If negative affect is present, task difficulty remains unchanged. This asymmetry indicates a conservative adaptation strategy, prioritizing performance-driven progression while minimizing risks linked to lowering task demands.

No Adaptation

Unlike studies that incorporate adaptive mechanisms, some investigations do not adjust game elements in response to emotional recognition. In these instances, affective computing serves primarily analytical functions and does not directly influence system dynamics.

For example, Funabashi et al [47] evaluate user engagement and affective responses without altering gameplay. Similarly, Rodriguez et al [40] use electroencephalographic signals to identify emotional states, but do not use this information to modify game behavior.

Other studies use various machine learning algorithms for emotion recognition, but these data are not used to adjust game elements in real time. However, the authors agree that identifying states such as pain, anxiety, or fatigue aims to personalize rehabilitation tasks.

Specifically, Rivas et al [42-46] focus on improving the accuracy of affective state inference and propose involving adaptive mechanisms in future research. These mechanisms include adjusting difficulty levels and modifying the virtual environment to maintain a safe, motivating, and needs-based therapeutic context for patients.

The results show that affective computing in rehabilitation remains in a validation phase focused on identifying affective states. Analysis of the studies indicates that researchers have prioritized accurate identification of patients' affective states, such as stress, fatigue, or anxiety, before delegating clinical decision-making to software. The limited implementation of adaptation implies a lack of consensus regarding appropriate system responses to detected emotions, such as whether the system should halt or adjust task difficulty when negative emotions are identified.

RQ4: What specific hardware was used to support the rehabilitation process?

Analysis of the 9 included studies identifies a diverse technological infrastructure designed to support therapeutic exercise and enhance interactivity. Hardware used in physical rehabilitation can be categorized into 3 functional groups: nonintrusive motion capture sensors, haptic devices, and visualization and immersion hardware.

Nonintrusive Motion Capture Sensors

The reviewed studies demonstrate the use of nonintrusive technologies to capture movement during rehabilitation, allowing natural user interaction without invasive wearable devices. Rivas et al [42-46] use 3D position sensors to record therapeutic movements and supplement this data with webcams to capture facial expressions and gestures, enabling richer analysis through multiple data sources.

Similarly, Funabashi et al [47] use the Microsoft Kinect for Xbox One, which uses RGB-D (red, green, blue, and depth) technology to track and evaluate body movement. This device supports rehabilitation therapies by enabling patients to manipulate virtual objects with hand movements, fostering intuitive interaction within gamified therapeutic settings.

Collectively, these approaches demonstrate a trend toward the incorporation of accessible and nonintrusive sensors that enable accurate motion capture and integration with additional modalities. This integration supports a more comprehensive assessment of patients' performance in rehabilitation settings.

Haptic Devices

The literature highlights the use of specialized hardware to facilitate user interaction with rehabilitation environments. These technologies vary according to therapeutic objectives, ranging from high-precision haptic devices such as the Novint Falcon for controlling serious games [41] to advanced robotic assistance like the *Lokomat*. The *Lokomat* enables lower-limb rehabilitation by integrating body-weight support and robotic legs with a treadmill [40]. Additionally, customized interfaces have been developed, including sensorized levers designed to quantify grip strength and finger pressure during exercise [42-45].

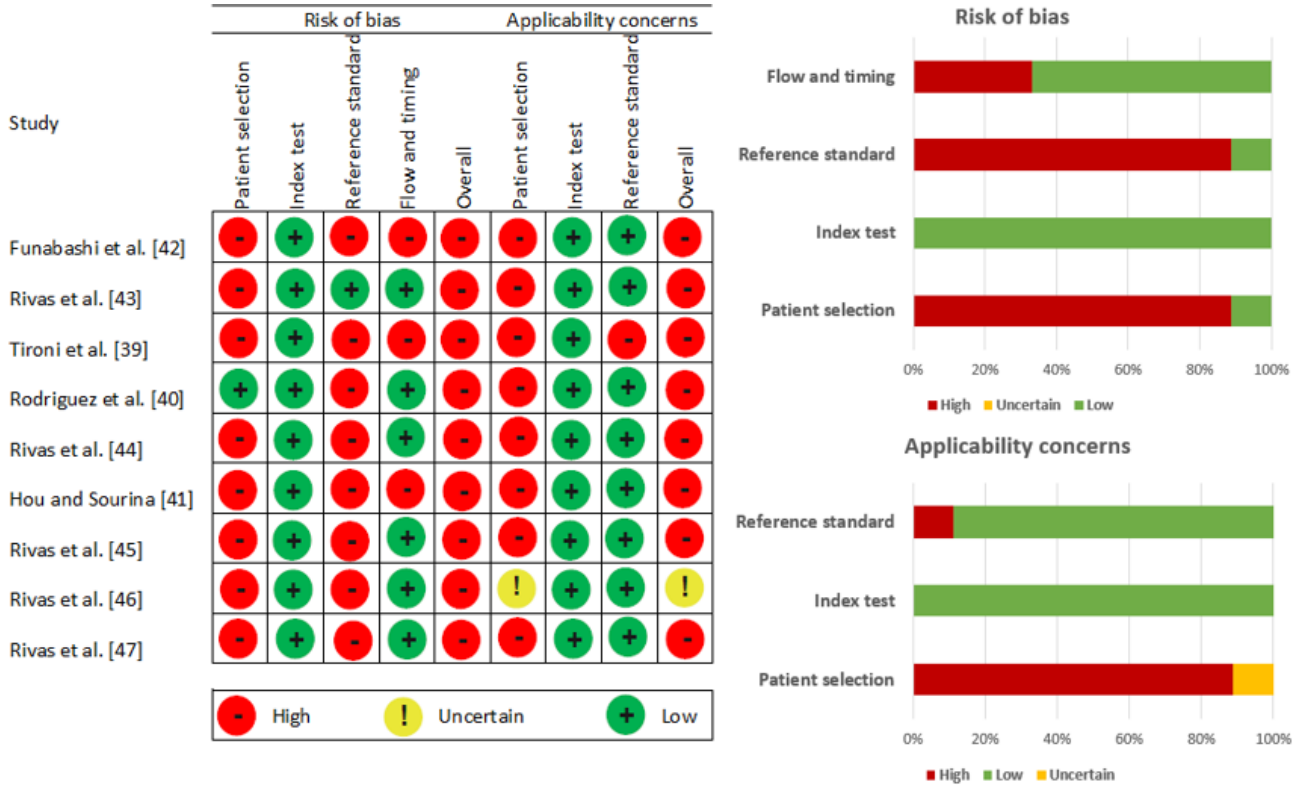
Visualization and Immersion Hardware

Advanced visualization systems, such as the *Oculus Go*, enhance immersion and realism in rehabilitation environments. As documented by Rodriguez et al [40], these devices provide high-fidelity 3D visuals, increasing patients' sense of presence, which is critical for engagement and motivation during therapy.

Synthesis of Results

The affective states detected across the studies included engagement, valence, tension, pain, satisfaction, happiness, sadness, anger, surprise, boredom, excitement, frustration, and meditation. The most frequently recognized emotions were engagement, pain, tiredness, and anxiety. Only 3 studies used theoretical frameworks of emotion. The most commonly used affective computing techniques were facial expression analysis and gesture recognition, while user behavior analysis was the least used technique. Merely 2 studies adapted serious game elements based on the affective states of users. The adaptive elements identified included modifications to background music, visual interface parameters, game difficulty, and avatar facial expressions, movements, and gestures.

Quality Assessment



Quality assessment using the QUADAS-2 tool indicated that 88% (8/9) of the included studies exhibited a high risk of bias

XSL•FO
RenderX

in the patient selection category, mainly due to insufficient descriptions of recruitment procedures. Neither random nor consecutive recruitment was reported, which substantially increases the risk of selection bias. In the index test category, all studies (n=9, 100%) clearly defined the algorithms or techniques used for detecting affective states. For the reference standard, although no gold standard exists in affective computing, it is recommended to use multiple emotion recognition methods to improve accuracy [49]. However, 88% (8/9) of the studies did not use appropriate methods to assess reliability or validate their findings. In the flow and timing domain, 33% (3/9) of the studies demonstrated a high risk of bias due to the lack of explanation of the number of sessions and the failure to report participant dropout rates.

Regarding applicability, 88% (8/9) of the studies showed a high risk of bias in patient selection due to small sample sizes, limiting the generalizability of the findings. Additionally, patient recruitment from a single center further restricts the representativeness of the results for the wider patient population with varying severity levels. All studies presented low applicability concerns for the index test, as the techniques or algorithms used were clearly described. For the reference standard, 88% (8/9) of the studies exhibited low applicability concerns because they relied on clinical experts to validate emotions or used at least 2 emotion identification techniques, thereby ensuring that the system measures clinically relevant outcomes. Figure 3 illustrates the quality assessment outcomes.

Figure 3. Risk of bias assessment of the included studies using the QUADAS-2 (Quality Assessment of Diagnostic Accuracy Studies) tool [39-47].

Discussion

Implications for Clinical Rehabilitation

Given the critical role that affective states play in the rehabilitation process, this scoping review provides a comprehensive examination of the application of affective computing techniques within serious games designed for physical rehabilitation.

Studies involving healthy participants were excluded to ensure the analysis was relevant to clinical contexts. Patients frequently experience emotions such as anxiety, depression, and fear during rehabilitation. Thus, it is crucial to assess whether recognizing and adapting to these affective states can improve therapeutic outcomes. As a result, only 9 studies were included in the final synthesis. This highlights an important opportunity for future research to design studies involving patient populations where emotional state monitoring is integrated into the rehabilitation process.

Analysis of the 9 studies shows clear differences among techniques, each with specific implications for rehabilitation: (1) gestures and motion analysis, used by Rivas et al [42-46] and Funabashi et al [47], represent the predominant technique. The main advantage is its nonintrusive nature, which uses sensors already required for therapy to measure variables such as hand position and finger pressure. This characteristic makes it suitable for routine clinical practice, as it does not increase the sensory burden on patients, although its inference capability may be less direct than that of other techniques; (2) facial expression analysis, applied in multimodal approaches by Rivas et al [42-46], helps detect states such as satisfaction or pain. However, its efficacy can be compromised when patient expressions are altered, for example, throughout intense physical exercise, which may lead to misinterpretation by monitoring algorithms; (3) EEG, as implemented by Hou and Sourina [41]

XSL•FO
RenderX

and Rodriguez et al [40], directly measures brain activity and allows precise detection of affective states such as emotional valence. However, EEG used in serious games for physical rehabilitation is limited because electrodes can be intrusive for patients, and the technique is highly sensitive to noise from muscle movements. This sensitivity may limit its use during dynamic exercise in clinical settings.

A common limitation across the reviewed literature is the small sample size, which raises concerns regarding the generalizability and reliability of the reported findings. Future studies should aim for larger, more representative samples. Methodological guidelines, such as those proposed by Fritz et al [50], should be used for sample size calculation. Additionally, the reasons for participant dropout in physical rehabilitation interventions should be thoroughly documented, as this information can help inform and improve the design of future studies.

Research involving human participants is one of the most highly regulated areas in scientific inquiry, particularly regarding ethical standards. Data obtained from affective computing studies may be used for various secondary purposes, including video labeling, database inclusion, or training AI models. Consequently, adherence to ethical frameworks, such as those established by the American Psychological Association [51], is essential. Among the studies reviewed, only Rodriguez et al [40] explicitly reported compliance with the Declaration of Helsinki, received ethics committee approval, ensured data protection, and obtained explicit consent for video and photographic recordings. In contrast, several studies [42-44,46] merely acknowledged consent for video recordings, and others did not mention compliance with ethical guidelines at all, raising serious concerns regarding the ethical implications of affective computing applications. Clinical data privacy, especially in pediatric populations, must be a priority. Ensuring data confidentiality in storage, transmission, and usage is essential.

Regarding emotion theory, there is a lack of standardization, which makes direct comparisons between systems difficult; most studies did not justify their choice of emotion model. Among those that did [39-41], the dimensional approach to emotion was the most frequently adopted. This approach appears sufficient for many serious game applications, as determining whether a patient's affective state is generally positive or negative may be adequate for making gameplay adaptations such as altering difficulty or modifying environmental elements.

Another issue identified is the classification of pain as an emotion, which was reported in 50% (4/8) of the studies [42-46]. However, existing literature [52,53] suggests that emotions like depression, anxiety, and anger often emerge as psychological responses to pain rather than being emotions themselves. Therefore, classifying pain as an emotion may be conceptually inaccurate, highlighting the need for a more nuanced and consistent emotional taxonomy in future research.

However, detecting pain and fatigue (physical and psychological) is essential in rehabilitation, as these are major barriers to motor recovery. Pain may cause anxiety and fear of movement [43,46]. Nonintrusive pain detection allows systems to adjust challenges in real time, prevent secondary injuries, and maintain patient safety, which can improve engagement. By detecting patient fatigue, the system can recommend breaks, adjust exercises, or lower the difficulty to maintain high motor quality and enhance the rehabilitation process.

Clinical applicability is a further consideration when translating research into practice. When selecting data acquisition devices, factors such as cost, precision, portability, patient comfort, and mobility should be considered. Some devices, such as standard webcams [42-47], are easily accessible and cost-effective, while others, like the Emotiv Insight [40,41], require a more substantial investment.

Patient characteristics should also inform the choice of emotion recognition techniques. For instance, in pediatric rehabilitation, noninvasive methods should be prioritized to accommodate children's natural restlessness and their need for freedom of movement. In studies using facial expression analysis, factors such as ambient lighting, camera specifications, and the distance between the patient and the device can influence outcomes. However, these conditions were not reported in the included studies, and such factors must be considered when selecting or developing software libraries or AI algorithms.

An emerging trend identified is the integration of machine learning techniques. Findings suggest that combining multiple machine learning methods or modifying existing classifiers, such as the one proposed by Rivas et al [45], can enhance emotion recognition accuracy in virtual rehabilitation settings. These findings point to promising future directions for the integration of advanced AI methods in affective computing research.

Due to the variability in study designs and small sample sizes, the findings of this scoping review must be interpreted with caution. While affective computing appears to be a feasible strategy for enabling emotion-sensitive adaptations in serious games, the evidence for its clinical efficacy remains inconclusive. Accordingly, future research should adopt more rigorous methodologies, including larger patient samples, standardized protocols, and validated outcome measures, such as the Fugl-Meyer Assessment or Berg Balance Scale, to better assess the therapeutic impact.

Zhao et al [49] suggest that using multiple affective state recognition techniques can improve classification accuracy and the effectiveness of affective adaptations. However, only 4 of the studies [42-45] used more than 1 recognition method, with gesture and facial expression analysis being the most common combination. It is therefore recommended that future studies use at least 2 complementary techniques, selected based on their noninvasiveness and their ability to preserve patient mobility during rehabilitation.

User behavior analysis was the least explored approach, despite its potential for nonintrusive emotion detection. In this review, only Tironi et al [39] incorporated this technique, and its effectiveness remains to be validated. Future research should consider the application and validation of this approach in clinical rehabilitation settings.

The field remains underdeveloped, with most studies focused on technical validation or proof-of-concept, rather than rigorous experimental designs. The lack of randomized controlled trials

XSL•FO
RenderX

is a significant limitation, preventing affective computing from being established as an evidence-based intervention. As a result, these technologies are still considered experimental. Future research should use multicenter designs with statistically significant samples and control groups to validate the long-term clinical value of affective computing.

Analysis of the 9 studies highlights a major limitation in translating affective state recognition into functional application: adaptive approaches are infrequently implemented, with only 2 out of 9 studies [39,41] using a functional closed-loop system that detects emotion and adapts therapy accordingly. Three primary barriers account for this limitation: (1) clinical safety, as incorrect adaptations based on false positives may delay patient progress or compromise treatment effectiveness, for example, if physical effort is misinterpreted as pain and exercise intensity is reduced; (2) technical complexity, since real-time integration of patient signal processing with game engine logic requires considerable coordination among components such as game mechanics and hardware; and (3) the absence of theoretical intervention models, as current psychological models define affective states but do not provide protocols for automatic responses in affect-based rehabilitation systems [13]. As a result, researchers frequently use open-loop systems, in which software monitors the patient, but a human expert, such as the therapist, ultimately adjusts the therapy.

The application of the QUADAS-2 quality assessment tool revealed a high risk of bias in study participant selection, as most studies have small sample sizes. A high risk of bias was also found in the reference standard, since emotions were labeled through expert observation of video recordings. Subjectivity raises concerns that the emotion-detection algorithm, or index test, may simply replicate the biases of human observers. A moderate risk was observed regarding flow and timing, as several studies did not specify the testing interval. Considerable concerns also exist regarding the applicability of patient selection, since studies are often conducted in controlled research laboratories that may not accurately reflect real clinical practice, given patient variability as well as environmental factors such as movement and external noise.

The combination of serious games with affective computing facilitates the identification of states that may hinder rehabilitation, such as pain, fatigue, or anxiety. Failure to deal with these barriers can result in treatment abandonment or injuries due to overexertion in the short or medium term. Nonintrusive detection of pain or fatigue has direct implications for patient safety. In conventional clinical practice, therapists rely on patient self-reports, which may be biased by a desire to please health care professionals, communication difficulties, or embarrassment. Automated detection systems can support health care professionals in making more informed rehabilitation decisions. Affective serious games may serve as objective safety monitors, enabling the system to reduce challenge intensity before patients reach risk thresholds. Additionally, the inclusion of empathetic virtual agents offers a clinical strategy to address loneliness or depression associated with disability. Furthermore, integrating affective computing improves the feasibility of home-based therapy systems by delivering health care providers and family members with alerts regarding patient progress and emotional health.

Limitations

This scoping review presents several limitations. Although systematic search strategies were used to identify relevant studies across major electronic databases using carefully selected keywords, terminological heterogeneity within the literature may have resulted in the inadvertent omission of pertinent studies.

A major limitation of this review is the small number of included studies (n=9), which limits the ability to draw robust generalizations about the implementation of affective computing in serious games for physical rehabilitation. As a result, the identified trends should be viewed as preliminary, indicating that the integration of clinical rehabilitation and affective computing is still in an early stage of development.

The exclusion of gray literature further limits the scope of this review. By focusing exclusively on peer-reviewed studies, the review ensures a consistent standard of quality, coherence, and reliability. In contrast, gray literature often lacks external validation and standardized reporting structures, which increases the risk of methodological errors and interferes with the assessment of bias, sample representativeness, and the robustness of conclusions.

Another limitation is the absence of searches in languages other than English. All included studies are published in English in high-impact journals or specialized conferences, such as IEEE. This approach may exclude relevant research in other languages and obscure relevant regional developments.

Finally, the findings of this review should be interpreted in light of the methodological limitations of the included studies. First, most studies use small sample sizes, typically 1 to 11 participants. Second, there is also significant selection bias, as many studies rely on samples from specific institutions and often do not clearly describe the patient selection process. Third, most studies focus only on inferring and classifying affective states without implementing adaptive mechanisms to complete the functional loop.

Conclusions

This scoping review presents an updated overview of the state of research on the application of affective computing in serious games for physical rehabilitation. The studies analyzed identify various emotional states in patients undergoing rehabilitation through serious games. These papers use machine learning algorithms or commercial software development kits for emotion detection through at least 1 modality, such as facial expressions, EEG, gesture recognition, or user behavior.

The study shows that applying affective computing techniques to serious games for physical rehabilitation offers a promising complement to traditional rehabilitation approaches for various types of disabilities, incorporating patients' affective states into the design and adaptation of these games. While affective classification methods have advanced, closing the affective loop through automated interventions remains rare in serious game-based rehabilitation systems. Moreover, the limited

XSL•FO
RenderX

availability of primary sources weakens the conclusions regarding adherence and functional performance. Consequently, there is a strong need for multicenter studies with rigorous methodologies to develop systems with a greater impact on rehabilitation.

Therefore, the current evidence base for affective computing in rehabilitation through serious games is technically advanced, yet methodologically fragile. Existing studies remain in a model exploration phase, demonstrating the feasibility of emotion detection but lacking reliability at scale due to selection biases and uncertainties regarding real-life applicability.

Future research should consider the following key aspects: (1) methodological design, including a clear description of the theoretical approaches to emotion, patient selection criteria and characteristics, and a detailed description of the index tests and reference tests used; (2) the adaptation of serious game elements based on the patient's affective state; (3) use of validated motor function assessment scales to evaluate improvements in the rehabilitation treatment; and (4) promotion of multidisciplinary collaboration among experts in affective computing, physical therapists, and mental health professionals such as psychologists or psychiatrists.

We hope this study serves as a foundation for future investigations seeking to advance physical rehabilitation by integrating affective computing technologies.
